Contribution to the History of Vaccination. THE following fact, illustrative of the value of the Jennerian discovery, seems worth recording. A granddaughter of Mrs. M.’s was attacked in April, 1833, with small-pox, which ran its course and terminated favourably. About six weeks

afterwards, viz. on the 1st of June, Mrs. M.'s daughter and grandson (residing in the same house with the first patient), the former aged thirty-five, the latter eighteen, were attacked with head ache and fever, followed on the third day by an eruption which presented the ordinary features of varioloid, and ran the usual course of that disease. The eruptive fever in the grandson was very mild, but three pocks appeared on his face, and proportionally few on his body. On the tenth day he had sufficiently recovered to go abroad. The daughter had severe head-ache and high eruptive fever, had forty-three pocks on her face, and a proportional number on the rest of her person.

When children, the grandson had been vaccinated, and the daughter innoculated. The latter had the small-pox at that time, (as the mother informed me), pretty severely, had several pocks, and subsequently she had had chicken-pox.—*American Journal of the Medical Sciences.*

—
ONCE MORE, BUT NOT FOR THE LAST TIME—WHAT ARE THE TWENTY-TWO DOING?

UNLESS the organ of the College of Physicians has been throwing dust in the eyes of the profession (which, by the way, is not at all improbable), it is the serious intention of that learned body to subject itself to a spontaneous and very extensive reformation. So sweeping, indeed, are the contemplated changes, that the out-door friends of the College, to wit a few apothecaries who have filled their pockets by the "good understanding" system, in other words by officiating as lackeys to the fellows, are apprehensive that the latter, seized with some dire delusion, have passed from one extreme to another—have become mere *sans-culottes*, and, hanging up their breeches as votive offerings to Æsculapius, are about to dance, in the disencumbered wildness of democratic fury, over the ruins of all that is venerable in our medical institutions. However this may be, it is clear that the College regards the de-

mand for reform as too powerful to be openly resisted, and is resolved either to cajole the profession, or to yield to it.

But there is another College whose intentions are less obvious. What course do the twenty-two fine fellows of Lincoln's Inn mean to pursue? Not a whisper is afloat by which we may guess at the secrets of their prison-house; one of three suppositions, however, must be adopted to explain the mystery: either the twenty-two are so stupified with the consciousness of detected guilt, and approaching retribution, that they lack wit to frame a device, or they mean to overwhelm their adversaries by a grand and unexpected burst of liberality, or they are determined to stand their ground to the last, and die with harness on their backs. The first supposition is the most natural, but the last, we fear, the most probable; and if it be actually true, the twenty-two have certainly acquired one title to admiration—they are the gamest men alive!

They must be endowed with no small magnanimity, who can stand firm when the arm of public justice is uplifted to crush them; when the voice of an outraged profession is loud against them; and when the consciousness of deep and long continued iniquity "cows their better part of man:" they must indeed have

—robur et æs triplex
Circæ pectus!

But can they not be persuaded? Will they persist in courting disgrace and ruin, rather than perform a few acts, not of generosity—no one asks it of them—but of plain justice and common decency? We tell them there is only one way to avoid impending destruction; that way is to give up at once the self-perpetuating system. It may be urged that the council was originally constituted on this principle; it was: but how could it have entered the mind of any human being, that a council

framed to perpetuate itself by selection from the members of the College, should limit that selection to a small and inconsiderable body of surgeons, to the entire exclusion of nine-tenths of the members, who are thus utterly shut out from all participation in the government of their own College?

The fact that such an abuse can exist, ought for ever to prevent any corporate body from being again constituted on the same principle, and would now lead to the immediate abolition of that principle, if the twenty-two had a spark of good or honourable feeling among them. The College will never be anything but an object of detestation and ridicule to the great body of English surgeons, till the council is elected by the members, and every member is eligible to the council.

—o—

PARISH JOBBING.

SOME time ago we alluded to the rumour that the parochial officers of Saint Anne, Soho, were about to elect to the office of surgeon of the parish, an individual who we have heard was unable to exhibit those legal qualifications of medical education, that are generally and very properly required from candidates for public responsible situations. We are grieved to state, that the churchwardens and overseers have allowed their personal predilections to outweigh their sense of public duty, and have elected the individual in question. Meantime, though the election was made only a fortnight since, a requisition signed by ninety-one rate payers, calling on the churchwardens to convene a vestry for the purpose of taking their choice into consideration, has been got up. The churchwardens have thought proper to refuse a vestry for such a purpose, and a statement of the whole case has, we understand, been forwarded to the Poor Law Commissioners, for their opinion and interference.

The object of the requisitionists is a double one: first, to wrest the election

of the medical officer from the hands of the parochial officers, and place it in those of the parish at large; and next to, by this means, introduce a certain apothecary of their own way of thinking, into the vacant situation. Now, against the popular election of a professional medical officer, we loudly protest. The profession is already sufficiently buffeted by the public, and it only requires the degrading begging from door to door, for the "sweet voices" of the "unwashed," to plunge it irrecoverably in the slough of contempt. Let our readers only imagine the annual canvass of an extensive parish (for the office of surgeon is annual), and say whether it is probable that men of refined minds, and extensive acquirements, would submit themselves to it! For ourselves, we very much doubt the *patriotic* motives of the promoters of this parochial *emeute*; it is not so much dislike of the principle of electing a person *if* non-qualified, as the desire of placing their own man—be he what he may—into the office, that actuates these Hampdens on a small scale. The principle of popular election once established in such a ~~matter~~, we shall find the man that can knock at the greatest number of doors in a given time, and *romance* with the greatest volubility, carry important and responsible appointments over others, who display indeed a minor aptitude in these accomplishments, but possess the more desirable attributes of medical skill and humanity.

The just and most advisable mode of proceeding is, that the parochial officers should recal their appointment, and choose some one against whom no objection on the score of legal disqualification can be brought. We say legal; and surely the officers can have but little idea of the fearful responsibility to which they are exposing themselves, by persisting in their choice of a person (if) without a legal qualification to practice, or to give medical evidence in

legal inquiries In what situation will they be placed, should the sudden or mysterious death of some inmate of the workhouse necessitate the calling of an inquest to look into the cause of the event? Why, the evidence of their medical officer would be refused: it would be refused in the coroner's, as well as in every other court of the land; his opinion, unless legally qualified to practice, is worth no more than that of any other individual, who is not, even as he is, practising medicine. The confusion likely to arise from such deficiency on his part, would assuredly be laid at the door of those who deliberately and knowingly made choice of him. We, therefore, once more advise them to reconsider the question, and act from prudential as well as from just motives.

In a neighbouring parish—St. Martin in the Fields—the gentleman who has for many years served, and, from all that we have heard, served faithfully and skilfully the office of surgeon, has been ejected, and replaced by a Mr. Bainbridge, the idol of a party now dominant in the parish. We doubt not that gentleman's capability to do justice to the appointment, but this we are certain of, that had he been ever so unfit for it, the party in question would have chosen him. Here then is an instance *per contra*: parties of opposite shades govern in these parishes, and medical men are chosen by the colours they bear. What on earth has party to do with the knowledge of disease, and the capability of treating it?

—o—

SUGGESTIONS TO RENDER LESS FREQUENT THE CRIME OF POISONING—A HINT TO MR. WARBURTON.

It ought to be the law in every civilized country, that poisons should not be sold in any quantity, however small, to non-professional persons, as they can go from druggist to druggist until they procure a sufficient quantity to destroy life. This plan was adopted by Bishop

and Williams, the murderers of the Italian boy. One of them went from shop to shop, bought a pennyworth of laudanum in each, until he had accumulated a sufficient quantity to destroy his victim. This he mixed with porter, administered it to the unfortunate youth, and when it narcotized him, put him head foremost into a well; suffocation was the immediate result. The remedy for the frequency of the horrible crime of poisoning is simple. It is this, that no chemist, druggist, apothecary, or vender of medicines, should ever sell any quantity of a poison, opium, prussic acid, henbane, fox-glove, hemlock, nux vomica, arsenic, corrosive sublimate, &c. &c., to any person whatever, unless he or she produced the prescription of a legally qualified medical practitioner—under a penalty of ten or twenty pounds, to be recovered before a justice of the peace. All the poisons are most valuable remedies in small doses. Moreover, these substances should be kept apart from ordinary medicines, and never dispensed by apprentices, under the like penalty. The neglect of this precaution has been the destruction of thousands. Many have been poisoned by oxalic acid sold for Epsom salts, others by nitre sold for Glauber salts, more by oil of tar substituted for the black draught, &c. &c.

The Irish Apothecaries' Act does not allow arsenic to be sold indiscriminately; but omits all the other poisons. In England there are no apothecaries; those qualified as such are medical practitioners, the physicians of the poor and middle classes, who leave the vending and compounding of poisonous medicines to their school-boy apprentices, persons totally incompetent to discharge this serious duty. In this country too, our chemists and druggists who have received no medical education, are in reality our apothecaries, and the sale of poisons is simply a matter of pounds, shillings, and pence, with them. These facts were most amply proved

before Mr. Warburton's committee, and must be abated by the medical reform bill. There ought, must, shall, and will be some competent persons to prepare and compound dangerous, or poisonous medicines. If apothecaries will not discharge this duty, chemists and druggists ought to be educated and perform it.

A French writer has proposed to add colouring, bitter, and odoriferous medicines to poisons; but this plan is imperfect and objectionable. It requires the greatest caution and skill at all times to prescribe poisonous medicines; and to vend them indiscriminately to non-professional persons is neither more nor less than homicidal; and, for the consideration of a penny or a sixpence, is human life endangered or destroyed. Our statement is not exaggerated. Let any one peruse a file of any of the leading newspapers for a year, and he will find numerous examples of individuals destroyed by laudanum, prussic acid, arsenic, &c. &c.; he will also learn, that persons seduced into the scenes of vice, are first narcotized, then robbed, and often murdered. Such enormities cannot continue longer in an age so enlightened as the present, or in a country the most civilized in the world.

If the public press would only aid us in diffusing our sentiments among society, the monstrous evils we have portrayed would be speedily abated by the legislature.

We hope and trust, that our hint will not be lost sight of by Mr. Warburton, and the Parliamentary Committee on Medical Education and Practice, over which he so ably and zealously presided. We agree with an eminent statesman, that Mr. Warburton, in carrying the anatomical bill into a law, has done more for humanity than any member of either House of Parliament; and we feel fully convinced, that his medical reform bill will be based on impartial justice and expediency, and will

hand his name down to posterity as one of the greatest benefactors to his species. In saying this, we must observe, that we have not the honour of his personal acquaintance; but having attentively watched his progress on the occasion alluded to, we observed that public good, and the improvement of our profession, were his sole objects; while the glorious axiom of Magna Charta was the leading star—"*Salus populi, suprema lex esto*," the enormities of each university, each college, each monopoly, were exposed, and doomed to be annihilated.

—o—

THE PHYSICIANS OF THE FRENCH REVOLUTION.

AMONG the professions that were particularly active in the revolution, the lawyers and medical men were especially distinguished. And though the latter did not possess the same influence as the lawyers, they nevertheless played a remarkable part in the stormy scenes of this stupendous event. Many of them entered into the hazardous career which had raised the lowest citizen to power and renown. Of some of them the names are engraved on the iron page of history; others are lost in the names, committees, directories, &c. Among the former are found, though in widely different degree, and with widely different principles, Marat, Guillotin, Chambon de Montaux, Barthez, Le Hardy, Lanthenas, Guiton-Morvau, Cabanis, Baudat, Bo, Bousquet, Du Gers, Clede, Dubouchet, Thery, Fourcroy, Lavoisier, Pelissier, Plaichard-Chatteire, Taillefer, &c.

Who has failed to hear the character and fate of John-Paul Marat? Every one knows that he was strangled in a bath in the Rue du Paon by a young and beautiful girl, that his body was conveyed to the Pantheon, and afterwards, at the commotion of Thermidor, thrown into the common sewer: that after burning his effigy, the ashes of the figure were placed in a chamber-pot and cast into the Montmartre sink. But it is not equally well known that Marat, previous to the time when revolutionary

ideas so violently took possession of and agitated his mind, was of a mild and peaceable temperament. Then he was devoted to science, and ten or twelve works proceeded from his pen, which were not without merit; witness his "*Traité de l'Homme*." Though born in the neighbourhood of Neufchatel, in Switzerland, Marat practised his profession in Paris; his name is to be seen inscribed in the books of the Faculty of Medicine for the year 1785. At that time he lived in the Rue de Bourgogne, and was for some time attached to the Guards of the Duc d'Artois, since Charles the 10th. Marat was a thick short man, with a vulgar countenance, traversed with the restless expressions of envy and pride, a countenance that gave evidence of a low uncompromising ferocity; withal his stature was unattractive and his manners inelegant. Yet his language and style were in singular contrast with what he had always hitherto been. Who could fancy the same man in the author of the "*Traité on Medical Electricity*," and the editor of that journal of horrors, *l'Ami du Peuple*? Marat was certainly insane: the scent of blood drove the old puritan of the Mountains partly from his reason!

Very different from this fiery demagogue was Joseph Ignatius Guillotin the deputy from Saintis. Mild, benevolent, the sincere friend of humanity, he sought only to be useful to his species, even when he invented the fatal instrument which bears his name. When the legislative assembly had determined that there should be but one kind of mortal punishment, and that it should be decapitation, Guillotin laboured unceasingly to find the means of rendering the last moments less painful. It has been asserted that the instrument he proposed had been long before used in China: no proof of this is however adduced. But it cannot be doubted that in the 16th century, an instrument bearing a strong resemblance to his was employed in Italy, for the purpose of amputating limbs. It became necessary to abandon it in consequence of the crushing and injury done to the bone by its action. Be this as it may, Guillotin thought that a similar instrument, carefully modified, might attain the end he had in view. So occupied was he with the subject, that he

was continually repeating to his friends and colleagues, "With my instrument I will take off your heads in a twinkling, and without the slightest suffering." This enthusiasm caused more than one epigram to be launched at him, of one of which the following lines form the commencement, being sung to the air of the *Kaudet*.

" Guillotin,
Medecin
Politique,

Invente un beau matin
Que pendre est inhumain
Et peu patriotique," &c.

Very lately the correspondence of M. Roederer, regarding the mode of decollation proposed by Guillotin has been published, but it presents nothing worthy of interest. Guillotin's own report on his instrument would have been much more interesting, including his experiments with it previous to his definitive proposal of it to the government; as would also have been the report and correspondence of Louis, secretary of the Academy of Surgery, on the same subject. Guillotin's instrument was tried on five bodies lying in the Bicêtre, and its success at first appeared to be complete. When, however, for the first time employed in its real capacity, the decapitation was imperfectly performed; indeed so badly effected was it, that, had not an armed force interfered, the people would in their fury have broken up the instrument; besides which, the basket for the reception of the head not being then known, the scaffold was inundated with blood. Louis on being consulted, remarked, that if the section of the neck would be perfect, if, instead of having the "*contenance de la loi*," as the blade was denominated, horizontal, an oblique direction were given to it, and this on the principle that all cutting instruments act by sawing. The hint was followed up; and with what frightful precision the machine has fulfilled its office since then, is well known. The success indeed was such, and so immediate, that it was proposed to call the instrument the "*Louissette*," to do honour to the great surgeon who had brought it to perfection; but the former name was already fixed in the popular mind. Here was a strange fatality: while the name of Columbus was never attached to his vast discovery,

that of Guillotin could never be detached from his invention. Guillotin lived many years after the date of his discovery; nothing pained him more than the mention of his instrument, and horrible recollections shook him when, as sometimes happened, some mischievous fool addressed him with "Why, doctor, how come you to have escaped—you know *what* death?" He died in 1814 of a large carbuncle on the left shoulder. His *confrere*, Bourru, delivered his funeral oration, the same Bourru who, in 1793, *re-baptized* his two sons, and called one Hippocrates, and the other Galen.

Barthez, piqued against certain of the nobility, and particularly against the Duc d'Orleans, whose medical attendant he had been, adopted the doctrines of the revolution. On the opening of the States-General he put forth a pamphlet entitled, "*Libre discours sur la prerogative que doit avoir la noblesse dans la constitution et dans les états generaux de la France.*" (A free inquiry into the right of the nobility to form part of the constitution and States-General of France).

This publication might have proved fatal to him, for the populace very shortly after came and broke the windows of the aristocratic physician. Barthez, whose *foible* was certainly not long-suffering, became furious and cried out to them, "You may break my windows, but I defy you to destroy my arguments." However, he afterwards prudently kept out of the way, and left Paris for Montpellier.

Le Hardy was a good-natured Breton, who entered warmly into the cause of the revolution, but detested its excesses, although he held the presbyterian doctrine of the responsibility of kings to the people. Le Hardy sided with the party of the Gironde and perished with it. An anecdote is told of Le Hardy, that having examined the body of Valagé, who had stabbed himself during the session of the Convention, he said, "The wound is through the heart and he is dead." "Then, doctor," replied Vergniaud, "Sacrifice a cock to Esculapius, for here is one of your patients cured."

Lanthenas, the physician, who was included in the same prosecution as Le Hardy, was however more fortunate than him, for Marat erased his name from the list, as

poor-spirited, too paltry even for the guillotin.

Thus the medical men were not spared in the general slaughter of the first French revolution. Punishment even awaited their minor offences. Thus the health-officers of the military hospital of a town in the north of France, having failed to make their appearance in the popular society of the place, the representative of the people, Lebon, ordered them to come, in a letter bearing the gracious protocol, "*Citoyens, purgons, citoyens bistouris, et vous canules, vous êtes invites, &c.*" (Citizen purgers, bistouris and canulas, you are invited, &c.) Thus too a chemist of Paris, having taken for his device the words "*Ventre libre ou mourir,*" (Open bowels or death), with two clyster syringes *rampant* for supporters, the joke had nearly cost him dear; he was brought to trial, and it was for some time debated whether he should not have a close view of and perhaps a closer knowledge of the guillotin.—(From the *Fouilleton* of the *Gazette Medicale* of April 4.)

—o—

Hospital Reports.

WESTMINSTER HOSPITAL.

Ovarian Disease—Abscess opening in the Groin.

MARCH 2nd.—Maria Bassett, aged 43, was admitted into the hospital, Jan. 2nd, under the care of Mr. White; it being the third time of her being in the hospital during the last two years. On the first of these occasions she was under the care of Dr. Roe, and on the second, under that of the late Sir George Tuthill, at the period of her admission; but the case being considered as admitting rather of surgical than medical aid, she was both times transferred to the care of Mr. White.

Her history is as follows. She is a married woman, and the mother of ten children; on the occasion of her last pregnancy, two years ago, she had a miscarriage, and subsequent to this the present affection commenced. A tumour appeared in the left groin, which gradually increased in size, and at this period she was first admitted into the hospital. Mr. White inclined to believe that the seat of the tumour was the left ovary. However, after remaining some time in the hospital, the tumour gradually became more superficial, and at last afforded marks of fluctuation; in fact, an abscess presented in the groin, which on being opened, discharged a considerable quantity of matter. She now obtained speedy relief, and soon left

the hospital. She has not menstruated since. About twelve months since, having been quite well for a period of about six months, she was a second time admitted into the hospital, with indefinite complaints referrible to the same seat, and after remaining there for about four months, these terminated in the appearance of a second tumour of a chronic inflammatory kind, which, on being evacuated, afforded her corresponding relief, and she soon got well, and returned home. Half a year had scarcely elapsed before she had a third return of the affection, which was ushered in with rigors and perspirations. Retention of urine was produced by pressure on the urethra, for which Mr. Hancock, who attended her as an out-patient at her own house, had to employ the catheter daily. As the case required constant attention, she was at this period received into the hospital. The tumour increased rapidly in size, progressively extending from the left iliac region into the hypogastric and right iliac, and at last invading the umbilical and epigastric regions; it finally equalled in size the uterine tumour of a female at the full period of gestation. The tumour was attended with excessive pain in the iliac and hypogastric regions, with occasional paroxysms of bearing down of the uterus, with tenesmus and bloody stools, which latter had occasionally the characters of mæna. This distressing train of symptoms was suddenly relieved by the abundant discharge of matter from the uterus, per vaginam, which has continued during the last three weeks, and has not yet altogether ceased. The general symptoms have nearly quite subsided, the countenance is good, pulse 84; the retention of urine has ceased.

March 4th. During the last two days the discharge from the womb has assumed a bloody character, and the retention of urine has returned in a slight degree.

Habeat morphine acet. gr. j; omni nocte.

9th. Since last report, a large quantity of coagulated blood has been discharged from the uterus, which has produced some irritation in the system. The retention of urine has, however, disappeared, as likewise the tumour in the left groin, which had been much increased in size. She continues to take the morphia, and is occasionally obliged to have a double dose, in order to ensure her a night's rest.

11th. Her health has gradually improved since the escape of coagulated blood, and her feelings are, she says, much improved.

14th. Masses of coagulated blood are still occasionally discharged, but she continues much better with respect to her general health.

21st. The discharge of coagula has considerably increased, and there is at the same time increased tenderness and pain in the groin, leading to the idea of matter again forming in that situation. There is not any

tenesmus, but she is again troubled with bearing down uterine pains; there is also painful and difficult micturition, not, however, to the extent of requiring catheterism. She has at the present time a slight attack of cynanche tonsillaris.

26th. Tumefaction has again appeared in the left iliac region, and there is redness, with increased pain and tenderness. The inflammatory symptoms have, however, been diminished by the application of sixteen leeches to the region affected.

28th. Large quantities of coagula are still passed, and Mr. Snowdon, the house-surgeon, reports, that whilst they were formerly almost black in colour, they have now become nearly red. There is still great tumefaction in the left groin, and she likewise suffers from severe pain. She continues to take the morphia.

April 2nd. The coagula are still discharged, and in other respects she continues much the same.

8th. There has been no discharge during the last two or three days; but since its cessation she has complained of rather severe pain in the loins. Fifteen leeches were applied to the groin yesterday, since which she has been better.

14th. Her general health is much better, but considerable discharge is again present. This has been somewhat increased to day by her preparing to leave the hospital, which Mr. White has recommended her to do, for the sake of change of air, which he thinks may be of advantage to her. She is to be admitted again at once, in case of her becoming worse.

—o—

ALLEGED MALPRACTICE IN OBSTETRICY AT DUBLIN.

WE have received a pamphlet published by Fannin and Co., of Dublin, containing an account of an inquest upon the body of an exhumed infant which was delivered by craniotomy. It has seldom fallen to our lot to record a more unjust or a more unprofessional course than that which gave rise to an unnecessary and a most disgraceful inquiry—disgraceful if a member of the profession have got it up.

The coroner it appears is an apothecary, a Mr. M'Carthy. His brother-in-law of the same craft, according to the report before us, which may for ought we know be incorrect, had hatched this proceeding.

It appears that Mr. Hayden, a lecturer on midwifery and surgeon to an obstetric institution, was compelled to perform craniotomy to save a woman's life, and succeeded under most unfavourable circumstances. It also appears that he had previously determined to employ the ergot of rye, and said to the patient's husband, that as he had found it frequently fail, when procured indiscriminately, he would advise him not to purchase it from his apothecary,

but obtain it from one of the hospitals as there it could be depended upon, though that from the apothecary might, but he was *certain* of the efficacy of the latter and would prefer it. The medicine was procured and given, and it excited uterine action, which did not however advance the labour. The woman had always had tedious labours during each of her four preceding confinements, and was four days ill in labour, when Mr. Hayden was called to see her. The labour had ceased and the woman began to sink. The husband was informed of the necessity of craniotomy, and at last consented to it. The operation was performed, and the woman's life was saved.

Our readers will exclaim, What necessity was there for an inquest in a case of such frequent occurrence? The reply must be inferred from the following:—

It appears, according to the statements in the report, that the husband answered emphatically, that it was not his wish, and added "I suppose Mr. Buckley, the brother-in-law of Mr. M'Carthy, the coroner, and also apothecary, could explain." This Mr. Buckley was the apothecary of the husband, and it was his ergot of rye which Mr. Hayden declined to use. Mr. H. also proved that 34,000 patients had been relieved during the last six years at the Anglesey Lying-in-Hospital, to which he is obstetrician, and that the profits of a medical establishment auxiliary to the institution were the cause of the "invidious and diabolical inquiry now before the jury." He also quoted several obstetric works in support of his practice, and called two experienced practitioners, who declared they would have acted as he had done.

*"Verdict of twenty-three Jurors.—*We find, that the child, in relation to which our inquiry has been held, was in all probability dead before the operation was performed by Surgeon Hayden; and we further find, that even if the fact were otherwise, then, that the operation performed by Surgeon Hayden was both well-judged and well-executed, and the result of which has been the saving of the life of the mother; which would, as it appeared on evidence, have been sacrificed by the delay or omission of such operation—and we feel it our bounden duty to give expression to these sentiments, lest any, the slightest, imputation might be thoughtlessly attached to Surgeon Hayden."

Before we comment upon the preceding facts, we must inform our British readers, that Irish apothecaries in general, are mere compounders of drugs, who until within the last six or ten years never attended lectures on medicine, anatomy, surgery, midwifery, &c. and are perfectly innocent of a proper knowledge of either the science or correct practice of the healing art. The junior ones are well educated, in some measure similar to the general practitioners of

England. To which class Mr. M'Carthy or Mr. Buckley belong, we know not; but if the report of the inquest before us be correct, we should be disposed to refer them to the genus of the old school. We draw this inference, because no man who has studied obstetrics, and is acquainted with its principles and records, could by possibility advise a coroner's inquest in the case that gave rise to these strictures, more especially after an educated midwife who possesses a diploma, a lecturer and obstetrician to a large lying-in charity, and two other experienced practitioners, had agreed as to the necessity of the operation. Did these men intend to shew the operation was unnecessary? or prove that they or either of them could by any other means have saved the mother, or preserved the child? No.—But they or one of them or neither of them, but some malicious or evil-disposed person imagined, that by instituting such an inquiry, public clamour would be raised, and an able, scientific, and experienced obstetrician ruined by the proceeding. The respectable jury, however, frustrated such base intention, and a crowded auditory scouted it. "A simultaneous groaning and hissing arose from about 150 individuals, which caused the suspension of the examination for some minutes" p. 10.

What in the name of professional dignity was the cause of this inquest? Was it the loss of the sale of a pennyworth of ergot of rye? Was it to satisfy public justice? Was it the profound ignorance as midwifery practitioners, of those who would disgrace the science of modern obstetrics, if they pretended to practise it, or if they belonged to the class of surgeon-apothecaries, or to the profession, which, we think impossible? or what in the name of humanity and common sense gave rise to this coroner's inquiry? If midwifery practitioners gave it origin, we boldly tell them they are grossly ignorant of a scientific knowledge of that art, and would add, woe betide their patients in similar cases. The fact is almost universally known to educated practitioners, that the operation performed by Mr. Hayden is recommended and practised in similar cases by all the distinguished obstetric physicians and surgeons of the present age. It is also important to add, that Mr. H. was justified in giving the ergot to excite the uterus, for all pains had ceased, so as to be assisted by its action after opening the head. This point of practice is not so clearly stated in the report as it ought to have been, but the midwife proved that the pains had ceased before the medicine was administered, and that the woman was sinking. "Mr. Hayden directed the ergot of rye in order that all means should get a fair trial, and as instrumental delivery was indispensable, the renewed action would assist in the delivery of the child, the head being lessened in the first trial by the compression of the forceps, and in the dernier resort by the evacuation

of the brain of the foetus." p. 13. The exact presentation of the head is not however stated, except in a loose indefinite manner by the midwife: "The head was at the upper opening of the pelvis; opening the head in order to diminish its size, by the evacuation of the brain, was indispensably necessary, as the head was too large to pass without this operation; the forceps had been tried, delirium had set in, the pulse became exceedingly quick, abdomen tender on the slightest pressure, pelvis deformed, the patient was now exhausted," &c. p. 12. This assuredly was a proper case for craniotomy.

A word to the medical coroner. He quoted some antiquated law Latin, at which the young medical jibs of old Trinity raised a hearty laugh—we suppose something after this fashion, "*primus strokus sine focus, absolutus est provokus*," against counsel cross-examining the witnesses. "He objected in the strongest terms to the examination of witnesses by counsel, and said he remembered a great many authorities, but could not think of them just now."

Mr. McDonough declared he would not forego the rights of his profession. He reminded the learned coroner of the Rathcormac inquest, as a recent instance in which counsel were employed on both sides.

Mr. McCarthy, the medical coroner, having still persisted in his attempt to silence counsel, the senior coroner arose and stated, that if Mr. McDonough were not heard, he would appoint him as his assessor, and in that capacity he should be heard."

Mr. McDonough would act in his professional capacity only, and Mr. McCarthy in the most complimentary language declared, "he felt a personal respect for Mr. McDonough, but he was unwilling to set the precedent." p. 8. It is clear that the schoolmaster has not yet visited the learned gentleman, and that he is a century behind the progress of medical reform.

We shall not offer a remark on his official conduct further than this, that it would, in our opinion, have been better taste and more in accordance with the conduct of judges and respectable magistrates, not to preside at trials in which themselves or their near relatives are concerned. It is true a magistrate, is too often judge and jury in his own case in Ireland, and the worthy coroner could no doubt cite many precedents. We cannot agree with a contemporary that the unfortunate display on this occasion invalidates the opinion of those who advocate the expediency of appointing well informed medical men as coroners. Were an intelligent medical coroner the judge in this case, one who was well acquainted with obstetrics, no inquest would have taken place, for he would know that such was unnecessary.

In conclusion, we add that we do not know one of the parties who were engaged

in this inquest. We do not wish to hurt the feelings or to injure in the slightest degree the professional reputation, legal or medical, of any one of them; but we exercise our right as public journalists, to criticise, fairly and impartially, a point of medical practice which has long and seriously occupied the attention of our profession, and is of deep interest to the welfare of society. If unnecessary inquiries, like this inquest, were to become general, and experienced practitioners were to be dragged before the bar of the public for saving human life by formidable operations, we feel convinced that humanity must suffer much more than superficial and non-professional persons might imagine.

—o—

Porriago Favosa.

Our French contemporaries are now employing the various preparations of iodine in cutaneous complaints. M. Bielt uses an ointment composed of ioduret of sulphur, gr. xxiv—xxxvi, and lard, ʒj.

M. Dauvergne employs the following lotions. Iodine, ʒij; ioduret of potass, ʒvi; distilled water, ʒij.

A drachm of this is mixed with half an ounce of the following, and then added to a basin of tepid water.

Sulphuret of potass, ʒiv; distilled water, Oaa.

—

Lepa Vulgaris.

We have lately cured a young woman of lepra vulgaris, of five years' standing, which covered the whole cutaneous surface, and defied a variety of remedies, with the following ointment. Her general health was duly attended to.

Rx. Hydriodate of potass, ʒiss;
Prepared lard, ʒiss;
Tincture of opium, ʒj.

Several pupils have witnessed the treatment at the Western Dispensary. M. Gibert found the following successful at the Hôpital St. Louis. Ioduret of ammonia, ʒi—ʒj; adipis, ʒj—daily for twenty-nine days.

—

Chloride of Lime in Itch.

Dr. Hospital uses the following ointment with success.

Rx. Lac. Sulphur, ʒiss;
Pulv. chlor. calcis, ʒij;
Adipis, ʒvj.

Double this quantity effects a cure.

LUNATIC ASYLUM.

THE new building at Hanwell, though holding 500 patients, is already full.

—

HORTICULTURAL SOCIETY.

THE Society rooms in Regent-street, were highly ornamented on Tuesday, by contributions from the fellows—these were unique specimens of several rare plants.

Dr. Lindley resumed the reading of a paper by Mr. M'Gregor Drummond, on the cultivation of French pears in Scotland. Some of the observations on the uses of pond and spring water were exceedingly interesting.

EXECUTION OF MARY ANN BURDOCK.

THIS unfortunate woman was executed at Bristol, for the poisoning of Mrs. Smith with yellow arsenic. The facts of the case were reported in a former number. The execution of this culprit was the consequence of medical evidence. Alas! poor Gordon Smith, founder of medical jurisprudence in England; we remember when you and ourselves were the only lecturers on this branch of science in London.

EGYPTIAN MEDICINE.

WE understand that an epidemic epiphora is at present raging among the crocodiles throughout Egypt. This extensive lachrymation is supposed to be occasioned by the sympathy of the reptiles for the green lizard on which we lately inflicted so frightful a laceration.

THE contest for the vacancy in the Academy of Sciences, by the death of M. Dupuytren, has terminated in the election of M. Breschet. The numbers of votes for the several candidates were as follows:—M. Breschet, 41; Civiale, 7; Velpeau, 4; Lisfranc, 3,

Ointment for Scrofulous Inflammation of the Eyes, Psoric Disorders, &c.

Sub-borate of soda..... 15 parts.
Fresh butter 145 ...
Journ. des Sc. Phys. et Chim.

Water for the Preservation of Dead Subjects.

Common salt and alum, of each.. 33 ounces.
Saltpetre 15½ ..
Water 6 gallons.

Cure for Jaundice.

FREZE LE OME used to cure jaundice by giving a drachm of dried and powdered walnut-tree leaves, infused in a glass of white wine, taken every morning fasting; from fifteen to twenty doses were for the most part sufficient to annihilate the disorder.

BOOKS.

The Medico-Chirurgical Review, and Journal of Practical Medicine. Edited by James Johnson, M.D. Physician Extraordinary to the King, and Henry James Johnson, Esq., late House Surgeon to St. George's and the Lock Hospitals. No. 44, April.

The Pathology and Diagnosis of Diseases of the Chest, illustrated especially by a rational exposition of the physical signs, with the new researches on the sounds of the Heart. By Charles J. B. Williams, M. D. &c. Third edition, 8vo., pp. 209. London: J. Churchill. 1835.

The Sphygmometer, an instrument which renders the action of the arteries apparent to the Eye, from the French of M. Hérisson, translated by Dr. G. S. Blundell, 8vo., pp. 46, 1 plate. London: Longman and Co. 1835

A Few Practical Observations on the Art of Cupping. By Joseph Staples, Cupper to St. George's and St. John's Hospitals. 12mo. plates. Longman and Co.

A useful manual for students and junior practitioners.

CORRESPONDENTS.

Hibernicus—Erinensis is one of the most powerful writers of this age, and is not to be provoked. If knights errant choose to attack him, they must bear the results. There are some of the profession in Dublin who think themselves superhumanly renowned, but Erinensis has taught, and so have we, that those residing in glass-houses should not be the first to throw stones. The head and front of our offending was, that we exposed their delinquencies before Parliament, and would again to-morrow, if called upon. Nevertheless, there is a just proportion of able and clever professional men in Ireland as well as in all other civilized countries.

A Reformer—Fudge; the editor of the *Lancet* is not to be caught with common, though he might with attic salt. The leather-headedness of the article is too palpable. A rejoinder would be an honour and an essential service.

Fair-Play—The trick has been practised to a great extent. But medical men are not gullible. The poverty of the land is too visible.

We have received a letter in reply to our correspondent J. F. C.; but the signature to it is perfectly hieroglyphic. The purport of it is against the writer, and not against his reasoning.

LECTURES
ON
MEDICAL JURISPRUDENCE,

DELIVERED BY PROFESSOR A.T. THOMSON,

F. L. S.,

At the University of London; Session 1834-35.

LECTURE XXVI.

GENTLEMEN,—Without entering into the consideration of the question respecting the nature of the changes which are effected in the lungs during respiration, either as regards the blood or the inspired air, it is evident that this function cannot be suspended, for many minutes, without life ceasing. The energies of the brain and nervous system depend, in a great measure, on the properties of the blood resulting from pulmonary circulation. If blood, of the description which circulates in the veins, be conveyed to the brain, an instant and powerful sedative impression is produced on the energy of that organ, and asphyxia or death ensues. That this actually depends on the nature of the blood, was undeniably demonstrated by the experiments of Bichat, who injected both arterial and venous blood from one animal into the carotids of another. The transfusion of the venous blood caused death, almost as soon as it reached the brain; whereas no effect was produced by the transfusion of arterial blood; unless when it was employed to a dog in a state of asphyxia, in which case the animal recovered. These experiments, and many others which might be detailed, are sufficient to demonstrate the intimate connexion between the functions of the brain and those of the respiratory organs.

Now the inference to be drawn from the facts which I have just mentioned is this:—that in every instance of suspended respiration, by whatever means effected, the asphyxia which follows is the consequence of the impression of dark, venous, or unaltered blood upon the brain. As far as the heart is concerned, we shall find that it is little influenced in itself by such a state of the blood; the left ventricle continues to contract and circulate the blood for some time after the function of respiration

ceases, and this continues until the influence of the destroyed energy of the brain is felt on the rest of the system. This fact is further beautifully illustrated by experimenting on animals which admit a suspension of one part of the respiratory function, whilst the function of the other part is entire. Thus in caterpillars, who breathe by stigmata, if you close with oil the stigmata of one side, hemiplegia is induced; if one half of the stigmata in both sides, paraplegia follows; and if all the stigmata, the animal dies.

When respiration is suddenly impeded, so as to produce sudden death, the animal is said to be suffocated; in whatever manner this is accomplished, whether by closing the inlets to the entrance of the atmospherical air into the lungs, as in *smothering*, *hanging*, *drowning*, or *immersing* the body in *carbonic acid*, and some other *unrespirable gases*; or by the *inhalation of noxious gases*. Any of these circumstances occurring, whether accidentally or intentionally, as an act of suicide or murder, become subject of medico-legal investigation, and consequently demand our attention.

In treating of infanticide, I mentioned that children are not unfrequently smothered under bed-clothes, and by other means; and I pointed out the method of detecting this as far as an opinion can be deduced from the examination of the lungs by the hydrostatic test, and the absence of any other probable cause to which the death of the infant can be attributed. The history of crimes for the last few years has proved, that this mode of destroying life is not confined to the state of infancy. The art to which the infamous Burke has given a name, perpetrates murder in this manner. The mouth and nostrils are held firmly closed, whilst the thorax is compressed by a person sitting or kneeling upon the chest: or a pillow or other substances may be firmly compressed on the face, whilst the person is held down, and prevented from struggling by a person sitting on the thorax. Smothering has, also, occasionally occurred from accident, when a person in a state of intoxication falls in such a manner, or in such a place, that the entrance of the air into the lungs is prevented; and from the

neck by suicides, and the double mark thus produced. These circumstances, therefore, as well as the time elapsed from the hour of death, if known, should always be taken into account, in deciding whether an act of suicide or of murder has been committed. If no previous strangulation appears to have taken place, a most decisive evidence is the state of the lungs; for, if the body has been hung up after death, the appearances which I have described, as characteristic of death by suffocation, do not present themselves. With regard to the second question, Whether the person has hung himself, or been hung by others? The absence of the appearances of any struggle indicate that hanging has been an act of suicide; as it is very unlikely that any one would submit to be hanged against his will, if not legally condemned to be so as a punishment for crime, without making great resistance. The importance of attending to these circumstances, is well illustrated in a case quoted by Fœderé from the "*Causes Célèbres*," and translated by Dr. Beck.—See his work, p. 284.

But, although the appearances noted in this case indicate suicide, yet you must also recollect, that bruises and wounds on the body do not always bear testimony of force having been employed. A person may swing himself with violence, with the view of speedily destroying himself, and may thus be wounded.* An apprentice boy, working alone in an attic, tied one end of a rope loosely round his neck, probably without any intention of destroying himself, and twisted the other round the projecting top of a door, the planks of which were irregular, and somewhat apart; a small stool on which he stood slipped from under him, and when he fell forwards, he struck his temple against the corner of a box, which cut him to the bone; he lay along the floor, his head and shoulders only elevated a few inches above it; and in this state he perished. The master of the boy, who was from home when the accident happened, was accused of having first murdered, and afterwards suspended the boy. But, from the appearances on dissection, the turgid vessels of the brain, the broken thyroid cartilage, the blue nails, and the clenched hands, in confirmation of important circumstantial evidence, exonerated the master, who was properly acquitted of all blame by the Coroner's Jury.

But suicides have been known to inflict wounds upon themselves, and afterwards destroy life by hanging. De Haen mentions the case of a young clergyman, who first partially cut his throat, and then hung himself in the vestments of his office, which he had arranged for that purpose. In this case, without circumstantial evidence, it would have been impossible to divest oneself of the idea that murder had taken place.

A very interesting case is related by

Fœderé, and quoted by Dr. Beck, to show the necessity of the utmost caution in examining cases in which there is any difficulty in determining whether murder or suicide has been committed.—See case in Beck, p. 283.

In those who hang themselves, from the clumsy mode in which the work is accomplished, the appearances in the lungs differ from those found in the lungs of those hanged by others. From the pressure of a badly-adjusted rope, the cheeks, lips, eyes, and tongue, are generally also more swollen; and, as the death is more protracted, in consequence of the ligature not wholly intercepting the transit of air, the lungs are less gorged with blood, and contain much less gaseous matter. There is also more apoplectic appearances in the brain, from the death being less rapid. In those properly hanged, Dr. Godwyn found two hundred and fifty cubic inches of air in the lungs. Now this quantity is never found in cases of hanging by suicide. In the state of the lungs in natural death, the average quantity is one hundred and nine cubic inches.

When any doubt exists, every minute circumstance relative to the state of the body when found should be noted down—the surrounding objects and their state, both in relation to their usual appearance and to the body—the manner in which the rope is fixed—and every fact, however minute, should be recorded. The necessity of recording the position of articles near the body is well demonstrated by a case recorded by Dr. Gordon Smith, which happened in Northamptonshire, in 1831:—"A girl, thirteen years of age, was swinging in a cow-house, and near the swing hung a rope with a noose in it, for the purpose of drawing up slaughtered sheep. As she swung backwards, her head got through the noose of this cord; she was dragged out of the swing, and was thus actually hanged." The position of the body is often remarkable. In some cases of suicide, the rope, or handkerchief, is so long, that the feet might rest on the floor; and the knees are therefore either bent under the body, or the limbs are thrown forward, so that they rest on the heels, and leave the whole weight of the body on the rope. The Prince de Condé, who hung himself in August, 1830, was found suspended from a window-shutter, with his feet touching the ground, and his knees bent; and a prisoner who was found hanging to the bars of a window, in one of the Continental prisons, was in a sitting position, and with his hands tied together: yet there was no doubt of the suicide.—*Annales de Hyg. pub. et de Med. Let. t. v. p. 156.* As the medical practitioner is generally the first person called in on such occasions, all these particulars should be noted by him. In doing this, if the body should be found in a brothel, although suspicion may be strongly excited, yet he must not permit himself to be influenced by it, in

* Dr. Male relates a case in point.

examining into the causes of the death. It is a fact, not very honourable to human nature, that persons have permitted themselves to be hung, for a few minutes, as a mode of exciting the venereal appetite, and, if the courtesan be drunk, or stupid, she might unintentionally exceed the time, and fatal asphyxia thus follow. In examination of the body of a sailor who was found hanging to the top of a bedstead, in a house of ill-fame in East Smithfield, it was proved, on trial, that his hands were tied behind his back; a handkerchief drawn over his eyes; and that this was fastened by what is termed a sailor's knot. It was therefore evident that he could not have hung himself, but a sailor was concerned in the murder: this man, the keeper of the brothel, and a woman of the name of Hughes, were tried for it, found guilty, and executed.

3. With respect to the last question—Whether a body found not hanging was killed by hanging? As it is possible that few external signs may be present, it is important, in making a dissection, that we draw a proper distinction between the effects of *hanging*, and those of *apoplexy*, *smothering*, *drowning*, and *carbonic acid*. The distinction, in the first case, depends on the state of the brain. In *apoplexy*, the extravasation of blood into its substance or cavities, or its effusion between the membranes, or the effusion of serous fluid not corresponding with the condition of the lungs, their gorged state, the gestion of blood in the right side of the heart, and their not collapsing when the chest is opened, afford strong suspicion that that disease, not suffocation by hanging, has been the cause of death. In *smothering*, the same state of the lungs that occurs from hanging, presents itself on opening the body; and, if the struggle to escape have been great, the vessels of the head will not only be found full, and the sinews distended with blood, but a section of the brain will exhibit an unusual number of red points; and, occasionally, effusion of serum is found in the ventricles, and on the base of the brain. Thence, in such a case, if no external mark of the rope appear, the difficulty of distinguishing between smothering and hanging is very great.

When no struggle has taken place, all the vessels of the brain remain in a natural state, and no difficulty presents itself. In a case of *Burking*, which as I have stated is a modification of smothering, the pressure on the thorax, by forcing nearly the whole of the air out of the chest, the circulation is so quickly arrested, that no time is afforded for accumulation of blood in the venous system; the body in this case presents no discolouration of the skin, unless on the face, around the mouth, nor yet always engorgement of the pulmonary vessels; there is no difficulty, therefore, of forming a diagnosis in this case. In *drowning*, as I shall afterwards describe to you, the state of the brain is perfectly different

from that produced by hanging; the face is pale, and much frothy mucus is found in the trachea, bronchia and air-cells of the lungs, and also some water, which is never found in bodies of those who have been hanged alive. In cases of fatal asphyxia from *carbonic acid*, there is gorging of the cerebral vessels, and those of the lungs, which also appear as if emphysematous, and other appearances which render the diagnosis difficult, if no mark of a rope remains, or if the body be examined too soon after death. In many instances, however, of poisoning by carbonic acid, no rigidity of the body takes place: but except for the mark of the ligature, some distortion of features, which always accompanies hanging, the bent fingers and the clenched hands, the diagnosis in this case, is always doubtful, and ought to be delivered with caution. It is altogether more akin to apoplexy than to hanging. In inquiring, also, into the cause of bodies supposed to have been hung, we must recollect that a person may be suffocated by any hard substance getting into the gullet, and sticking there so as to cause suffocation; and ignorant persons may grasp the throat so as to attempt to push it down.

Substances may also be impacted in the glottis, as was the case with the celebrated poet Anacreon, who lost his life from a grape-stone lodging there when he was quaffing some new wine. Care must therefore be taken to leave no part of the air tubes or their entrances unexamined.

The most prominent diagnostic signs, and those to be depended upon, are,

1. The mark of the cord, seen either at first, or appearing after a few hours have elapsed.

2. The distortion of features, and the contraction of the muscles which raise the shoulders.

3. The fingers bent, the nails blue, and the hands firmly clenched.

4. The erectile state of the penis, with the emission of semen, and the expulsion of urine and fæces.

The absence, however, of this sign, is no proof against the conclusion, that hanging has been the cause of death: for although in every instance erection takes place in the act of hanging, yet, an hour or two afterwards, this state has disappeared, or a semi-erection only exists.

. See some remarks by M. Guyen, Anderson's Med. Quar. Jour. vol. i. p. 151.

5. The corresponding appearances in the brain and lungs, perceived on dissection.

Strangulation, another cause of sudden death, is a modification of hanging. In both, the cause of the fatal issue is external pressure on the trachea, so great as to prevent the passage of the air into and from the lungs: but, as in strangulation, in the ordinary acceptation of the word, there is no suspension of the body, it differs from hanging in several particulars.

Much, in these cases, depends on the man-

ner in which the strangulation is performed, and the degree of resistance made by the sufferer. If a ligature or rope, or handkerchief, have been employed, or the bowstring, as in Turkey, the mark left is generally lower, and more horizontal, than that which is produced in hanging; but, if the fingers be the means used to compress the trachea, the evidence is more decisive, because the death is likely to be more protracted, and the extent of the violence more obvious and diffused. It is scarcely possible to suppose, that one man can strangle another with his hands, unless he throw his victim upon the ground, and press also upon his chest; in which case, besides the bruises and coagulated blood in them on the neck, the lungs are found almost empty; a state, the opposite of that which occurs in hanging.

The body of General Pichegru, whom I knew well, and who was strangled in prison in Paris, it was supposed by the order of Buonaparte, who was then First Consul, was found lying in bed, on the left side, in an easy attitude, the knees bent, and the arms lying naturally by the side; a black silk handkerchief was twisted round the neck by means of a stick passed under it, and which had torn the cheek in its rotation. Remer, who thus describes the case, doubts whether it was murder: "*J'accorde que ce genre de mort n'est que tres rarement le resultat, d'un suicide, mais je doute que sur cette suite consideration, et sans autres preuvers plus fortes, au puisse absolument affirmer qu'il y a en meurtre.*"—*Ann. de Hyg. Ad. Med.* let. iv. p. 186.

With respect to the question, whether the marks seen, as if of a ligature, were produced during the life of the individual? This question must be tried by the same tests as in cases of supposed hanging. If there be fractures of the vertebræ of the neck, but no dislocations, there is reason for supposing that the death was effected by strangulation, rather than by hanging: nevertheless, this admits of a fallacy, as occurred in the case of Sir Edmund Godfrey, who was murdered on the 12th of October, 1677, by strangulation. A handkerchief was twisted round his neck; but on the supposition of one of the murderers, that the purpose was not effectually accomplished, the neck was violently twisted round, and dislocation produced.

Sometimes, when the hands are employed, one small bruised spot only is perceptible on the neck. Metzger mentions an instance of this kind. A young officer was strangled in bed by a soldier. The surgeon of the regiment, who examined the body, could find one small spot only; which was explained by the confession of the murderer, that he had killed his victim by violent pressure with his thumb on the trachea.

With regard to the question, can strangulation be an act of suicide? I should, *a priori*, reply, this is impossible, as the asphyxia, which implies strangulation, must deprive the

man who attempts it of all control over his muscular energies; and, consequently, the act could never be completed. Yet cases are recorded which appear opposed to this opinion. Dr. Desgranges, of Lyons, relates a case of a man found in a hay-loft, who had strangled himself, by means of a handkerchief, tightened by a stick: and Dr. Dunlop, relates another of a surgeon of the navy, on board a ship of war in India, who tied a handkerchief round his neck, and with a small stick twisted it several times; then secured it behind, to prevent it untwisting; and by this means succeeded in destroying himself. But although these instances demonstrate the possibility of suicide by self-destruction, yet such cases are extremely rare.

It is sometimes of vital importance to the cause of justice, to ascertain the time when death, from asphyxia, by whatever means induced, takes place. In strangulation, if no direct evidence can be brought forward on this point, it should be remembered, that if the body be cold and stiff, we may be certain that more than twelve hours have elapsed since the fatal event; for in strangulation, the heat of the body, and its pliability, continues for that period of time. If the time has been so long that putrefaction has taken place, then we can only draw our proofs from the extent of its progress, in conjunction with the collateral circumstances tending to forward or retard this event: as, for instance, the degree of dryness or moisture of the place where the body is found; its exposure to stagnant or moving air; the elevation of the spot; the nature of the erections in the neighbourhood, whether lime-kilns, steam-engines, &c.; and the probability of terrestrial exhalations that may effect animal decomposition.

M. VIREY'S CODE OF UNIVERSAL GENERATION.

(Continued.)

Animals do not copulate but when impelled by desire at the rutting season, and hence their unions are almost always fecund. It is not so with the human species, who too often abuse the faculty they possess of engendering at all times. From this it happens that the human sperm is badly elaborated—is not always fecund; and the uterus of the woman too often stimulated by frequent approaches, opens itself and recommences without ceasing the work of Penelope; and thus most courtezans, who abandon themselves to vague and indifferent unions, rarely become pregnant. They only engender with those for whom they entertain a peculiarly strong predilection. For the same reason prostitutes seldom conceive, until they are reclaimed, and confine themselves to one individual whom they prefer. It is to obviate the escape of the sperm that cold water is poured over

mares, heifers, &c. after copulation, for the purpose of contracting and closing the womb. The Arabians exercise their mares by hunting before the access of the male, because they, being fatigued, lay down, and their repose is supposed to facilitate impregnation.

For the same reason, it is advantageous to a woman to repose quietly in bed after coition, more especially when she is relaxed by leucorrhœa. In this last disease the retentive power of the vagina and uterus is diminished or destroyed, the male sperm will be too much diluted and rendered incapable of fecundation, and will often escape when the erect position is assumed. It is generally supposed, that impregnation is more readily effected a day or two after menstruation, as the uterus is open; but previous to menstruation this organ is congested and engaged in the performance of a function preparatory to, but different from, fecundation.

Animals confine their amours to their own species. Love is diminished in proportion as the species are more distinct from each other; there is great disproportion between their sexual organs, and copulation is, in most cases, impracticable. Mules cannot be engendered unless among species somewhat similar, and they are generally sterile. Those of birds are sometimes fecund, but mules in general are sterile, or they engender through successive generation until their offspring resembles the original parents, male or female, as the influence of the one or the other predominates. Moreover, the periods of uterine gestation are different among animals, which is an effectual bar to indiscriminate copulation. Neither can a human hermaphrodite engender in itself; nor was there ever such a being, as it would be the object of love, and possess the means of gratification, life would be continually injured and exposed to perpetual amorous transports, and the being should speedily die.

Conception is sometimes announced in women by tremblings and voluptuous horripilations. In women and quadrupeds the male seed is sometimes rejected, and conception does not happen, either when the female is indifferent to amorous impulse, or that the womb is in a state of insensibility or atony. The latter conditions are removable by the mulating aliments, or by particular excitations. Woman and the mare are said to be the only animals that receive the male after conception, almost the rest refuse him; and, like the daughter of Augustus, do not admit any more passengers when the ship has its cargo. Nevertheless, several other females are subject to superfœtation, as those of rabbits, hares, &c. &c.; which proves that these animals do not always refuse the male during gestation. It is true that one copulation impregnates several eggs: but it is

still more marvellous that one female insect—one fecundated by the male—produces eggs capable of engendering, without any further intervention of the male. The second generation produces another, independently of the males; so that the species is perpetuated for some time by the female only. This effect of the fecundating seed of the male is transmitted for nine successive generations, which are all composed of females, except the last, which contains males: then there is another copulation, which serves for nine other generations. Reaumer and Bonnet have attested this fact by multiplied examples, as will be found in their works; and Spallanzani declares that he observed analogous facts in the *helix vivipara*. The eggs of insects impregnated by the male withstand the winter, as they possess more vitality than others which are not. The fecundating power of the male passes from generation to generation, until its exhaustion. Thus the insect can be a mother and a virgin at the same time. The same fact was observed by Jurine in certain water insects (*monoculus apus* Lin.), of which there are fifteen generations of these without copulation. Audebert also assures us that a spider is fecundated for two years by one copulation; so that the fecundating influence of the male is considerable in most animals. It is not at all so with vegetables: but it is extraordinary to see a plant of one sex, as the *juniperus candensis* L., to be one year male and another female: at one time the fecundator, at another fecundated. Thus the insect is father and mother at once, and may be one or the other.

We also know that a woman has brought forth a black and a white infant at one birth; there are, therefore, superfœtations, and these are not rare among quadrupeds. Moles are false conceptions, but do not exist without the male seed, whatever indulgent practitioners may say to the contrary. Animals and plants which reproduce from prolongations or sprouts, such as were already mentioned, have no need of fecundation; they have within them all the principles of life sufficient for the propagation and conservation of the species. The male roots of dioic plants cannot multiply from twigs; whilst the female increase with facility; and this proves that the female participates more than the male in the propagation of the species; that she is truly the essential shoot, and that the male is but an auxiliary, or an excitator. All the gemmiferous may be considered similar, and are sufficient in themselves.

The duration of gestation varies very much according to species. The ordinary period of pregnancy with women is forty weeks, or nine calendar months; but it appears to be longer for female than male infants. At the fourth month the infant

stirs and quickens. During the commencement of pregnancy, abortions are more common than towards the end; and, in general, women and domestic animals are more predisposed to this danger than the other species, either on account of menstruation, or on account of the abundance of their nourishment, which renders their sexual organs susceptible of excretions and hæmorrhages, and especially in the former at the period of menstruation. Copulation very much increases this disposition to abortion; and delicate, nervous women, of an ardent disposition, or of a plethoric constitution, are particularly liable to this frequent and dangerous disease. It is important to state, that abortion may become a habit, and it is only sufficient to have aborted once or twice to be liable to it for seven or eight times, and often for the remainder of life.*

Parturition is a safe and simple function, except in civilised countries, where nature punishes the violation of her dictates in the act of maternity.

We observe great difference in the various individuals of animals and plants, relative to the generative function. Some are fecund; others are sterile; malformation of the genital organs, which prevents coition, or the secretion or ejaculation of sperm, are frequent causes. Sterility may depend on a weak or diseased state of the sperm, as after severe disease, ill-cured syphilis, &c. But sterility is more common to women, either on account of not retaining the male fluid, or when the genitals are impervious, or when the temperament is too humid or too dry; too excitable or too inert; or of extreme fulness of habit, or of extreme thinness. In fine, sterility often depends on disgust, repugnance of individuals, or a state of languor or disease, a defect of love, insalubrity of habitation, influence of the passions, excessive exertion of mind or body, fatigue, exhaustion, effeminacy, libertinage, masturbation, delicacy of constitution, too vivid a sensibility, apathy, and, in fact, a thousand other causes. Animals and plants that follow the laws of nature, much better than the human species, are very rarely sterile. Extreme youth and old age are also causes of infecundity. Individuals who are too fat, whether male or female, are often sterile; and this is the case with most of the inferior animals.

* There is much more hæmorrhage in abortion than in natural labour. If this be profuse, it impairs the general health, develops consumption, disease of the liver, or any other organ predisposed, and, in some extreme cases, destroys life. I have known a young lady of good stature, florid complexion, and great beauty, who had five abortions during the first fifteen months after marriage, at which time she died of consumption. Women, in general, suppose that a miscarriage is unworthy of notice, though many lose their health and life by it. In some cases, transfusion alone can save them.—Ed.

During the season of love all animals are thin, and do not become fat, except in the time of repose, as in autumn.

It is a hopeless attempt to pretend to explain the mystery of generation in all beings. The power of the human mind is as fragile as ice, when compared to the impenetrable veil with which nature has enveloped it. The efforts of thirty ages of researches have been unsuccessful. Most men, it is true, have only considered this problem as respects the human species and some animals; but it is evident that the generation of plants and polypi, of the oviparous and viviparous, of all that enjoy life, belonging essentially to the same principle, because nature is always conformable to herself in her works, and no one can admit several causes for the same effect. It is therefore necessary to have recourse to some general principle.

All the theories hitherto offered are unsatisfactory. We know not in what manner life begins or ceases.

There is but one primitive generation.

Love, generation, and life, are the same thing. Of these very fully hereafter.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS, FROM BIRTH TO PUBERTY,

BY DR. RYAN,

Delivered at the Medical School, Westminster Dispensary, Gerrard-street, Soho;

Session 1834-35.

LECTURE XXXIV.

Displacements, Irregularities, Transpositions, and Protrusions of Soft Parts.—Transpositions of the Thoracic and Abdominal Viscera.—Arrest of Descent of the Testis.—Hernia.—Strabismus.—Twinkling of the Eyelids.—Congenital Malformations and Diseases of the Skin.

GENTLEMEN,—Having described the displacements and deformities of the bones, it now remains for me to treat of those of the soft parts, and to conclude this part of our subject with an account of the congenital malformations and diseases of the skin.

Displacements or Irregularities of Soft Parts.

—Displacements of soft parts are most common to internal organs, every one of which has, at one time or other, been found transposed. The transposition of the organs, from one side of the body to the other, is occasionally observed. The heart has been found in the right side of the chest; the liver in the place of the spleen, and vice versa; the stomach, &c. have been displaced; one kidney has been found in the thorax. The causes

of these displacements are unknown. The health of individuals so affected does not suffer, and they may survive to old age.

The testicles may be absent from the scrotum, and in such cases they are enclosed in the abdomen, as in their embryonary state. One may be in the scrotum, and the other in the abdomen. It is important to know, that the presence of one or both in the abdomen is not a cause of sterility. They may develop to the full size in that cavity, (*John Hunter, Sir Astley Cooper, &c. &c.*) and perform their functions as well as in the scrotum. An apprentice of Sir Astley Cooper's shot himself, under the impression that as the testes were not in their usual situations, he was impotent. The celebrated Baronet states, that a piece of paper was found on his table, containing these words, "I am impotent."

A gentleman of fine stature came from a distant country to consult me lately as to the propriety of marrying, as there was but one testis in the scrotum. I told him the other was in the abdomen; and probably was as well developed as the one that descended; but whether it was developed or not, the normal condition of one organ was sufficient to justify his entering into a matrimonial union.

It is also important to know, that the descent of the testicles at the abdominal rings in the groins has been often mistaken for hernia. The empty state of the scrotum would at once indicate the real nature of the case.

When hernia is said to exist in young infants, the scrotum, on the affected side, ought to be examined between the index finger and thumb, so as to ascertain whether the testicle has descended or not. I have repeatedly known practitioners mistake the descent of the testicle, proceed to reduce it, and then apply a truss, or a cork covered with lint over the ring, and secure it with a bandage passed round the loins and between the thighs. This is obviously bad practice, though good in obstinate hernia; but even in this case very seldom necessary.

When the testicles are retained in the groins, Levret advised the rings to be separated with the fingers, which would cause the infant to cry, and the succussion caused by the strong expirations would precipitate the testicles into the scrotum. Warm emollient fomentations or poultices would be preferable to this method, and relax the rings without any accident.

In most cases the testicle descends in a few weeks after birth into the scrotum, though it may remain during life in the abdomen. It should be recollected, that both testicles are in the abdomen during the early period of intra-uterine life; both are supplied with arteries, and these will convey an equal quantity of blood, whether the organs remain in the abdomen, or descend into their usual situation at birth. If a practitioner mistook the arrest of one or both testicles in

the groins for hernia, and pressed on them forcibly to reduce the supposed rupture, or applied a steel truss on the testicle, the result might speedily prove fatal.

I lately attended a case in point with Mr. M'Cann and Mr. Brady, in which it was supposed the infant had hernia before we saw it.

Some children and adults have a power of elevating the testicles to the groins, and the tumors formed by both have been often mistaken for hernia. Mr. Copeland Hutchinson relates the case of a recruit who possessed this power, and exerted it to evade impressment into the navy. Mr. H. observed the scrotum pendulous and empty, and detected the real nature of the case. M. Capuron met with a case of a man aged twenty-five years, whose testicles had not descended into the scrotum. This man had indulged much with women. There may be hernia, numerous hernia.

Hernia.—There may be hernia of the brain (encéphalocèle), as already described, and life protracted to an advanced period (Geoffrey St. Hilaire). These tumours may be present on all parts of the head, as already stated; but are, according to the illustrious author just quoted, most common on the vertex (cystocephale and podencephale), on the occiput (derencephale), or on the back (notencephale).

The viscera of the abdomen have passed through a perforation in the diaphragm into the chest. The stomach and liver have passed in this manner, according to Duges and others; and though such malformations are generally mortal and irremediable, it is essential to be aware of their existence, as it would enable us to form a correct opinion in medico-legal investigations on the viability or non-viability of infants.

Abdominal hernia are of much more frequent occurrence. The umbilicus often allows a portion of bowel to protrude, and this is popularly termed "starting of the navel." It may be congenital, or be induced soon after birth by coughing or crying. It is, in general, easily cured by compression. In scientific language, the disease is termed omphalocele, or umbilical hernia. It occurs when the umbilical ring, or opening, does not close; or when the bandage, which is usually placed round the bowels and body, is carelessly or too loosely applied. This disease is of common occurrence in hospital, dispensary, and private practice. The hernia may exist in the umbilical cord, and be observed when the practitioner is going to apply a ligature on it when about to divide it.

The chief indication of treatment is to reduce the hernia, or push it into the abdomen; and to prevent its protrusion by means of a pledget of lint, secured with straps of soap plaister and a bandage. These simple means are generally sufficient to effect a cure. The infant should not be allowed to cry but as little as possible; and should it suffer from cough, immediate attention to cure this com-

plaint is advisable. In most cases, the navel closes in two or three weeks after birth.

Dessault mentions nine cases of infants, under two years of age, in which, after having reduced the herniæ, he passed a needle with a double ligature through the sac and tied it; and thus effected a cure. It is, however, the general opinion, that such an operation is seldom, if ever, necessary.

Hepartomphalos.—The first description of this kind of hernia with which I am acquainted is that of Rockholtz, entitled, *De Hepartomphaloce congenita*—1768. The disease consists of some part of the liver protruding as a hernia at the navel; and hence the term, derived from the names of both parts. The disease is common to infants born prematurely, or to abortions; but is seldom observed in full-grown infants. Dr. Underwood met with one case only, and the infant survived until the sixth month. I have repeatedly seen monsters, whose abdominal viscera protruded through the whole anterior parietes of the abdomen: and examples may be observed in our large museums. In the cases cited, the anterior walls of the abdomen were defective; and, consequently, a cure could not be expected.

Inguinal Hernia. Bubonocoele.—The inguinal canals often remain open after the descent to the testicles. A portion of bowel or omentum descends, and forms a tumour in the groin. The weight of the intestines pressing against the inguinal canal is the cause of this variety of rupture. The tumour is enlarged when the infant cries, coughs, or laughs, and diminishes when the infant is placed on the back or in the horizontal posture; and it often entirely disappears in this posture with a gurgling noise. It should be distinguished from the tumour formed by the testicle when arrested at the inguinal ring, which is not characterised by the preceding symptoms, and by the absence of one or both testicles in the scrotum or purse that usually contains them. The indication of treatment in inguinal hernia is to reduce the tumour, apply a compress and bandage, or a small truss. The application of cold water twice a day, in the manner recommended in the cure of hydrocele, is also conducive to the removal of the disease. Some writers advise astringent lotions to contract the rings. In general, a cure is effected in a few months.

The term *oscheocoele* is applied to hernia when the portion of bowel slips through the abdominal or inguinal ring, and descends after the testicle. It is also termed *scrotal hernia*. The bowel and testicle are covered by the portion of peritoneum, called *tunica vaginalis*, which envelopes the latter.

Scrotal hernia will vary in size; may exist on one or both sides; be increased by coughing, crying, laughing, or sneezing; and disappear, like inguinal, when the infant is placed in the horizontal position, the bowels falling towards the spine by their gravity. It is important to distinguish this disease from

hydrocele; the one grows from above, downwards, the other from below, upwards, and affords distinct sense of fluctuation.

The method of cure is the same as in inguinal hernia. Reduction of the tumour by the taxis, or pressure with the fingers; the application of a pad or bandage, or truss; and affusion of cold water over the ring.

Prolapsus Recti.—Protrusion or falling of the rectum beyond the anus is rarely congenital, though of common occurrence in delicate infants. The reduction of this is easily effected with the finger, smeared with simple cerate or olive oil, introduced so as to push the upper part first, and then the lower. A starch and opiate clyster should be administered; a compress of lint placed on the anus, and over this a bandage properly applied. Astringent clysters, with opium, are sometimes necessary; and when the infant strains much, or evinces a frequent disposition to evacuate the bowels, a proper dose of opium or syrup of poppies should be administered by the mouth.

When the disease attacks children under five years of age, and continues for some days, in despite of the remedies already recommended, it will be advisable to use astringent fomentations and injections; as, decoction of oak bark with alum, or an injection of cold water with a few drops of liq. plumbi acet. and tinct. opii. In some cases, great pain and inflammation come on; and then leeches, with fomentations of chamomile and poppies, must be had recourse to. In chronic cases, a T bandage should be applied, and regularly worn; the child should sit on a hard, flat-bottomed chair, and of such a height that its feet may not touch the ground. This disease is sometimes troublesome to the adult, and its management is best described by Mr. Salmon.

Strabismus, or squinting, is caused by a torsion or displacement of the eyeball; the axes of vision are neither parallel nor direct, but converge or diverge, and are inclined upwards, downwards, or laterally.

One or both eyes may be affected; and the disease is congenital, hereditary, or accidental. The immediate cause of it is an unequal action of the motor muscles of the eyeball. The disease is sometimes induced by the nurse allowing the infant to view objects laterally, when the cot, or cradle, or bed, is so placed towards the light as to compel the infant to strain the eyes; or when the nurse wears a remarkable head-dress, &c.; or it may be induced by convulsions, hydrocephalus, dentition, irritation in the intestinal canal from worms, and many other causes.

When the disease is congenital, it is cured with difficulty, indeed, very rarely; but when accidental, it is easily removed.

When the infant squints, it should never be exposed to a direct light, the objects which please it are to be presented in the direct, and not the lateral position; and it should wear leather or wooden goggles, with the apertures

in the axes of vision, and, according to some, the openings in these instruments should be opposite to the direction of the eye; others advise spectacles, obscured except in one point, either directly in the centre of the axis of vision, or a little to the side opposite to that which the eye is turned.

When the period of childhood arrives, the eye must not be fatigued by reading; nor should other children be allowed to associate with the one so affected, as the power of imitation is great; and those whose eyes are well-formed may often contract a habit of squinting, and more especially if frightened; but they are seldom affected permanently.

I have known several children cured by the instruments already advised; but when the disease is hereditary, it is generally incurable.

There is another disease to be included among the displacement of parts which is occasionally observed, and that is *twinkling of the eyelids*.

I have known one case, in which the disease was incessant while the subject of it was awake. It may be congenital or accidental. It is ascribed by some writers to the conduct of parents and nurses in exposing young infants to the glaring light of theatres, fires, and candles immediately after birth, when the objects are too vivid and transitory to admit of an intent or steadfast gaze.

The real cause of this disease is as yet unknown; it is most probably dependent on a defective condition of the nerves which supply the eyelids; and as these are peculiarly sensitive and irritable, in such cases it would be most imprudent to expose an infant with this disease to a vivid light, more especially on awaking from sleep. It should be allowed to gaze upon objects which it cannot see distinctly. Its general health should be improved, by mild alteratives, aperients, and tonics; reading is injurious, all means likely to improve the health and strength should be employed; and if the disease continue, which it sometimes does, the use of partially obscured spectacles or goggles, as in strabismus, would be, most probably, advantageous. It may, however, continue incurable for life. The last class of external congenital diseases, comprises malformations and diseases of the tegumentary apparatus or skin. The diseases of this group are numerous, of equal interest with all others to the practitioner, and the source of great distress to parents. I shall first describe them, and in subsequent Lectures direct your attention to dermatonozology, or classifications, the definitions of cutaneous diseases, dermatopathology, or the nature of these, and their treatment.

The congenital diseases of the skin may be arranged as follows:—

Malformations and Congenital Diseases of the Skin.—It is well known that marks, deformities and diseases of the skin of the new-born infant, are by no means uncom-

mon. In some cases the skin is partially absent, altered in colour, is covered with excrescences, spots, various eruptions, ecchymoses or bruises, wounds, ulcers, and mother's marks, or *navi materni*. The scalp may be more or less tumefied, in consequence of the pressure it may sustain in certain cases of parturition, when the infant's head is large, and the pelvis or bony passage through it has to escape is small, or contracted. In some cases the cuticle, or scarf skin, is exfoliated or partially separated.

If we recollect the development of the skin and its extreme delicacy when first formed, we shall be able to understand how easily it may be affected with disease; though this knowledge will not account for many of the maladies to which it is liable in utero. It is proved that the skin is partially formed at first about the middle of the second month of embryonic life, when, according to Autenreith, the cuticle begins to appear. When certain parts of the body are absent, there will necessarily be an absence of skin, and its edges will be hard and adherent to subjacent or vicinal organs. Thus, in malformations of the head, chest, or abdomen, there may be more or less absence of the skin. — A familiar example is hare-lip.

Absence of the common integuments depends, according to M. Billard and others, on two different causes: 1. When the skin originally existed, but was destroyed, as in anencephaly, or want of portion of the skull; or spina bifida, or want of a portion of one of the vertebræ or bones of the spine; 2dly. When the skin never existed, in consequence of arrest or want of development of parts which it was intended to cover; and this is what usually happens in absence of the parietes or walls of the head, chest, or abdomen. M. Billard thought there were two modes of destruction of the skin of the embryo, during its sojourn in the uterus or womb. Tumours of the spine (*spina bifida hydrorachitis*), which increase, press on the integuments, cause them to ulcerate and rupture. We observe this happen in new-born infants, as the fluid in such tumours accumulates, distends the integuments, excites the absorbent vessels to thin or remove them; and the irritation is increased by the rubbing of such tumours, which can scarcely be avoided: by the most careful mother or nurse. Hence it is that a great majority of infants born with spina bifida, or a round soft tumour on some part of the spine, are generally destroyed in a few days or weeks after birth, though a few have grown to the adult age, and the tumour had increased to the size of an infant's, and sometimes even a man's head.

M. Billard endeavours to explain the cause of some diseases of the skin of the fœtus, by maintaining that the presence of tumours in the uterus during pregnancy may press on certain parts of the infant, and produce cutaneous disorganisations. In attestation of this opi-

nion, he relates the case of a new-born infant, in whom there was absence of the skin over the left parietal bone, in consequence of hernia cerebri (protrusion of the brain). It was replaced by a depressed cicatrix or scar, united, red, of an inch and a half in length, and four lines or about one-third of an inch in width: the bone was also absent about an inch; and this would have been ascribed to the pressure of a polypus, or some projecting body, against the cranium, had not the woman received a severe blow on the abdomen. It appears to me that it is possible the uterine cavity may be diminished by tumours or projections of some of the bones of the pelvis; and that undue pressure may be made on some part of the embryo; but when the fact is remembered that the fœtus after the occurrence of quickening, which may happen earlier than the fourth month and a half of its existence, is frequently changing its position, I cannot easily conceive how one part of it could be subjected to continued pressure.

This opinion was maintained by Hippocrates. He held in his treatise on generation (*De Genitura*, c. vi.), that if a pregnant woman received a blow on the abdomen, her infant would be injured on whatever part that corresponded with that on which the injury was inflicted, and also if the womb was narrow in any part. M. Lesage related a case in which the infant was injured in the uterus by a blow inflicted on the abdomen of the mother (*Bulletin de la Faculte*, 1805); and M. Geoffroy St. Hilaire cites a similar example, which was observed by Professor Chaussier. (*Mem. de la Societe Medicale d'Emulation*, t. ix. 1826.) Many analogous facts are recorded. It is well known to practical obstetricians that the infant, while in the womb, may not only be injured, or its bones fractured, but even killed by falls or blows inflicted on the abdomen of the mother: some examples of the latter have fallen under my own observations. Pregnant women have frequently declared that they never felt the fœtus move after the receipt of a violent blow on the abdomen; and offered this explanation for the infant having been born dead. Dr. Blundell, Dr. Merriman, and myself, were lately required to state in one of the law courts whether we had ever seen a case of fracture caused by a blow on the abdomen during pregnancy, but none of us had. Another explanation of the cause of the absence and ulceration of the skin is adduced by the zealous and lamented author whom I have quoted. Another cause still remains, M. Billard observes, to determine inflammation or ulceration of the skin of the fœtus before its birth. The absence of the contact of atmospheric air on the skin may, in some cases, produce in this membrane a local transformation, which gives it the characters of mucous membrane. It is this which we observe in the deep folds that the flexion of

the extremities causes in very fat infants, and as the consequence of old muscular contractions. Hébréad has long since cited facts of this kind, to demonstrate the analogy which exists between the skin and mucous membranes. (*Mem. de la Soc. Med. d'Emulation*, tom. viii.)—an opinion now generally received. There is no doubt, says the author, but the water of the amnios exercises on the surface of the fœtus in the womb, an action analogous to that of the air on the body of the infant after birth, when the position of the fœtus subjects a certain part of it to the action of this fluid which bathes it. Then the skin may become softened, inflamed, or ulcerated. The following case, observed by M. Ollivier (d'Angers), offers a very remarkable example:—

A female infant, aged two days, was brought to him on the 24th of April, 1828, who presented a rare variety of club foot, in which the two feet were reversed on both legs, in such a manner, that the dorsal face of each was directly applied to the anterior surface of the leg. On the left side there existed, above the external ankle, in the depression caused by the forced flexion of the foot on the leg, two ulcerations of the skin, very red and bloody, resembling a recent burn in the second degree. The right foot at its internal part, and in all the extent of the dorsal face, as well as the inferior kind of the anterior face of the corresponding leg, presented a large eschar of a greyish yellow colour, surrounded by a very red and bloody inflammatory circle. It strongly resembled a burn. The accoucheur observed these alterations at the moment of birth, and he applied proper bandages to secure the legs in the natural position, and saturnine applications, which finally effected a complete cure.

In cases of absence of the skin at birth, a bandage ought to be applied to protect the organs which are deprived of the natural teguments; and other means should be used to favour the cicatrization or healing of the ulcerated parts.

Exfoliation of the Cuticle.—This disease is occasionally observed very soon after birth, especially in the folds and creases of the skin as in the groins, between the nates, in the folds of the neck, behind the ears, and under the arms. M. Billard attempts to account for it in the following manner:—The integuments of the infant have been immersed in a fluid for seven months, and hence they are in a state of continued suppleness and humidity. The epidermis is, as it were, imbibed with the amniotic fluid which surrounded the infant in the womb, at the period of birth. On exposure to the air it undergoes dessication, loses the suppleness it possessed during intra-uterine life. There results from this dessication, which the cutaneous imbibition or insensible perspiration cannot oppose, a scaling and falling-off of the

epidermis or cuticle, either in the form of scales or of powder.

In proportion, as the layers of the epidermis are elevated, the subjacent layers form an evident substance. The skin under the elevated layers is red, very irritable, and very readily inflames. This is of common occurrence on the genitals, groins, and about the anus, from the irritation of the urine and fæces, together with that caused by severe friction with napkins, for the purpose of cleanliness; and these parts are often attacked with inflammation, ulceration, erysipelas, and sometimes with gangrene. Nurses often induce it by means of a piece of flannel called a "pilcher," which is stitched to the dress so as to cover the napkin. This becomes saturated with urine, prevents the nurse from discovering when the infant has wetted itself; and the consequence is, irritation, excoriation, and often ulceration of parts about the pelvis. This piece of dress should never be used; it is an excuse for laziness on part of the nurse, and the cause of serious disease to the infant. The infant should be changed, powdered, and a dry napkin applied whenever it wets or soils itself.

It appears to me that the accumulation of perspiration in the folds of the skin is more likely to act as a source of irritation than the exposure to the air; because the cuticle of the face and limbs, which is most exposed, very rarely, unless in cold weather, exfoliates. If we add to this the rude frictions which are so generally employed as preventives, we have more obvious causes for epidermic desquamation than the dessicating effects of the atmosphere.

The author, from whom I quoted, partly admits this view, as he observes, the epidermis not only re-produces itself in those parts which are freely exposed to the contact of the air; but in the folds of the skin, as under the arms, in the neck, groins, &c., the exfoliation is effected by these parts being deprived of the contact of the air—these secrete like mucous membranes, or muciform fluid, which dries readily, and favours the formation of a new epidermis by the application of a dessicating powder (starch, tutty, flour, fuller's earth, &c.), on the secreting surface. This circumstance proves that the epidermis is a cutaneous secretion, an organic layer, destroying and re-establishing itself according as the cutaneous surface is exposed to the air, or when its direct influence is removed.

The removal of the epiderm in new-born infants favours cutaneous absorption, as the derm (skin) is not covered by the layer which protects its absorbent surface. By this means we are enabled to convey medicines into the system which in some cases are administered with difficulty to new-born infants. This is an endermic method. The iatroleptic method was formerly at-

tempted by immersing delicate infants in baths of milk, broth, wine, &c., but as the cuticle was entire, the absorption was scarcely perceptible.

Desquamation of the cuticle is often seen in infants of one or two months old, more especially when they are affected with cutaneous eruptions. We have had many such cases at St. John's Hospital, and at the Western Dispensary.

The best mode of treatment is the application of cold water, or a solution of liq. plumbi acet. or vegeto water, and then the free use of the absorbent powders just mentioned. The general health should be attended to, the bowels regulated, the secretions rendered natural by calomel, castor oil, manna, magnesia, with small doses of rhubarb and hyd. cum creta, and nutritious aliment, ought to be administered freely. If ulceration or gangrene supervene, quinine, wine, aromatic spirit of ammonia, with antiseptic lotions or poultices, sprinkled with a weak solution of the chloride of lime or soda, will be indispensable.

Cutaneous Excrescences.—Prolongations of the skin are sometimes observed on different parts of the body, but more commonly on the face, hands, and feet. M. Billard saw a case of female infant, at the Foundling Hospital, in Paris, (l'Hospice des Enfants-Trouvés,) on each of whose cheeks was a prolongation of skin, about half an inch in length, and as thick as a crow's quill. There were two others under each ear. The infant was healthful. He advises a ligature in preference to excision, for the removal of such growths: but he does not state whether he had used it in the case above-mentioned.

He refers to horny growths on adults and aged persons; and thinks they may possibly exist on new-born infants.

Hairy Infants—Diseases of the Hair.—Haller, Valisnieri, and others, describe new-born infants covered with hair; and examples of this kind have been observed within a few years in London. Hairy children have been exhibited at the Medical Societies and Hospitals, within a recent period. In these cases, the lower part of the trunk and extremities were covered with hair; but Haller saw the face, body, and limbs, entirely covered. It is impossible to explain the cause of this excessive capillary growth, except as an irregularity of the general laws of embryogeny. It has happened that new-born infants who were covered with long hairs were delicate and badly developed, and as they acquired strength, the hair fell off without the use of any remedy. In such cases, great caution is necessary before resorting to topical applications; because the skin is extremely sensible, easily irritated, and inflamed; and these conditions would be followed by a decline of health, or by convulsions or death.

In some cases there is scarcely any hair on the body; and this can be accounted for by

want of the normal development. It only exists at, and seldom continues beyond, the first years of birth. Another anomaly of the hair, is its detection in deep-seated subcutaneous tumours, in the wall of the amnios and in the ovary. This is most commonly observed in adults.

Parey describes a disease of the hair, which he calls *malum pilare*, which arises from the hairs being loosened at the bulbs, but not expelled from the cuticle. This is most common on the backs of infants. The disease is accompanied by constant itching, and the evolution of irritable papulæ or pimples. The treatment consists in the use of warm fomentations and bread poultices, and as soon as the hairs are loose, to extract them with a forceps or tweezer. This disease must be distinguished from the *lichen pilaris* of adults, which is caused by derangement of the digestive organs. But of this, more fully hereafter.

The bulbs of the hair are subject to inflammation, as exemplified in *plica Polonica*, and the pilous or hairy follicles may be atrophied or destroyed by the pressure of subcutaneous tumours, *trinea favosa*, or syphiloid diseases. Supernumerary hairs may exist in different regions of the body, on which they do not appear naturally. Facts of this kind are attested by many writers. The colour of the hair may gradually or suddenly change, more especially in adults, after violent mental motions, or during convalescence after acute diseases; or we may observe patches of different colours on the head of the same individual. This, however, is a rare occurrence in infants. I lately attended a learned judge, whose hair all over the body changed colour during convalescence, but finally gained its natural hue. Another adult lost all the hair of the body, and did not regain it.

Diseases of the Nails.—The nails may be absent, abnormally enlarged, or malformed in new-born infants. They vary very much in their structure; they have been found in melicerous and steatomatous tumours. They are also liable to many diseases during infancy, which will be noticed hereafter.

Alterations in the Colour of the Skin.—Alterations in the colour of the skin are numerous. Infants may be born with varied coloured spots on different parts of the skin. Haller reports examples of black infants born of white parents, and white infants born of negro parents. Many modern writers, however, doubt the truth of this statement. Alterations in the colour of the skin are only to be explained by our notions on embryogeny. M. Billard well observes: "The skin does not evidently offer, at the early period of the evolution of the embryo, all the parts which ought to enter into its structure:—it is a simple, thin, transparent pellicle, which may be said to be a continuation of the amniotic tunic, which covers the umbilical cord. We do not as yet distinguish

the line of demarcation which exists at the point of insertion of the umbilical cord.—It remains thin and uncoloured to the fourth month, but then augments in consistence and thickness; the blood abounds in the subcutaneous capillary network, and the teguments of the foetus assume a very manifest rosaceous colour. It is to this afflux of blood towards the skin it owes its colouration; and it is to different modifications which the blood undergoes in furnishing the colouring principle to the skin, that this last owes the different shades of colour it presents according to species."

The blood undergoes different changes in its composition and in its course; and these M. Billard explains in the following manner:—

1. It sometimes happens that the blood is suddenly interrupted in its course—is extravasated—escapes from its natural passages to be deposited irregularly in the surface, and in the thickness of different organs. It is this that Werlhoff, Stoll, and many other authors, have observed;—it is this that constitutes what is called spotted disease (*maladie tachetée*), petechiæ, or hemacelinose (Werlhoff, Stoll, Rayer).

2. The blood accumulated in a part, whether by yielding to the laws of gravity, or whether by the inflammatory stimulus there concentrated, often terminates by acquiring a violet, brownish, and finally a black colour. It is this that we remark on the surface of the lungs and intestinal tube; and it is this that almost always forms, according to me, the striated and black patches which we observe on the surface of mucous membranes.

3. In fine, the blood cannot always furnish to the skin its colouring principle, because that part of the sanguineous fluid destined to produce this may be wanting in certain individuals, or the cutaneous vessels may not be able to receive it; and then the integuments and hair preserve the colouration they presented at the early period of foetal evolution, offering an aspect peculiar to Albino.*

After these considerations, it is possible that infants, who are said to be born with spots, black or white, have been found in such circumstances during intra-uterine life, that the blood which is extravasated to form spots or petechiæ, has not furnished to the integuments the matter which habitually colours them; it is this that produces Albino infants, or it has been subjected to an alteration of colour, which has caused a brown or blackish aspect of the integuments; and this has been recently observed in an adult at the hospital of La Charité. This is the best explanation I have seen of congenital spots on the skin. The au-

* *Reflexions sur la Leucopathie considérée comme le résultat d'un retard de développement. Par Dr. Mansfeldt. Journ. Complém. du De des Sci. Méd. 1826. T. 23.*

thor might, however, have added some observations on congestion of the skin (apoplexia cutis), the interruption to the circulation, which causes lividity of the cheeks in asphyxia of new-born infants, and the cadaverous lividities (maculæ morientium) which are observed on the most dependent parts of the body in the agony of, or immediately after, death. He has omitted to notice in the above remarks,—but does in a future section,—the morbus cæruleus, cyanosis, or blue jaundice, the subcutaneous hæmorrhages or dermatorrhagia, as (ecchymoses, sugillations, or bruises), hæmacelinoses, or spotted hæmorrhagic disease, formerly termed purpura hæmorrhagica, or petechiæ sine febre. He has, however, described general and congenital leucæthiopia, albinism or general whiteness, but not aurigo, icteritia, or jaundice. It is but justice to add, that some of these are scarcely to be considered as congenital diseases; though I am disposed to think it possible all of them may be observed on the skin of the new-born infant. I am led to hazard this observation, as Gaultier has described congenital bronze marks. (*Recherches sur l'Organisation, de la Peau de l'Homme*. Paris, 1819.)

EXTRAORDINARY CASE OF TETANO-EPILEPTIC CONVULSIONS.

The following case is one of great interest, and we shall therefore place it in full before our readers. We copy from our valued contemporary the *Medico-Chirurgical Review* for April:—

A case of this kind lately occurred in practice, which exceeded in melancholy interest any thing ever witnessed by ourselves, during a very long course of observation and experience—and we believe we can say the same on the part of several other physicians and surgeons who were in professional attendance—among whom were Sir A. Cooper, Dr. Bright, Dr. Farre, Dr. Watson, Mr. Macintyre, Mr. Chisholme, and others.

The patient was a gentleman of large fortune, aged about 52 years, though apparently much older; but who had been remarkably active and strong till within the two or three last years of his life. At that time he fell from his horse, while at some distance from his mansion in Wales, in a kind of fit, the exact nature of which could not be ascertained, as it was over before medical attendance could be procured. It was considered to be epileptic, because he had subsequently several attacks of the epileptiform character. In the latter part of November last, Dr. Johnson was called into attendance on this gentleman, in consequence of a bronchitic affection under which he was labouring, and a very obstinate constipation of the bowels. The bronchitis

was not very acute, and was readily relieved by the usual means. The bowels were also brought into a more manageable state by proper aperients, and the patient was as well as to go out in his carriage, and Dr. J. only called occasionally to see him. It was during this period that Dr. J. learnt some particulars of the epileptic seizures which had previously occurred. The patient, though not a man of much intellectual power, did not appear to have had his sensorial energies in the least degree impaired by the epileptic paroxysms.

On Friday night (26th Dec.) the patient, after some anxiety and want of sleep, occasioned by a domestic event, not of a mournful nature, was seized with a violent fit, or, rather, series of fits, which lasted several hours. They were evidently of the epileptic kind, and were followed by a semi-apoplectic sopor, such as often succeeds the epileptic convulsion. When the stupor subsided, the patient was perfectly sensible, and merely complained of soreness in the muscles, but no head-ache, except when he coughed. His bowels were opened by medicine, and it was hoped that the paroxysm would not return. In this hope we were grievously disappointed. It was only the first of a series of paroxysms that attacked this unfortunate gentleman, with more or less violence, and with longer or shorter intervals, from the 26th of December till the 2d day of January, when death put an end to the most dreadful sufferings which patient ever endured, or physician witnessed in this world.

Although the paroxysms varied considerably, in respect to intensity, duration, and intervals, yet they were so identical in kind, that the description of one may serve for all. The premonition was a quivering sensation in the muscles of the lower extremities, which caused the patient to cry out—"The spasms are coming on—hold me, hold me!" He then groaned loudly, till the spasms took away all power of speech. The face was drawn violently towards the left side, as were the eyes. The left arm was bent, and drawn across the chest, the fist being clenched. The left leg and thigh were drawn upwards, and bent across the other leg and thigh. Thus the flexors and abductors of the left extremities overcame the extensors and abductors; but not by one uniform convulsive contraction, as in tetanus, but by a series of the most rapid and painful vibrations. These vibrations could not be counted; but they were perfectly cognisable by the eye and the touch. The muscles of the other side of the body, and of the limbs, underwent similar convulsive vibrations, but were not rigidly contracted at the same time, as on the left side. Thus the abdominal muscles could be seen and felt in this convulsive and vibratory state, and it was evident, from the respiration and the voice (when the latter was

audible), that the diaphragm suffered in common with the muscles of voluntary motion. There never was well-marked opisthotonos or embrothotonos, though the muscles on the front of the body were more convulsed and contracted than those on the back, with the exception of the large muscles about the back of the neck, which generally drew the head backwards, while the face and eyes were drawn to the left. After all the severe paroxysms, the left arm remained, for a time, completely paralytic. If the interval was of some duration, it regained sense and motion in a considerable degree.

The paroxysms were very various in duration—lasting from one minute to fifteen or twenty. They differed much in intensity; since the patient, in some attacks, retained his consciousness, and in others he was totally insensible, and remained so for many minutes after the paroxysm was over. Whenever the consciousness did return, whether immediately on the cessation of the spasms, or after a short lapse of time, the intellectual functions were as clear as at any period of the patient's life. The intervals were also very various as to duration. Sometimes they extended to several hours—at other times, they actually ran into one another—one paroxysm having scarcely ceased, when another commenced. In every attack, the pulse rapidly increased in frequency, and became smaller in calibre. In the severe paroxysms, it was almost imperceptible, and quite innumerable. After the paroxysm, it gradually became developed, full, and strong.

In all the severe paroxysms, the breathing became dreadfully laborious, quick, and wheezing. Many times we expected that the patient would expire, from the collection of mucus in the trachea and bronchia, and from the inadequate supply of air to the lungs. These attacks continued day and night, with longer and shorter intervals, till the 29th of December, when, after a series of frightful paroxysms, the patient fell, apparently, into the "agonies of death," or rather into that state of insensibility which precedes dissolution. The breathing was laborious and stertorous—dead rattles in the throat—eyes open and inanimate—total paralysis of the whole body—mouth wide open—evacuations passed involuntarily—skin cold and clammy—in short, he appeared in *articulo mortis*, from which not one of his medical attendants conceived a possibility of emergence. Several of them waited, hour after hour, to see the final close. This state lasted six hours and upwards. In the course of this period, we occasionally perceived a slight tremor or quivering in the tendons of the wrist, during which, as in the severe paroxysms, the pulse became nearly extinct, the breathing short, broken, and hardly perceptible, and life itself in the act of

vanishing! Strange to say, from this low ebb he rather suddenly emerged—spoke; took nourishment, and became considerably better than he had been at any period during the two preceding days. Sanguine hopes were entertained of his recovery during the 30th and 31st days of December—there being often a considerable interval between the paroxysms, during which he was cheerful and full of hopes himself!

It was after this miraculous resuscitation that we observed a phenomenon not before presented, and which did not afterwards recur. In two successive paroxysms, the face and eyes were drawn violently to the right side, the spasms in the extremities and trunk continuing nearly the same as usual.

The constitution, which had hitherto borne up wonderfully against such unparalleled tortures, now evidently began to give way. The features became shrunk, and expressive of unutterable suffering; and he expressed a conviction—almost a wish, that the Almighty would release him from his agonies, one way or other! The paroxysms continued, but neither so violent nor so protracted as at an earlier period of the disease:—he got some sleep in the night of the 2nd of January, and expired towards the morning.

We have not interrupted the narrative of this terrible malady, by an enumeration of the remedies employed—for, candidly speaking, we very much doubt whether the disease was, in any material degree, even mitigated by the various means that were tried in this deplorable case. When the list of medical attendants is referred to, it will hardly be doubted that every remedy which talent or experience could suggest was fairly employed. Cupping, leeching, blistering, purging—and, lastly, *mercurialization*, were tried—and all failed. The dissection will well excuse the want of success in therapeutic agents. One feature was prominent throughout—the extreme vitiation of the fecal evacuations. They continued of the most depraved kind till the last—or till there was nothing more than mere watery secretion to come away. Opium was not extensively employed, on account of a most decided antipathy which the patient entertained against the medicine. In early life this gentleman had studied physic, and he was able to detect at once the smallest quantity of opium, when exhibited, by its effects on his bodily and mental functions. It is very doubtful, however, if the extensive exhibition of opium, in any shape, would have been productive of any material benefit. The only remedies which seemed to promise any mitigation of the symptoms were purgatives and mercury. The former generally diminished, for a short time, the frequency and violence of the spasms:—the latter (calomel in two or three-grain doses every two or three hours)

promised, at one time, a relief that engendered hopes of a happy result; but alas! these hopes were delusive, and every remedy failed in the end. The calomel could not be got to affect the mouth—and ultimately so irritated the bowels, that opiates became indispensable.

Dissection.—It was with the greatest difficulty we got permission to examine the head. Sir Astley Cooper, Dr. Bright, Dr. Watson, Dr. Johnson, Mr. Macintyre, Mr. Balderson, and Mr. H. J. Johnson, were present. The cranium was remarkably thick, especially about the os frontis, where the diploe was obliterated. The membranes covering the fore and upper part of the right hemisphere were thickened, and strongly adherent to the subjacent brain. In the falciform process, deep between the anterior lobes of the brain, and near the inferior longitudinal sinus, was found a rough and jagged bone, an inch and a quarter in length, by about half an inch in breadth, well calculated to irritate both hemispheres. In the middle of the anterior lobe of the right hemisphere, near its upper surface, was found a portion of brain, larger than a walnut, reduced to the consistence of a yellowish fluid, contained in a cavity lined by a polished surface, but not exhibiting the organization of a membrane, or cyst. Surrounding this cavity and its liquid contents, the medullary substance of the brain was preternaturally hard and firm, like an indurated circle, contrasting remarkably with the brain in general. The substance of the brain, immediately under the thickened and adherent membranes, was in a state of *ramollissement*. There was considerable vascularity about the base of the brain and pons varolii, but no other morbid appearance deserving of notice.

Many circumstances, which cannot be mentioned here, combined to render this case exceedingly interesting—and not the least of these was the horrible torture experienced by the patient himself, once one of the faculty, and nearly connected with some of the first medical characters in this or in any other country. We here see an organic lesion, or rather lesions, of the brain, which must have been of several years' standing, and yet producing functional disturbance only occasionally—and often at long intervals—the health, in such intervals, being apparently good—at all events, without any impaired state of the cerebral functions. It may be a question, what part the bony deposit in the falx took in the chain of causation. We are of opinion that, in conjunction with the great thickness of the cranium, this irritating body, placed deep between the two hemispheres of the brain, must have conducted largely to the epileptic attacks with which the patient was troubled for some years previous to his last illness. The diffident portion of brain, in the anterior lobe of the

right hemisphere, must have been of some standing; but we are inclined to think that it was rather an effect than a cause of the epileptic seizures—at all events, that it took place *posterior* to the early attacks, and, consequently, could not be considered in the light of *their* cause. But that it was mainly instrumental in the fatal catastrophe we have little doubt. The convulsions were always greater in the left than in the right side—while the face, excepting in two paroxysms, was constantly drawn to the opposite side in the fits. The most inexplicable part is the circumstance of the paralysis, which generally succeeded the violent spasms of the *left* arm, but without any such event in the left side of the face. Why was the face drawn twice to the *right* side—and all the rest of the times to the opposite side? This is a puzzler? Could the bony deposit in the falx, situated *between* the two hemispheres, account for this phenomenon? Circumstances might possibly arise, in the course of the disease, that might cause the irritation to be more directed towards one hemisphere than towards another, at different periods. It is remarkable that, with such lesions, health should be but slightly impaired—and the mental functions not at all—the day before the fatal attack commenced! The disordered condition of the bowels was the only ostensible cause why the disease was called into such destructive activity. This gentleman had strong prejudices—we might say antipathies, especially against calomel, and every preparation of opium. He had also the strongest objections to many other medicines—circumstances that crippled his medical attendants in the first few days of the malady, and probably proved detrimental to the patient himself. Considering that the organic changes must have existed for a long time, it is by no means improbable that, if the digestive functions had been restored to a healthy state during the first two or three days of the spasms, the termination might have been otherwise than it was, and that a temporary respite might have been obtained.

—o—

Therapeutic Agencies of the Stinging-nettle, Urtica Urens.

M. Fiard concludes from some experiments, 1. That the decoction of nettle should be tried in moderate doses as an anti-diuretic in diabetes. 2. That it would most probably prove an efficacious means of producing a derivation in hydro-thorax and hydrocephalus. 3. That in serious disorders resulting from the suspension of the lacteal secretion in lying-in women, it would be likely to cause a renewal of secretory activity in the breasts.—*Gaz. Med.*, April 18.

A NEW PRACTICAL FORMULARY

OF HOSPITALS, OR A

Collection of Formulae of the Civil and Military Hospitals of France, Germany, Italy, Great Britain and Ireland, &c., containing the Indication of the Doses in which simple Substances, magistral and officinal Preparations of the Codex are administered, the use of New Medicines, and general receipts on the art of prescribing. By M. EDWARDS, M. D., and P. VAVASSEUR, M. D., of the Hospitals of Paris—1834. Translated and augmented by M. RYAN, M. D. &c. &c.

Mellis scillæ, ʒj.

Dosis, cochleare unum secundâ horâ.

BELLADONNA.

In large doses, belladonna is a narcotico-acrid poison; in small ones, a narcotic. It is much recommended in the treatment of whooping-cough, convulsive cough, tic douloureux of the face, and other nervous affections. It is employed with advantage in cases of cancer, dysentery, hydrophobia, jaundice, &c. It is sometimes useful as an external application in combating acute and chronic inflammations of the skin, white swellings of the articulations, rheumatic affections, &c. It acts on the iris, and is employed in contraction of the pupil. It is also used to cause dilatation of the pupil before performing the operation for the extraction of cataract, as likewise of dilatation of the neck of the uterus, in cases of spasmodic rigidity of that organ, which impedes labour. [I have never found it successful. T.]

INTERNALLY. Powder. Gr. j—xij, in pills.*Infusion.* ʒj in ʒ viij of boiling water, of which ʒj—ij should be taken daily.*Extract.* P. Gr. lʒ—iv, in pills.*Powder of Belladonna.* H. of Germ.R_x. Pulv. rad. belladonnæ, gr. iij;

Sacchari albi, gr. xvij.

Divide in chartulas ij in die sumendas.

Pills of Belladonna. H. of Italy.R_x. Extracti belladonnæ, gr. iv;

Succi sambuci, q. s.

Fiant pilulæ xvj, de quibus capiat unam secundâ quâque horâ.

In whooping cough and scarlatina.

Prophylactic Solution against Scarlatina.
(Hahneman.)

Rx. Extracti belladonnæ, gr. ij;
Aque destillatæ, ℥j.

Liqua.

From one to five drops should be given four times a day.

For children under six years, and above that age, gut. vi to x may be given.

[The prophylactic power of this remedy is lauded by the Germans, and by Dr. Mac-michael. T.]

Syrup of Belladonna. H. of Germ.

Rx. Belladonnæ foliorum, ℥ij;
——— radicia, ℥j;
Sacchari albi, lbj;
Aque fontanæ, q. s.

Coque ad Oj, et cola.

The dose is a tea-spoonful in whooping cough.

Anodyne Potion. H. of Germ.

Rx. Extracti belladonnæ, gr. ij;
Aque destillatæ, ℥ij.

Fiat potio, cujus capiat guttas v, ad x pro doli.

In nervous vomitings.

EXTERNALLY. *Infusion*, in lotions, &c.

Extract, in frictions on the eyelids, to obtain dilatation of the pupil, and on parts affected with neuralgia.

[Also as a plaster in lumbago and spinal irritation. T.]

Pomade of Belladonna. H. de la Mat.

Rx. Extracti belladonnæ, ℥ij;
Aque destillatæ,
Cerati simplicis, ā ā ℥ij.

Fiat unguentum.

Employed with success to obtain dilatation of the neck of the uterus, in difficult cases of labour. About ℥ij should be applied to the organ, by means of a small syringe.

The Ointment of Belladonna, of the English Hospitals, is composed of equal parts of the extract of belladonna and cerate. It is employed with advantage in frictions, in cases of white swellings, and to prevent spasmodic contractions of the urethra, and the sphincters.

Enema of Belladonna.

Rx. Folior. belladonnæ, gr. xij;
Aque ferventis, ℥vj.

Macera.

Employed with advantage in spasmodic contractions of the urethra, which sometimes prevent the introduction of a catheter into the bladder.

HENBANE.

In large doses, a narcotico-acrid poison, in smaller ones it acts as a sedative on the nervous system. It is recommended in the treatment of neuralgia, epilepsy, hypochondriasis, nervous coughs, plumbers' colic, muscular trembling, &c.

[Mr. Houlton has made many improvements with this medicine, and is of opinion

that the London College of Physicians has erred in advising the plant to be collected annually—it should be biennially. T.]

EXTERNALLY. The leaves are employed in cataplasms on cancerous tumours, to abate pain; as likewise in lotions, fomentations, baths, &c.

INTERNALLY. *Powder.* Gr. j—℥j. Not much used.

Extract. P. The same doses, in pills.

Sedative Boluses. H. of Italy.

Rx. Extracti hyoscyami, gr. viij;
Gummi acaciæ, ℥vi;
Succi sambuci, q. s.

Fiant boli xij, de quibus sumat unam tertiam quaque hora.

In gastrodynia, spasmodic colic, &c.

[I have found the following pills extremely valuable in hysteria, and for nervous women during uterine gestation:—

Rx. Extract. colocynth. comp. ℥ij;
——— hyoscyami, ℥j;
Hydrargyri subm. gr. vi—xij;
Olei menthe piper. ℥v;
Strychninæ pulveris, gr. j.

Tere intime, et in pilulas xij—xv divide, capiat j mane vespereque.

This is an efficacious aperient, not only in the diseases mentioned, but also in the different forms of dyspepsia. The hyoscyamus is requisite to correct the drastic effects of the colocynth; the mercury is necessary in the majority of cases, as most patients suffer from disordered liver; the oil of mint is a carminative, and the strychnine a most powerful agent on the nervous system. T.]

Narcotic Emulsion. H. of Germ.

Rx. Olei amygdalarum, ℥j;
Aque fontanæ, ℥iv;
Mucilaginis acaciæ, q. s.

Fiat emulsio et adde,

Syrupi simplicis, ℥j;
Extracti hyoscyami, gr. x.

Misce.

Dosis cochleare modicum omni hora.

Sedative Potion. H. of Germ.

Rx. Extracti hyoscyami, gr. v;
Aque lactucæ, ℥iij;
Syrupi communis, ℥ss.

Dosis ℥ss pro re nata.

EXTERNALLY. *Decoction.* In frictions, fomentations, &c.

Oil of Henbane. P. In frictions.

Narcotic Cataplasm. P. q. s.

Lotion of Henbane. H. of England.

Rx. Extracti hyoscyami, ℥j;
Aque destillatæ, ℥iij.

Collyrium of Henbane. H. of Germ.

Rx. Extracti hyoscyami, gr. x;
Aque destillatæ, ℥ss.

Fiat collyrium.

Employed to dilate the pupils, and in ophthalmia accompanied with spasmodic contraction of the eye-lids.

Anodyne and Resolvent Liniment. Hôt. D.

Rx. Extracti hyoscyami, 3 ss;
Saponis duri, 3 ij;
Olei tilis, 3 vj.

Fiat linimentum.

A spoonful employed in frictions, in certain cases of glandular swellings.

WHITE HENBANE.

This is not so active as the black. It is employed in the form of

Sirap of White Henbane. (Chevalier.)

Rx. Extracti hyoscyami albi, gr. iv;
Syrupi simplicis, 3 iv.

Liqua. Dosis 3 ss. In a sedative potion.

HEMLOCK.

In large doses a narcotico-acrid poison, whose action is principally on the brain. In small doses its action resembles that of belladonna. It is employed as a sedative in the treatment of nervous affections, priapism, obstinate cough, &c. It is also recommended in cases of enlargement of the mammae, and in scirrhus and cancerous affections, of which it diminishes the pain. It appears to be also useful as an external application in certain chronic enlargements of the viscera.

Subst. incomp. The acids.

INTERNALLY. *Powder.* Gr. ij—3j, in pills.

Extract. P. Gr. ij—3j, in pills.

Extract préparé sans fécule. P. Gr. j—xv.

Suc exprimé. P. Gutt. xiv—xxiv, in a potion.

Teinture Éthérée. P. Gutt. x—xx, in a potion.

Pills of Hemlock. (Stoerck.)

Rx. Extracti conii, 3 j;
Pulveris folior. conii, q. s.

Fiat massa, in pilulas granorum ij, distribuenda, de quibus sumat unam ad quatuor bis in die.

[Some recommend the extract combined with acetate of lead, but the solution of the latter is preferable.—(See *Acetate of Lead.*) T.]

Pilules Depurative. M. de Santé.

Rx. Extracti conii, 3 iv;
—— opii, gr. xvij;
Hydrargyri submur. 3 ss;
Syrupi althæe, q. s.

Fiant pilulæ xxvi, harum capiat duas quotidie.

The number may be gradually augmented.

Used to allay the pains which accompany certain organic affections. Each pill contains gr. 8 of hemlock, gr. 1 of calomel, and gr. ½ of opium.

Infusion of Hemlock. H. of England.

Rx. Conii,
Coriandri sativi, ā ā 3 ij;
Aquæ ferventis, 3 viij.

Macera et cola. Dosis 3 i—ij bis vel ter in die.

Compound Mixture of Hemlock. H. of Eng.

Rx. Extracti conii, 3 j;
Sodæ subcarbonatis, 3 iss;
Aquæ cinnamomi, 3 vi;
Decocti glycyrrhizæ, 3 ix.

Misce. Dosis cochl. medium semel vel bis in die.

Anodyne Potion. H. of Germ.

Rx. Extracti conii, 3 j;
Aquæ cinnamomi,
Syrupi aurantii, ā ā 3 ss.

Dosis 3 ij pro re nata.

[The following mixture will alleviate the numerous nervous disorders, or pains in phthisis:—

Sedative Mixture. (Ryan.)

Rx. Extracti conii,
—— hyoscyami, ā ā 3j—3 ss;
Mucilaginis acaciæ, 3 j;
Misturæ camphoræ, 3 iv;
Tincturæ digitalis, 3 i—iss;
Acidi hydrocyanici, m vi—viij;
Vini ipecacuanhæ, 3 i—ij;
Syrupi toluani, 3 iv—vi.

Sit mistura, cujus sumat cochl. amplum, phialâ prius agitâtâ, secundis vel tertiis horis. T.]

EXTERNALLY. *Decoction,* 3 j—Oij of water, employed in lotions, fomentations, &c.

Oil of Hemlock. P. G. v, in embrocations.

Plaster of Hemlock. P. G. v.

Cataplasm. 3 ij in lbij of common cataplasm.

Fomentation of Hemlock. H. of England.

Rx. Conii folior. 3 ij;
Anthemidis florum, 3 ss;
Aquæ, Oij.

Macera et cola.

Cataplasm of Hemlock. H. of England.

Rx. Conii, 3 ij;
Micæ panis, 3 vj;
Aquæ, q. s.

Fiat cataplasma.

STRAMONIUM, OR THORN APPLE.

In large doses a narcotico-acrid poison; in small ones its action is similar to that of belladonna. It is recommended as a sedative in convulsions, neuralgia, rheumatism, &c. It is not much used at present.

[Dr. Kirby, of Dublin, employed it in facial neuralgia, and others advised it to be smoked in asthma. T.]

INTERNALLY. *Powder.* Gr. i—xx, progressively increased.

Extract. P. Gr. ½—ij, in pills.

Syrup of Stramonium. H. of Germ.

Rx. Seminum stramonii, 3 j;
Aceti communis, lbj.

Macera per dies duas in vase clauso cola et adjice,

Sacchari, lb ij.

Dose, ʒ ij—iv, in a sedative potion, or a tea-spoonful every three or four hours.

In nervous affections.

Wine of Stramonium. H. of Germ.

Rx. Seminum stramonii, ʒ ij;

Vini albi, ʒ viij;

Spiritus rectificati, ʒ j.

Decoque per duas dies lento igne, et cola. Dosis, gutt. vi—ʒj, ex cyatho aquæ cum saccharo.

As an anodyne.

Hufeland considers this preparation superior to that of opium.

TOBACCO.

In large doses a narcotico-acrid poison; in small ones it is a violent irritant of the intestinal mucous membrane, and a narcotic.

Tobacco is used in divers preparations in cases of chronic catarrh in individuals of a lymphatic temperament, in dropsy, &c. Tobacco enema is administered with advantage in cases of asphyxia, strangulated hernia, or to destroy ascarides.

[My distinguished and valued friend, Dr. O'Beirne, of Dublin, has used it in tetanus with great success. Might it not be employed in transverse or cross births, when the infant is dead, and all other remedies have failed to tranquilize parturient action. T.]

EXTERNALLY, it is useful in fomentations in cases of dysentery: baths prepared with a decoction of tobacco leaves newly gathered are sometimes useful in tetanus.

INTERNALLY. *Infusion.* ʒ j—ij in ʒ vj of boiling water, to be taken at two doses, as an emetic. Not much employed.

Fowler's Infusion of Tobacco. H. of England.

Rx. Tabaci foliorum, ʒ ij;

Aquæ ferventis, ʒ iv.

Macera in vase clauso, per horas tres, cola et adde,

Spiritus rectificati, ʒ j.

Dosis, gutt. xx—xl quotidie.

In asthma and hydrothorax.

Wine of Tobacco. H. of Germ.

Rx. Tabaci folior. ʒ j;

Vin. albi, ʒ xij.

Macera per dies octo et cola. Dosis, gutt. v—xxx in vehiculo apto.

In certain cases of dropsy.

EXTERNALLY. *Decoction.* ʒ ij—Oij of water.

Employed as a fomentation in cases of scabies.

Huile de Nicotine. P. *In frictions, in the treatment of scabies, chilblains, indolent tumours, &c.*

Cerate of Tobacco. H. of Germ.

Rx. Succu tabaci,

Cera flavæ, ā ā ʒ iiij;

Picis, ʒ iss;

Olei olivæ, q. s.

Misce.

Employed in frictions in tetters, when there is not much inflammation.

Enema of Tobacco. Hot. D.

Rx. Tabaci foliorum, ʒ j.

Coque in,

Aquæ, Oij.

Cola et adjice,

Antimonii tartarizati, gr. xij.

Employed as an energetic stimulant, in asphyxia, &c.

Fomentation of Tobacco.

Rx. Tabaci foliorum, ʒ j;

Aquæ, q. s.

Coque.

The leaves are applied to the epigastrium as an emetic.

[I have known a tobacco leaf applied to a chronic ulcer of the leg excite violent vomiting, diarrhoea, and syncope. Tobacco water, or a decoction of tobacco is a common remedy, in Ireland, for mange in sheep, and for cutaneous diseases, the most obstinate or different. It is, however, rarely employed in human diseases. T.]

STRONG-SCENTED LETTUCE LEAVES.

Narcotic and diuretic. They are administered with success in ascites, enlargements of the abdominal viscera, jaundice, &c., and as a substitute for opium, in neuroses. Not much used.

INTERNALLY. *Extract.* P. Gr. ij—ʒj, and even ʒj, in pills.

Lettuce-Lactucarium. (Duncan).

A sedative which does not produce narcotism, like opium. It is employed in a great number of cases, even inflammatory to produce sleep.

INTERNALLY. Gr. ij—iv, and progressively to gr. x or xv, in pills.

CHAPTER XII.

MEDICINES PRINCIPALLY USED AS EMETICS.

TARTRATE OF ANTIMONY AND POTASS.

In large doses it is a violent poison; in small ones, an emetic and purgative; in moderate quantities, and if long time continued, it acts as a diaphoretic alterant. It is administered as an emetic in cases of gastric derangement, bilious fevers, &c. In very small doses, and dissolved in a large quantity of a proper vehicle, it is employed as a purgative; as a counter-stimulant, it is used with success in pneumonia, hepatitis, and other inflammatory diseases of the parenchymatous organs.

[It is also given in strangulated hernia, in nauseating doses, to diminish the action of the heart and muscles, and also to allay powerful uterine action in cases requiring version, after opium and depletion have failed. T.]

EXTERNALLY, it irritates the skin, and pro-

duces an eruption of pustules peculiar in their nature. It is consequently employed as a powerful derivative.

[It does not always irritate the skin, or cause an eruption, and in such cases the addition of four or six minims of croton oil, to each ounce of antimonial ointment, will render it effectual. The simple ointment may fail to irritate when applied to a certain part, though an eruption similar to that usually produced may appear upon a distant one. T.]

Subst. incomp. Concentrated acids, metallic acids of the second class, and their carbonates, the soaps, gallic acid, bitter and astringent substances, cinchona, rhubarb, &c.

INTERNALLY. As an emetic, gr. j—iv, in two ounces of tepid water, half a glassful of which should be given every quarter of an hour.

As a purgative, gr. j—ij in Oij of a vehicle (veal or herb broth), of which a glass should be taken every hour.

As a counter-stimulant, gr. iv— \mathfrak{D} j, and progressively to \mathfrak{D} ij in the 24 hours.

Wine of the Tartrate of Antimony. P. (3j contains a little more than gr. l of antimony). As an emetic, \mathfrak{z} j—ij. Not much used, [as gastric irritation or gastro-enteritis is so common to infants. T.]

As a diaphoretic, \mathfrak{z} ij—iv.

Potion émetique. P. To be taken in three doses, at an interval of a quarter of an hour.

Emetic Potion. H. of Germ.

Rx. Antimonii tartarizati, gr. iij;
Aque puræ, \mathfrak{z} ijss;
Oxymellis scillæ, \mathfrak{z} ss.

M. Half of this potion should be taken at once, and the remainder in spoonful every quarter of an hour.

Pulvis Emeticus Communis. H. of England.

Rx. Pulv. ipecacuanhæ, gr. xv;
Antimonii tartariz. gr. j.

Sit pulvis statim sumendus, et vomitu moto, bibat æger pocula infusi anthemidis, vel aque calidæ.

[This powder will frequently succeed, when its component parts have failed. This emetic may be given in a draught with syrup. T.]

Emetic Potion, or Eau Bénite. H. de la Ch.

Rx. Antimonii tartarizati, gr. vj;
Aque, \mathfrak{z} vij.

Misce.

A very violent emetic, employed in the treatment of painters' colic.

The *Potion vomitive* of the H. des Ven. contains only gr. ij of the tartrate of antimony, dissolved in \mathfrak{z} iv of a ptisan composed of hound's tooth and liquorice. It is taken at one dose.

Emetic Potion. H. of England.

Rx. Antimonii tartarizati, gr. j;
Pulveris ipecacuanhæ, gr. xv;
Aque menthæ, \mathfrak{z} xij;
Syrupi croci, \mathfrak{z} j.

Fiat potio in dosibus duabus capienda.

Lemonade Emetice. H. of Italy.

Rx. Antimonii tartarizati, gr. ij;
Sacchari, \mathfrak{z} ss;

Misce.

Dosis semicyathus omni semi-horâ.

As an emeto-cathartic.

Eau Minérale. H. de la Ch.

Rx. Antimonii tartarizati, g. iij;
Sodæ sulphatis, \mathfrak{z} ij;
Aque ferventis, \mathfrak{z} .

Liqua.

To be taken hot in three or four doses, at a quarter of an hour's interval. Employed in painters' colic.

[It is, perhaps, unchemical, but very efficacious. T.]

The *Potion emeto-cathartique* of the H. des Ven. contains only gr. ij of antimony, and \mathfrak{z} ij of the sulphate of soda, dissolved in Oij of veal broth.

The *Potion emeto-cathartique* of the H. St. Ant. contains only gr. j of antimony to \mathfrak{z} iv of a vehicle.

Potion Stibio-Opiace. H. of Paris.

Rx. Antimonii tartarizati, gr. j;
Opii pulveris, \mathfrak{a} \mathfrak{a} gr. j;
Gummi tragacanthæ, \mathfrak{D} j;
Aque folior. aurantii, \mathfrak{z} ij;
Aque fontanæ, \mathfrak{z} vij.

Misce.

Dosis cochl. min. singulis semihoris.

In intermittent fevers.

Potion Anticroupal. H. des Enf.

Rx. Antimonii tartarizati, gr. jss;
Syrupi ipecacuanhæ, \mathfrak{z} j;
Oxymellis scillæ, \mathfrak{z} ij;
Infusi polygalæ senegæ, \mathfrak{z} iv.

Misce.

Cochl. amp. pro dosi.

To facilitate the expulsion of the false membranes.

[This was very much employed a quarter of a century since, but seldom at present. T.]

Apozème Contro-Stimulant of Lacnæe. H. de la Ch.

Rx. Antimonii tartarizati, gr. vj;
Infusi foliorum aurantii, Oj;
Syrupi simplicis, \mathfrak{z} ij.

Misce.

Dosis \mathfrak{z} ij. tertiâ quâque horâ.

In acute inflammation of the lungs, &c.

Antimonial Emulsion with Camphor. H. of Germ.

Rx. Antimonii tartarizati, gr. v;
Emulsionis camphoræ, \mathfrak{z} x.

Misce.

Cochl. amp. pro dosi.

As a diaphoretic and alterative.

Antiphlogistic and Sudorific Potion. (H. of Italy).

Rx. Antimonii tartarizati, gr. vi;
Mellis despumati, ʒ ss;
Infusi flor. sambuci, Oij.

Misce.

Cyathum minimum pro dosi.

In rheumatic and gouty inflammations.

[Other Italian physicians use it in larger doses.

Rx. Aquæ, ʒ vj;
Ant. tart. gr. xiv;
Syrupi croci, ʒ ss.

Dosis ʒ ss secundis horis ad sextam vicem.

[It has been given to the quantity of a scruple, in repeated doses, in twenty-four hours. It vomits most persons two or three times, purges others, or excites copious perspiration, while more are relieved of pneumonia without any evacuation. The mortality is one in twenty-eight. A drachm of syrup of poppies is added to each draught containing gr. ij, every second hour. It is strongly recommended after one copious bleeding, by the Italians, Laennec, Forbes, Southwood Smith, Tweedie, Graves, and others. Twelve grains are generally sufficient, though twenty have been given in twenty-four hours. T.]

ANTICATARRHAL PILLS.

Rx. Antimonii tartarizati,
Opii pulveris, ā ā gr. iij;
Gummi tragacanthæ, gr. x;
Confectionis rosæ, q. s.

Divide in pilulas l, quarum capiat duas mane nocteque.

In chronic pulmonary catarrh.

EXTERNALLY. Gr. xij—ʒj on a burgundy pitch plaster.

Pommade Stibice, called *d'Antenrieth*. P. (ʒj—ʒj of lard). In frictions two or three times a day, as a rubefacient.

The *Pommade Stibice* of the H. de Paris contains ʒj of antimony to ʒj of lard; it is twice as strong as that of the Codex.

These pommades are used in frictions on the skin; and their use is continued until an eruption of pustules is produced. This manner of using this medicine is very beneficial in certain affections of the chest, hooping cough, spinal irritation, &c.

Rubefacient Lotion. (H. of Germ.)

Rx. Antimonii tartarizati, ʒj;
Aquæ ferventis, Oj;
Spiritus camphoræ, ʒ ss.

Misce.

Strengthening Collyrium. (H. of Germ.)

Rx. Vini antimonii tartarizati, ʒ ss;
Aquæ rosæ, ʒ iv;
Balsami Fioraventi, ʒ ij.

Fiat collyrium.

Employed in chronic ophthalmia.

Purgative Enema. H. of America.

Rx. Tartratis antimonii, gr. xx;
Solutionis acacie, ʒ viij.

Fiat enema.

SUB-HYDROSULPHATE OF ANTIMONY, OR KERMES MINERAL.

In doses of a few grains, an emetic, whose action is less to be depended on than that of the tartrate of antimony; in smaller doses, it acts as a stimulant on the lungs and the cutaneous surface. It is often used in cases of peripneumonia, chronic catarrh, humid asthma, &c. It is also recommended as a sudorific in cutaneous diseases, chronic rheumatism, gout, &c. It is employed by the counter-stimulists in the same cases and same manner as the tartrate of antimony, although, according to the observations of Laennec, it is less efficacious.

Subst. incomp. All acids.

INTERNALLY. As an emetic, gr. vj—x, suspended in a mucilaginous fluid.

As an expectorant, gr. ʒ—iv, in an emulsive potion.

As a counter-stimulant, gr. xij—ʒj, and even to ʒj, progressively.

Expectorant Powder. (H. of Germ.)

Rx. Antimonii hydro-sulphatis, gr. xv;
Sacchari purificati, ʒj.

Divide in chartulas xv, quarum capiat duas vel tres pro dosi.

Powders used in Hooping Cough. (H. de Montp.)

Rx. Antimonii hydro-sulphatis, gr. ij;
Ipecacuanhæ pulveris, gr. vj.

Fiant pulveres vi, de quibus capiat unum quartâ quâque parte horæ.

Powder of the Hydro-sulphate of Antimony with Camphor. (H. of Germ.)

Rx. Antimonii hydro-sulphatis, gr. ʒ;
Camphoræ pulveris, gr. j;
Sacchari purificati, ʒj.

Divide in chartulas duas in die capiendas.

Diaphoretic Bolus. (H. of Germ.)

Rx. Antimonii hydro-sulphatis, gr. vj;
Camphoræ, gr. viij;
Ipecacuanhæ, gr. viij;
Succi sambuci, q. s.

Fiant boli vj, quorum capiat unum tertîâ quâque horâ.

In catarrhal fevers.

Expectorant Bolus. H. of Italy.

Rx. Antimonii hydro-sulphatis, gr. viij;
Gummi ammoniaci, ʒj;
Oxymellis scillæ, ʒ ss;
Pulveris glycyrrhizæ, q. s.

Divide in bolos octo, quorum sumat unum secundâ quâque horâ.

(To be continued.)

ABUSES IN HOSPITALS AND DISPENSARIES

THE Hospitals and Dispensaries of this metropolis are numerous, but the great evil, as observed by Celsus, besetting them, is that the poor, for whom they were ostensibly and originally declared to be designed, derive, comparatively speaking, little or no benefit from them; because on their personal application, they will be refused admittance, however severe in mind or body their sufferings may be.

The Governors thereof are not apparently inspired by the divine sentiment, "Seek and ye shall find, knock and it shall be opened to you," as the place intended for the friendless and the needy suppliant, many of whom have seen better days, they too often allow to be occupied by the bloated dependants or servants of the wealthy*. In truth we here take leave to state that these Hospitals, so much boasted of, are not the ornaments of our country; because, like the poor-rates, they have their origin in want of wisdom, want of patriotism, magnanimity and generosity, in the application of the resources of a great people.

How much better would it be to encourage industry, by modifying the laws of entail and mortmain, by attention to our fisheries at home and abroad, by permitting the Hebrews to purchase land, by the cultivation of the soil, on a still greater scale; by which combined measures the poor-rates, amounting to eight millions annually, would be saved, as also the expenses of these hospitals, and by which line of conduct the industrious man, whether in health or disease, from having scope for the exercise of his talents, would be able to remain under his own roof, and in the bosom of his own family—a consolation above all estimation, and compared with which, a palace has no charms. Those institutions that benevolently contemplated the expanding the human heart and mind by education, like those for the relief of mental and bodily infirmities, have also in this metropolis frequently taken the same worthless direction. Before admission to the latter, with which we intend at present to deal, the sufferer, although the most marked object of compassion, must have the recommendation of a subscriber; and this the poor and the stranger have extreme difficulty in

* Unless the governors of Hospitals shall allow misfortune to be insulted by neglect, they should insist upon a Physician and Surgeon being constantly on duty. Hospital dressers, and restrictions as to visiting the patients, should be particularly attended to, in order to prevent the diffusion of contagion throughout the metropolis. It is highly probable that the small pox, of which Sir Peter Parker died, was conveyed from an Hospital, or a receiving room thereof, or a Dispensary, by those frequenting them.

obtaining*. I am well convinced that thousands, who are slightly afflicted in the first instance, have their maladies irretrievably increased in the running after a letter from a subscriber, which they either never obtain, or if obtained it is of no use, as the result of delay†. These are well known and disgraceful deformities in the Hospitals and Dispensaries of the metropolis, which never would have been established, had the Colleges of Physicians and Surgeons honestly devoted themselves to the performance of those duties which they owed to their fellow creatures and to their profession. Let us suppose the father of a family attacked with acute disease of the head, chest, or abdomen, and that he is poor and unknown, and unable to pay for his lodging and medical assistance. In this deplorable condition he attempts to procure a letter of admission to an Hospital or a Dispensary, and in making these efforts towards obtaining relief, the proceeds of his labour are lost to his family, and the delay adds to the violence of his disease, by which he is compelled to abandon his work and take to his bed. His wife is now left alone in this appalling struggle, and as the result of poverty and mental anxiety, she also becomes the victim of the unchristian system of our Colleges and Hospitals; and thus are the children neglected, while death and misery extend their direful and leaden hand over the devoted family. Scenes such as these have their origin in the want of judgment, honesty, and discretion, in the management of the funds of our Hospitals, which ought to be open to all men labouring under disease. But the applications of those so afflicted are of no avail; their language, the offspring of pain and misery, is not felt, as the institutions declared to have been consecrated to charity are, as observed, preoccupied by those for whom they were never intended to extend their aid, to the exclusion of the needy—and all this takes place in the capital of a kingdom that boasts its literature, its humanity, and its civilization.

* The insisting that a patient, before admission to an Hospital of the metropolis, however, urgent and dangerous his disease, should give security as to the expense of his funeral being defrayed, presents an irrefragable, a horrid, and disgraceful picture of the shopkeeper system ascribed to this nation by a man of extraordinary talents, but not a great man, because he had no generosity, but when such answered his views; however, had he known the sickening hospital arrangements of this capital, they would have placed his sarcasm beyond a doubt among Frenchmen, who are gallant and brave, and despise insensibility to the unfortunate.

† The Free Hospital is a noble exception to the letter hunting; poverty and disease are the passports to the benefits of that excellent institution.—ED.

The picture just drawn is by no means overstrained, but of daily occurrence, as thousands perish annually from the want of that relief which, if administered at an early stage, would have averted the calamities of neglect, and the families of the sufferers from becoming burdens to their parishes, and a disgrace to their country; and for such events the Colleges of Physicians and Surgeons have entailed on themselves a grievous responsibility.

We are all of us called on to practise gentleness, consideration, and benevolence towards our fellow creatures under affliction, whether these evils shall flow from the dispensations of the Almighty, or from other causes. It is not only painful, but truly awful, to behold men preaching morality, religion, and liberality, some of whom are, from their age, on the verge of eternity; yet influenced by a mean and sordid spirit, and determined as it were to die as they have lived, hypocrites, exerting every nerve, and winding up every spring of established power and prejudice, to prevent the blessings of improvement extending themselves to the medical profession, by facilitating the education of its members, and thereby benefiting mankind and the poor in particular. The observations of Pater Familias are an appeal to the medical profession, in favour of independent minded men, who are often doomed to circumstances so circumscribed, as to demand the most rigid economy; and I am certain the appeal will not be made in vain, as it may be found practicable to devise some plan to meet his views, which are, I believe, acted on in many parts of the continent, and particularly in Holland.

The medical practitioner who is anxious to rise in his profession, and the one who has acquired reputation, whether as a physician or a surgeon, is equally averse to inaction; and to those the suggestions of Pater Familias hold out inducements for consideration and reflection.

The Lawyer induces his clients to repair to his chambers; and it would contribute to the interests of the community, were this plan applied, on a more extended basis, to medicine than at present, which would conduce to early consultations, and thereby to the prevention of disease. It is by medical men having a resource of this kind at their own homes, that the views of Pater Familias can be answered; and in adopting such a course, the enormous sums raised for the support of Dispensaries will become available to the profession, instead of being beneficial to those who have no claim thereunto. No class of men have done more towards the interests of society, by their exertions in the prevention and cure of the bodily evils incidental to this life, as also by dispelling the clouds that envelope the human mind, than medical men, because the examination of the human frame, so fearfully and wonderfully made, leads to the conviction of a great

and first cause, intimately pervading man and matter—a knowledge not only inspiring humility, but identifying the medical profession in all ages, with mercy, generosity and benevolence—the purest streams flowing from the heart of man. Unfortunately, however, medical corporate bodies have disgustingly distinguished themselves in this interesting field, not only by an utter neglect and insensibility to the advancement of their profession, but against which they have been at all times ready to conspire*. Had these men been influenced by elevated considerations, instead of those of an unworthy and grovelling character, the medical institutions of this empire would have presented a picture the most perfect, and would have been resorted to by all the world for medical knowledge. I concur with Celsus in the propriety of avoiding such foul materials in establishing a reform that will be regarded as efficient. A faculty of medicine can alone do justice to the profession and the community.

I have the honour to be

Your obedient humble Servant,

PHILO CELSUS,

London April 21st, 1835.

To H. Warburton, Esq., M. P.

—o—

The London Medical

AND

Surgical Journal.

Saturday, May 2nd, 1835.

THE LEGISLATURE AND THE PROFESSION.

THE enemies of medical reform are in high glee, on account of what they term the supineness of Mr. Warburton, in the great cause which he has so judiciously and ably managed; and they hope that nothing can be done during the present session of parliament. They cannot comprehend the reason why Mr. Warburton has not presented his report, though it is very easy to perceive it. That gentleman well knew the hostility of the late government to medical as well as to every other

* The labours of the immortal John Hunter, the miraculous efforts of a single mind, would have been consigned to destruction, had not the public and the profession poured forth their indignation against the barbarous and brutal negligence of the College of Surgeons, by which deed of negligence and envy they demonstrated themselves unworthy of public confidence.

useful reform; and he, as well as every friend to improvement, within and without the walls of parliament, was convinced of the speedy dismemberment of the late administration. This was expected daily; and it would have been extremely impolitic to introduce the important question of medical reform, which was certain of a fatal opposition from the late ministry, the avowed friends of collegiate, corporate, and all existing abuses. The times are changed, the administration which granted the parliamentary committee to inquire into medical education, practice, and abuses, is again steering the helm of state, and Mr. Warburton's most important measure is sure to be triumphantly carried, aye, and most probably during the present session of parliament.

It is highly amusing to notice the medical staff of St. Bartholomew's Hospital School in the race of reform, and to think of the intended improvements of the Rhabarbarians—doubtless spontaneous improvements, but such as were pointed out by at least 500 witnesses before the committee already mentioned. The medical world will therefore give due credit to such reformers.

The staunch friends of improvement in Pall Mall East and Lincoln's-inn Fields were perfectly mute, during the career of the short-lived administration lately defunct; but they will now of course resume their labours in setting their tottering houses in order, and appear in a few days among the other liberal and spontaneous reformers. There is no doubt but Mr. Warburton will estimate their sincere desire to be deprived of their privileges—it is so accordant with their past conduct. We tell them, however, they need not trouble themselves in proposing reforms, these will be effected without their good intentions or advice.

ESTABLISHMENT FOR TEACHING PRACTICAL LEGAL MEDICINE, ATTACHED TO THE UNIVERSITY OF BERLIN.

IN "Horne's, Nasse's, and Wagner's Archives," an account is given by Dr. Wagner of the above establishment, that has no parallel in Europe. Its title demonstrates the objects for which it is intended; but the report as given by Professor Wagner develops them more in detail.

The practical school of legal medicine in the university of Berlin, was opened in the summer session of 1833.

All the cases of legal medicine that have been met with in this city during the year, have been made applicable to the instruction of the physicians and students that belong to the establishment. The mode of teaching pursued is as follows:

At different hours of the day, according to the matter presented, each student is admitted in his turn to look into the cases of living subjects, to perform judicial post mortem examinations, and to analyse inorganic and inanimate substances; after which he is required to make a report on what has been submitted to him, in the same style as the district physician does. Moreover, the professor meets the students twice in the week, either for the purpose of explaining and discussing the facts already observed, or to distribute new cases among them; or lastly, to refute and pass judgment upon the reports that have been presented to him.

The students are exercised in the proper mode of examining adult and infantile corpses; and every one is aware how much practice and skill is requisite to appreciate the pulmonary docimasia of the latter. Every six months, a course is delivered on the modes of testing the presence of poisons, both mineral and vegetable; these modes the students practise.

The subjects comprised in medical police are included in this course of teaching. The students get an insight into every portion of this branch of judicial medicine, and a detailed explanation is given to them of all the instruments, apparatus, and collections that are necessary to its application. They are allowed to analyse alimentary substances and drinks, and the inspection of drugs is made by them in company and under the direction of a pharmacist.

A practical course of veterinary medicine is also connected with the objects of this establishment.

During the first year of its establishment (from July 1833 to 1834) the practical school of legal medicine has been attended by sixty-three students, some of whom are already in practice. The course of instruction has comprehended 253 medico-legal questions, 217 of which refer to living individuals, and 32 to dead subjects (judicial post-mortem examinations), and 4 required the analysis of inorganic substances.

The inquiries made into the cases of the living individuals turned, in 183 instances, upon the state of the body, and in 34 instances, upon that of the mind. Of the latter, 27 were civil cases, and 7 criminal.

Ununited Fracture of the Humerus.

(Continued from page 538, of vol. 6, for November 22nd.)

IN No. 147 of our last volume, will be found the report of a case of fractured humerus, in a female of middle age, which had remained without any attempt at union during thirteen months, and which Mr. Keate had operated upon by re-section of the bones, at the period of our report. Five months have now elapsed since that operation was performed, and all hopes of union have long since vanished. Mr. Keate has for some time past endeavoured to

persuade her to submit to the operation, which he this day (April 23rd,) has performed; and which consisted in the introduction of a seton between the extremities of the bones. An incision was made of about two or three inches in length above the outer condyle of the humerus, nearly corresponding to the cicatrix of the former operation. The integuments and tissues were divided, and the ununited ends of the bone thus brought into view. Mr. Keate endeavoured to denude them as much as possible of the cartilage with which they were tipped, and then passed a long and strong needle, armed with a skein of silk, through the wound; passing it between the ends of the bones, and bringing it out at the posterior surface of the arm through the sound integuments. The wound was then dressed, and the two ends of the skein of silk tied.

This case, and another under the care of Sir B. Brodie, which was reported in our Journal for Nov. 22nd, and Dec. 20th, and which the pupils of this hospital have had an opportunity of studying during the present session, exemplify, in a striking manner, how little any of the plans yet proposed for remedying ununited fractures of the bones, are to be depended upon, even in the hands of such experienced surgeons as Mr. Keate and Sir B. Brodie.

Mr. Keate subsequently removed an ulcerated malignant growth from the mamma of another female, which did not, however, present any particularly interesting feature.

WESTMINSTER HOSPITAL.
—

Contraction of the Arm, from Cicatrices left after Phlegmonous Erysipelas, treated by Passive Motion.

— FLAMSTEAD was admitted into Burdett Ward, in January last, under the care of Mr. White, having the right arm permanently and rigidly flexed at the elbow joint, to such an extent, that the fore-arm formed little less than a right angle with the humerus. This contraction is dependant upon the presence of two cicatrices on the inner side of the arm. These have existed during the last two or three months, having been produced by a severe attack of phlegmonous erysipelas in July last. It appears that no incisions were made to allow of the exit of the matter which had formed, but the abscess was allowed to burst, and two very extensive sores were the result, leaving the ci-

catrices, which have produced the present affections. One of these cicatrices, which is of considerable size, is situated over the belly of the biceps muscle, and the other extends over the upper third of the fore-arm. The former of these is evidently confined to the integuments, which play freely over the subjacent muscle; but the other obviously extends deeper—is more corrugated—cannot be moved over the muscles below, and indeed, would seem to involve their aponeurotic coverings, and in an especial manner the bicipital fascia.

The ligamentous and tendinous structures surrounding the joint, having evidently become associated in the contracted state. Thus, the tendon of the biceps is plainly seen to be rigidly extended across the joint between the arm and fore-arm; and there is considerable shrinking and loss of tone in the muscles of the extremity, in consequence, no doubt, of the long continued state of inaction to which they have been subject; this is more particularly observed in the supinators and extensors of the fore-arm. The contraction, it appears, has existed ever since the formation of the cicatrices, but has gone on progressively increasing.

Division of the cicatrix was at first proposed for the removal of the contraction, but it was subsequently thought by Mr. White, on the suggestion, we believe, of Mr. Thompson, that a fair trial might advantageously be given in the first place, to the employment of daily passive motions, employed in such a way as is calculated to put the integuments and other structures on a gradual stretch. The plan which Mr. Thompson has directed the patient to pursue, is the following. The upper arm is in the first place to be securely rested upon a table, and a mass of lead, the weight of which is from time to time to be increased, is to be supported by the palm of the hand, when the extensor and flexor muscles of the fore-arm are to be called into play alternately; and this is to be kept up twice in the day, for from a quarter to half an hour at a time.

Feb. 18th.—He has used the weight as directed, with considerable advantage, during the last week, the angle of flexion of the joint having already become much more obtuse.

23rd.—He complains of pain in the elbow-joint, from the use of the weight. The arm, however, gradually becomes further extended, and he has now much more power over the fingers.

March 14th.—Considerable amendment has ensued since last report.

21st.—Very decided improvement has now taken place; the arm is extended to a much greater extent, and as a consequence, he has recovered the use of it in a variety of ways, of which he had previously been deprived. Thus, he can now bring a cup to the mouth, and touch

the crown of the head; the motion of the elbow-joint is free and unattended with pain; he likewise is speedily obtaining more command over the fingers.

April 8th.—A very obvious improvement continues to take place; the angle formed by the flexion of the arm becomes more and more obtuse, and the motions more and more readily executed; supination, which he could not perform upon his admission, can now be readily produced.

21st.—Since last report, he has gone on progressively improving; he has increased the weight of the mass of lead which he uses, to about seven pounds. He leaves the hospital to-day; and although he has not entirely lost all traces of the contracted arm, yet there can be but little doubt, that by the use of the same means for a little longer time, he will ultimately do so.

—o—

NORTH LONDON HOSPITAL.

Traumatic Gangrene.

MARY PULLEN, aged 62, of intemperate habits, was admitted March 23rd, under the care of Mr. Cooper, having been run over by a heavy cart. She says she is subject to fits, and thinks she must have fallen down in one when the accident happened. The wheel appears to have passed, but partially, over the leg, as there was not any fracture; there was, however, a very extensive lacerated wound of the integuments and fascia, commencing at the internal side of the insertion of the ligamentum patellæ, and extending obliquely across to within an inch of the external ankle. The skin and fascia were separated from the muscles only to a small extent on the outside, so as to expose them as far as the edge of the peroneus longus, but on the inside, the separation of the skin extended back as far as the centre of the gastrocnemius. There was also another wound, about four inches long, obliquely across the popliteal space, also through the skin and fascia. Her appearance indicated an abused constitution, and she was in a state approaching to collapse. There was no hæmorrhage from either wound. The larger wound was immediately brought together by interrupted suture, and moderately warm fomentations applied to the limb. She was ordered a grain of the muriate of morphia directly, to be repeated in the night, if necessary.

24th. Passed a restless night, not having slept till this morning, although the morphia was repeated four hours after the first dose. Pulse 90. Tongue clean, but rather dry; bowels confined, skin cool; complains of much pain in the leg. Very little change has yet taken place in the appearance of it; two of the sutures were removed to day.

Hydrarg. submur., gr. iv. statim.

Haust sennæ horas duas post pil. sumend.

Half a grain of muriate of morphia every eight hours. The pulse got rather stronger in the evening.

25th. On examining the limb this morning, it was found that gangrene had taken place in the integuments implicated in the injury. The skin on the inner side of the leg where it was most separated, had become quite black, and on the outer side it had a mottled appearance. All this occurred during the night; there was not the slightest appearance of it last evening. Pulse 126; very small, weak, and slightly irregular. Tongue clean, but dry, bowels open; the features were collapsed, and the countenance extremely anxious. She was slightly delirious.

Vini rubri, $\frac{3}{4}$ iss. immediately; and $\frac{3}{4}$ s. every half hour afterwards.

At 12 o'clock Mr. Cooper, Mr. Liston, and Dr. Mott of Philadelphia (who happened to visit the hospital to day) met in consultation, as to the propriety of amputating; this was not, however, deemed advisable. To continue the wine, changing it for brandy every second time. She is gradually sinking.

26th. Still sinking; the gangrene has extended half way up the thigh; she died at 9 this evening.

Section Cadaveris—16 hours after death.

On examining the leg, the gangrene was found not to extend deeper than the skin and fascia, except in one spot, where ecchymosis was observed on her admission. The muscles above the knee were implicated. The foot remained perfectly healthy and natural. The femoral artery was found diseased, not ossified, though approaching to that state. In the abdominal aorta several portions of ossific matter were deposited. The saphena vein shewed marks of recent inflammation, and thickening on its internal surface. The internal surface of the femoral vein was also discoloured, though in a less degree. The brain was then examined, to account for the fits. Great thickening of the arachnoid was found, with considerable effusion under it.

Remarks on the use of Oiled Silk and Warm Water dressing. By Mr. Liston.

The plaster used by Mr. Liston to recent wounds, such as after amputations, &c., is composed of a spirituous solution of isinglass, spread over oiled silk; the solution is spread, when hot, on strips of the silk, and applied immediately. After amputations, the strips are used of considerable length, so as to give support to the flaps, and an interval is left between each, to allow the escape of matter, should adhesion not take place. Mr. Liston has used it for some years, and has found it to succeed in almost every case. It is easily applied, does not heat the limb, as the usual mode of dressing does, is easily removed in case of secondary hæmorrhage, allows the escape of offensive matter, and prevents the

factor attending the confinement of the discharge; often the wound does not require a second dressing, and the plaister frequently supersedes the necessity of a bandage. The use of warm water dressings, as employed by the same surgeon, consists simply in pledgets of lint, the size of the ulcer, dipped into warm water, and applied to the part, a piece of oiled silk a little larger being placed over it to prevent evaporation. It is found, in some cases, quite effective without the assistance of any other remedy; occasionally some slight astringent, such as a weak solution of sulphate of zinc or copper is indicated.

Both dressings are cleaner and less painful than any other; the last does not require a sponge; indeed, there have been no sponges used in the hospital for some time, except during operations. Mr. Liston said he had dispensed with them at Edinburgh, as he had seen the indiscriminate use of the same sponge by the various patients, attended with the worst consequences. It was often the cause of the spreading of one description of ulcers, of a malignant character, through the wards of the hospital.

It is not for the medicinal use of the water, as stated by a late writer on the subject, that this dressing is applied, it is in place of a poultice. It is by no means a novelty: many surgeons in the army and navy have employed it for years with success.

GUY'S HOSPITAL

Ossification and Ulceration of the Cartilages of the Larynx, with Fistulous Opening.

GEORGE BLACKGROVE, æt. forty-eight. During the former part of his life he was employed in some iron-mills, and was accustomed to drink spirits freely; but his habits lately have been temperate. He received a severe burn on the head five years ago, which healed very slowly (in twelve months), and reduced him considerably. After that, his occupation was changed, and he worked in a tan-yard, where he was much exposed to damp and cold; the early consequence was an abscess which formed behind the left ear, and proved as troublesome as the burn: after having been a patient at several public institutions, he was at length cured in fifteen months. For the last four or five weeks, his health has not been so good as usual; and, fourteen days ago, he had a small swelling, attended with pain, on the left side of the larynx, followed successively by two on the opposite side; they all burst, and discharged much. Four days before his admission, he noticed a hissing sound proceeding from the ulcer on the left side, and he coughed almost incessantly for about two days: at last he applied for relief at the hospital as an out-patient. He was admitted to the house

the following day, January 3rd: and on examination, a large portion of the cricoid cartilage on the left side, and of the thyroid on the right, was found ossified and denuded: there was a fistulous opening through the crico-thyroid membrane, through which air passed very freely while speaking, and generally without giving pain. He states that six months ago he strained himself while carrying a heavy weight, and that his throat has always been uneasy since.

Local applications, and those of a very mild nature only, were applied for several days; on the 7th January, Mr. Key ordered him Iodine gr. ss.; Potass. Hydriod. gr. iij.; Syr. Papav. 3 ss.

10th. His appetite, which was deficient when he was admitted, is increased; the ulcers somewhat improved, appearing less inclined to extend.—Pergat.

19th. Mr. Key attempted to remove a portion of the cricoid cartilage, but found it firm.

16th. His health and appearance are both much better: he requested a more plentiful diet, which was allowed him. A small portion of the cricoid cartilage was removed.

20th. He was ordered, as a gentle stimulant, a lotion of very dilute nitric acid (gtt. ij. ad 3 j. aq.); but, by mistake, he applied some pure acid, which was in the ward. This destroyed the integuments to some extent, but does not appear to have affected the cartilage.

21st. The ulcer is much inflamed. No ill effect followed the application of the acid except the extension of the ulcerating surface. Bread poultices were applied, and the iodine continued.

23rd. His throat is much better; he cartilage appears quite firm, and the ulcers on the right side cicatrizing.

28th. The smaller ulcer on the right side healed. One bare spot of cartilage can be felt by the probe, in the larger one on the same side. The opening in the larynx on the side smaller.—Pergat.

The opening was closed on the 12th of February, and he left the hospital quite well about three weeks afterwards. He suffered no inconvenience from the iodine.

Foreign Medicine.

Curious Case in which Sand and Gravel Stones were found in the Trachea after drowning.

C. F. H., aged 23, had been subject to epileptic fits since October 1830, with intervals of a week or a fortnight. On the 5th of May 1833, he was found dead in a rivulet; his face downwards, the head covered with the water, which was not a foot deep, and which therefore did not cover more than half his body.

On examination of the corpse, the most remarkable thing found was a quantity of sand and gravel stones of various sizes, in the trachea, below its bifurcation into bronchi; the largest of these stones was square, weighed at least a drachm, was half an inch long and broad, and half a line in thickness. It is almost impossible to conceive how this stone, which resembled others on the bed of the rivulet, could have passed through the glottis. A great quantity of the sand filled the bronchi, and some of it was even found in the pulmonary vesicles: the whole quantity of sand found weighed between three and four drachms.

This is an exceedingly rare case: Orfila mentions only one such out of 50 cases of drowning (Dict. de Med. t. 20, p. 26). The size of one of the stones, which exceeded the capacity of the glottis, proves that it could not have entered the trachea by a mere mechanical descent after death: but it renders it probable that it had been swallowed in the last moments of agony.—*Medicinisches Correspondenz—Blatt*.

Sudden Tumefaction of the lips after Fright.

M. Diez was called to Madame G., aged 24 years, of an hysterical habit of body. He found both lips, but especially the upper one, swollen and ready to burst. As this tumefaction extended to the gums and tongue, the patient could scarcely speak, and could only imbibe fluids. She complained of pricking pains, and sense of extreme tension in the affected parts. The swelling had risen in the space of five minutes, and was visibly on the increase. Besides, there was a copious flow of saliva, the respiration was short and quick, there was a sensation of sinking and fear at the chest, dry cough, shiverings, frequent and full pulse, head uneasy, though not aching, face red.

The cause of this disturbed state was a fright, induced by seeing a little girl four years old pass the blade of a penknife between its lips, without, however, wounding them. She said, that at the moment she experienced an excessively painful sensation in the lips, as if they had been wounded by some cutting instrument; and it appeared to her as if her circulation and respiration had been entirely suspended. Previously she was in comparatively good health.

Repeated applications of leeches, cooling lotions and aperients, reduced the swelling in four days, after it had extended to the eyelids; the cough, ptyalism, and difficult respiration, also ceased.—*Ibidem*.

Hæmorrhage from the Genitals of an Infant.

A young woman was delivered of a child which exhibited nothing anormal during the three first days. At the end of that time some blood was observed to proceed by drops

from the genitals. In a few hours this ceased, and a watery discharge followed. On the fourth day some drops of pure blood flowed, but, as before, soon ceased. The fluid had some resemblance to the catamenia. Five days after this hæmorrhage, the mammae tumefied without being inflamed. The child then completely recovered and passed quiet nights.—*Ibid.*

Aneurismal Dilatation of the right Cavities of the Heart, with Gangrene of the Skin.

A milliner, 26 years of age, who had been affected with syphilis two years before, and a year previously had suffered from puerperal fever followed by amenorrhœa, was seized in July 1832, with painful cough, debility, emaciation and nocturnal sweats. On entry to the hospital, the beats of the heart were found to be tumultuous, and to extend from the right side of the chest to the under part of the shoulder, and covering the respiratory murmur. The patient could not lay on the right side. All these symptoms announced an aneurismal dilatation of the right cavities of the heart, with affection of the valves. Digitalis with tartrate of potass was given, then borate of soda and aloes, by which the general condition of the patient was ameliorated, and she quitted the hospital on the 23rd of September.

She returned on the 3rd of November in a state of extreme emaciation and debility. Together with the symptoms of cardiac disease, there was a gangrenous condition of the skin, which first shewed itself on the edge of the left ear, and formed an eschar half an inch long, and several lines broad. It then successively shewed itself in both zygomatic arches, on the chin, the alæ nasi, the left arm, particularly at the elbow, and on the feet, which were also œdematous. Around these sphacelated plates, red spots like petechiæ, were observed. The plates themselves were insensible, but all around was acutely sensible, and the sense of heat extreme; there was intense head-ache, and she complained of a bad odour in her nostrils. The pulse was calm; the sclerotica blue. (Decoction of bark; lemonade for ordinary drink; pyroligneous acid to the sphacelated spots). The eschar on the ear, as also the other smaller ones about the body, gradually fell off: one on the left cheek was converted into a superficial ulcer. As the vinegar failed to calm the burning sensation, recourse was had to the chloruret of lime in ointment, which was also used to disinfect the nose: it is remarkable that while the stimulating remedy was easily tolerated, milder applications, as linseed oil, or white of egg, occasioned intolerable smarting. By degrees the sphacelus totally disappeared, and as her general powers rallied, the symptoms about the heart diminished. On the first of February 1833, the

patient left the hospital. The treatment had consisted of cinchona, acid elixir, and sulphate of iron.—*Ibid.*

Epitioraphia, a new Operation for the Cure of Prolapsus Uteri.

Dr. Frick thus denominates the operation of excising a portion of the labia majora, and uniting the edges by first intention. The stitches are only introduced along the lower half or two thirds of the vulva, in order that space may be given for the passage of the urine and menses: Dr. Frick says it may even allow of the venereal act, but this is scarcely compatible with the intended support of the uterus. Should pregnancy occur, a small incision would permit the exit of the child. The operation may occasionally supersede that proposed by Dr. Hall and Mr. Ireland namely, producing a contraction of the vagina.

College of Physicians.

At the College of Physicians, on Monday night, Dr. George Gregory read a paper on the mutual relations between small-pox and cow-pox. He considered the vaccine virus had lost its virtue, and that it was necessary to procure some fresh matter from the original source.

The Poor Law Commissioners.

We have received several communications from different parts of the country, complaining of the arbitrary conduct of the Poor Law Commissioners, respecting medical appointments to parishes. They first unite several parishes, and then appoint a surgeon, not a resident in the district, but some inexperienced young man brought down from London, the protégé of some one of themselves. This plan is injurious to the poor, and unjust to the resident medical men of such districts. The poor are entitled to the best advice and care, which can only result from great experience, and rarely from those who are about to enter upon the practice of the profession. It is also manifestly unjust towards local surgeons, if legally qualified, to have juniors made their rivals by a Board who are morally bound to better the condition of the poor, which is not done by appointing inexperienced medical attendants.

The Plague in Egypt.

Ten thousand persons have died out of 19,000, who, up to the 23rd of March, had been attacked with this disease.

Maize.

After repeated experiments, M. Pallas has procured a chrystalized sugar from Indian corn stalks; it bears a great resemblance to that extracted from beet-root.

New Process for Purifying Benzoic Acid.

Dissolve the acid in four or five times its weight of sulphuric acid, diluted with six parts of water. During ebullition, add a very small quantity of the purest animal charcoal, filter it, and while cooling, the acid will separate in crystals. Should long beautiful needles not be found, and should it still possess an odour, the operation must be repeated. Collect the crystals on a filter, remove the sulphuric acid by washing, and leave them to dry in the shade. Sulphuric acid dissolves the resin and oil, which render the benzoic acid impure.

To have this acid in beautiful crystals, dissolve in alcohol that which has been previously purified, and put the solution in a subliming apparatus, placed in a sand bath. Manage the fire in such a manner that the alcohol alone shall be volatilized, and long needles, perfectly white, and without odour, will be obtained. (*From the Gazette Eclettica di Farmacia.*)

The Apothecaries' Garden at Chelsea

Opened on Monday, when Professor Burnett gave his introductory lecture, which will appear in our next. Twelve beds have been laid out to illustrate the natural system: this is an improvement; but reform is the order of the day—it has reached even the directors of Rhubarb Hall—what is the cause? Is it to be found in the fears of the Rhubarbarians that their Hall and regulations would be found useless in the remodelling of the profession?

Serious effects of the Retention of a Thread of Lint in a Wound.

A girl had the right leg cut against a sharp stone; the wound was superficial, and

was dressed with charpie soaked in vinegar and salt water. The wound healed in three days. On the 10th day, she awoke in the night with excruciating pain of the leg; the whole thigh was burning hot, and in the morning she was found with suffused, turgid face, intense fever, rapid pulse, hot skin, head-ache, dragging sensation in the leg, partial delirium, leg swollen from the groin to the ends of the toes, and of a purple colour around the cicatrix of the wound. The wound was opened, hot fomentations applied to the leg, cold water to the head, she was bled, and purged with clysters. The pain ceased upon the application of the fomentation; and on the 12th day after the first accident, a rather large thread of lint was taken out of the wound. At noontime of the same day all the symptoms disappeared, and the wound again readily healed in a few days.—*Heidelberg's Klinische Annalen.*

CORRESPONDENTS.

Londonensis.—We shall insert the letter if the writer convince us that the facts are strictly true, and can be proved in a Court of justice.

Mr. Dyer's communication is too late for this Number.

A Borough Student.—Our Correspondent should have paid the postage. We know nothing of him or the matter about which he writes, nor do we notice advertisements in the body of this work. We published the Lectures as they were, if not satisfactory, the fault is not ours. We advise him to peruse Williams on Auscultation.

LECTURES
ON
MEDICAL JURISPRUDENCE,
DELIVERED BY PROFESSOR A.T. THOMSON,
F. L. S.,
At the University of London; Session 1834-35.
LECTURE XXVIII.

Drowning.

GENTLEMEN—Another cause of death by asphyxia is DROWNING. Man, like other warm-blooded animals, is furnished with respiratory organs adapted only for breathing air in its gaseous state; submersion, therefore, in water becomes a cause of asphyxia, and the mode of death from this cause, or *drowning*, is one of those which lie within the scope of our inquiries. The immediate cause of death by drowning, as in every other instance of asphyxia, is the paralysis of the brain and nervous system, from the circulation of unaltered blood in the head: but, in many cases, the effect is not so complete as to preclude the possibility of resuscitation, by endeavouring to restore the pulmonary circulation, and again supplying the system with arterial blood.

In forming a decision with respect to the causes of fatal asphyxia, from *drowning*, difficulties present themselves, which can only be cleared away by strict inquiry into the state of the person previous to the submersion, to accidents which may have happened to him in falling into the water, to the period of the day at which the submersion is supposed to have happened, and many other circumstances. The chief object of these inquiries, in a medico-legal point of view, is to ascert—

1. Whether a person who is found dead in a lake, river, or in any piece of water, was submersed, or drowned, whilst alive, or thrown into the water after death.

2. If any marks of violence appear upon the body; whether these marks were inflicted before submersion, or happened from accidents attending it.

3. Whether, independent of marks of vio-

lence, the drowning was the effect of accident, of suicide, or of murder.

1. The first question can only be answered by examining into the phenomena attending the act of drowning, of a healthy individual, in the possession of all his faculties, who accidentally falls into deep water: and the appearance presented on the inspection of the body by dissection after death.

If the fall have been from an height, the body is precipitated to the bottom of the water, when it is not of profound depth; but it quickly rises to the surface, partly from the natural gravity of the body, whilst the lungs are full of air, being less than that of the water, partly from much air collected and retained in the clothes. But if the person be not able to swim, and greatly agitated, he screams; by which effort the chest is partly emptied of the air it contained, and the body once more sinks to the bottom, but again rises; and this occurs several successive times. Whenever the mouth happens to be above the surface of the water, the necessity for fresh air in the lungs, instinctively leads to a hurried gasp to obtain it: but, frequently, water is gulped down with the air, which exciting a cough, the air is ejected as well as the water, and the body again sinks. Repeated efforts of this kind, and vain struggles for safety are made, every time the body rises; but, as the air in the lungs becomes more and more tainted, at each successive submersion, and, at the same time, the efforts made to avert the impending fate, determining the blood to the head, and this being unaltered or venous, asphyxia supervenes; consciousness and volition having then ceased, the body sinks motionless to the bottom of the water, the weight of which, pressing on the thorax, forces out a portion of the air remaining in the lungs; and a few air-bubbles, gurgling to the surface, afford to those present the evidence that the last vain effort is over. In accounting for these phenomena, it is evident that the frequent risings to the surface depend, in a great measure, on the struggles which are, instinctively, made to fill the lungs; and, the subsequent sinkings, to the air thrown out from the lungs, owing

to the various efforts to inspire taking water in with the air, and this exciting coughing. As the air within the lungs diminishes, it also becomes more and more venous; the skin changes to blue, particularly about the mouth; the pulse becomes weaker, and ceases; muscular energy is gone; and, like an inanimate substance, the body falls motionless and without sensation. The more the individual struggles, the sooner he dies, and the less chance of resuscitation exists: for it is the muscular motion which expends the oxygen: a fact which is proved by the effect produced on persons who have fainted, and in that state have been submerged in water: for in this case a much longer period of submersion can be sustained without destroying the chance of resuscitation. Foderè relates a case from Plater, of a young woman who was condemned to be drowned as a punishment for the crime of infanticide, and who fainted at the moment she was plunged into the water. She remained a quarter of an hour under it, and, nevertheless, recovered on being drawn out. This may also explain some of the extraordinary instances of recovery recorded in the reports of the Humane Society. One person is stated to have recovered after having been three quarters of an hour under the water.

Now, if the body has been drowned while living, what appearance does it exhibit when taken out of the water?

The whole body is cold and pallid; the face especially; the eyes are half open, and the pupils much dilated; the mouth and the nostrils contain a good deal of frothy fluid; the tongue is protruded between the teeth, and approaches to the under edge of the lips. It is said that the countenance, instead of being pale, is sometimes red and bloated, and presents all the symptoms of death from ordinary apoplexy, but I have never seen an instance of this condition, although I have seen the head much swelled. This swelling and lividness are generally present, when persons have fallen into the water in a state of intoxication. In addition to these external appearances, the ends of the fingers are seen to be excoriated, and the presence of dirt or sand is visible under the nails; but this can only happen when the water is not very deep, and when efforts to save himself from death are made by the drowning person on touching the ground: if the water be deep, however, the body never reaches the ground till all power of struggling is over; and a drunken man who falls into the water may expire without a struggle or an effort to save himself: thence this last sign cannot always be expected to be present.

The appearance which the body that has been drowned presents, if immediately opened, are the following.

On opening the head, the brain displays a darker colour than usual: but the vessels are not always turgid with blood: extravasation has never been observed in cases of simple drowning.

2. There is an unusual accumulation of black blood in the pulmonary arteries and veins, and in the right auricle and ventricle; whilst the left ventricle is only half filled with the same kind of blood—sometimes completely empty. The trunks and smaller branches of the arteries proceeding from the left ventricle are also filled with black blood.

3. Some water, mixed with frothy matter, and occasionally coloured with blood, is found in the trachea; but the quantity varies much in different instances. Much useless controversy took place upon this subject, until the experiments of Dr. Goodwyn set the question at rest. By drowning animals in a coloured liquid, he found that the quantity of fluid which enters the lungs was too small to cause death; for, although water injected into the trachea in moderate quantity causes some difficulty of breathing, and a feeble pulse, yet it is quickly absorbed, and does not cause death.

It is curious that so late as 1809, Larry should have attributed the cause of death in drowning to the introduction of water into the bronchiæ; and deduced this conclusion from anatomical examination of the bodies of persons who had been drowned. I may only repeat that the question is now set at complete rest; unless the body have remained long in the water, scarcely any water is found in the bronchiæ; and consequently, much of that which is found passes in after death. As to the quantity, this depends on the fact whether the last effort of the lungs of the person who falls into the water be one of *expiration* or *inspiration*; for, if it be the former, no water will reach the trachea. The frothy mucus in the trachea, however, is not peculiar to drowning:—you will recollect that I mentioned it as one of the signs not unfrequently present in cases of hanging: and we shall afterwards find that it is also present in cases of death from irrespirable gases. The frothy mucus, nevertheless, is a sign of some importance; for if the body be thrown into the water after death, unless the death of the person has been effected by strangulation or hanging, no frothy mucus is found in the lungs; and water entering the trachea of a dead person can never so mix with the air as to form a frothy mucus.

4. The diaphragm is said by some to be depressed into the abdomen, which would not *a priori* be expected. The experiments of Mr. Brodie have proved, that the diaphragm exerts itself nearly as long as the heart itself, and that the interval between the cessation of the movements of the diaphragm, and that of the movements of the heart, is even shorter in animals that are drowning, than in those of the throes of strangulation; thence the last efforts of life being those which aim at respiration, this position might be arrested as it were at the moment of death: but the fact is generally the reverse; and as the last efforts are those of collapse of the lungs, the diaphragm rises high into the thorax.

5. Little or no water is found in the stomach ; and when it is present, it can in no way have contributed to death : and there is even less chance of water being found in this organ, if the body have been thrown into the water after death. This fact, and that of little or no water entering the lungs, cannot be too widely propagated, as the popular prejudice is in favour of the opposite opinion, and bodies taken out of the water are still rolled in barrels and held up by the heels in order to dislodge it : a practice fraught with the greatest danger, if the smallest chance of resuscitation continue.

A curious instance of the pertinacity with which old opinions are adhered to, is found in a paper of Mr. D. Johnson, Surgeon, Torrington, published in the *London Medical Repository*, for July, 1824. In detailing a case of suspended animation in a seaman who had fallen from a yard-arm into the sea, when the ship was going at the rate of nine knots and a half per hour, and was afterwards picked up in an insensible state—Mr. Johnson says, “When brought on board the ship he shewed no signs of life. I had him immediately suspended with his head downwards, and well shaken for a minute or two :” he was then laid on the cabin table, and rubbed all over by two or three men, with flannels, &c. Tartarized antimony was rubbed into the root of his tongue, and tobacco smoke blown into his mouth and nostrils, &c. Singular as it may appear, after all this, the man recovered.

Such being the appearances of the body of a person submerged in water whilst alive, and the aspect of the viscera displayed by dissection, let us now inquire in what respect these differ from those displayed in a body which has been previously killed and thrown into the water after death.

In the first place, something must be endeavoured to be learned from the state of the body when found. If the clothes be much torn, as if a struggle had taken place with another person, and marks of violence be perceived, which are not likely to have been inflicted under water ; if there be no excoriation at the ends of the fingers, and no dirt or sand found under the nails ; if any mark, as of a cord, be perceived around the neck ; if, instead of being pale, the entire corpse appear covered in various parts with ecchymosis ; if, on opening the body, the surface of the brain be not found darker than usual ; if the lungs be not gorged with blood ; if the diaphragm be in a state of natural tension ; and if the blood be in a coagulated state ; there is much reason for supposing that the death of the person was not the result of his submersion in the water. Circumstances, however, may throw doubts upon the validity of such decisions ; and, therefore, they ought to be examined into. Thus, the clothes may be torn from the nature of the bank or spot from which the individual precipitated himself, by catching upon stumps

of trees, or rugged-pointed rocks in the descent ; and this will also account for some external bruises. The nature of the bank must therefore be examined ; and if there are foot-marks indicating a struggle ; if the hands be clenched and contain grass or twigs, as if they caught at these to resist being precipitated into the water, then the first opinion, if confirmed by the additional symptoms on dissection, remains unaltered. With regard to the excoriations at the ends of the fingers, and the dirt and sand under the nails, I have already stated that these are not likely to occur if an intoxicated person fall into the water, nor if the water be very deep ; and it has also been suggested that the presence of these marks is no proof that the person was drowned alive ; since in a struggle by which he may have been previously killed, his fingers may have received bruises from catching at the ground or at grass, or other things at the moment he was murdered ; and these appearances may thus occur, even when the body has been dead before it was submerged in the water. Some marks of violence are not equivocal ; for instance, those indicative of hanging or strangling, upon the neck ; those inflicted by cutting instruments or gun-shot wounds but contusions, fractures, and luxations may arise from the nature of the bank whence the person was precipitated ; the rapidity of the current and the nature of the channel of a river ; whether it contains stakes in its bottom ; whether mills are erected on its banks, or other causes likely to produce marks of violence. Dr. Gordon Smith mentions a cause of dislocation which would scarcely have been previously suspected. A man who had previously leaped from each of the bridges into the Thames with impunity, undertook to do so again for a wager, but was drowned ; and when the body was found, both arms were dislocated. On investigating the cause, it was ascertained that he had, previously, always plunged with the arms in a line with the body, or perpendicular above the head ; but in the last instance, he went down with them in a horizontal position, and both were dislocated. With respect to the liquidity of the blood, it must be recollected that the blood does not coagulate in poisoning by some of the unrespirable gases. The darker appearance of the surface of the brain than is usual, without the gorged state of the vessels, and the defect of any extravasation, is a symptom much to be depended upon.

I have insisted upon those appearances that tend to render the ordinary signs of drowning, when a person is alive, doubtful, because cases daily occur in which decisions are hazarded on the most careless and slight examination of the body, both as regards its external appearance, and that which is presented on the post mortem examination of the viscera.

And after all, a clever barrister might easily puzzle a medical evidence upon the points of demonstration which really entitle him to

pronounce that a body found in water had actually died by drowning. Perhaps it may safely be affirmed, that no circumstances are likely to enable a complete decisive opinion to be delivered on the negative side of the question, that is, that the body was dead before it was consigned to its watery bed.

A body may be found, in which, although from not being taken out of the water, no suspicion may at first arise that the death was caused by drowning; yet, on examination, this may be found to be the case. If, however, marks of strangulation appear, we must hesitate in delivering such an opinion, until the most minute investigation be made. Thus, in a case published in the *Times Newspaper*, of the body of a boy having been found in a field in a sack, two medical practitioners, Mr. Smart and Mr. Saunders of Cheshunt, stated on the inquest, "that, upon examination, they found several marks under the chin, occasioned either by a cord or the pressure of hands. There was a fracture on the skull; the skin on the shin bones was broken, and blood had evidently flowed from the nostrils: there was also a wound in the cheek. The gentlemen both agreed that the body had been immersed in water; and that suffocation, together with the injuries on the body, had been the cause of death." Now, from the perusal of this account, it is pretty evident that there was sufficient reason for the opinion that murder had been committed; but it is difficult to conjecture upon what data it was supposed that the body had been immersed in water. If it arose from the body being wet, an easy solution of that circumstance might be afforded by the length of time the body had remained exposed to the atmosphere. No rational object could be served by immersing the body in water, and then removing it from the water to leave the sack containing it in a field, where discovery would be more likely to occur, than if it had been left in the water; and assuredly the extent of the violence evident on the body was amply sufficient to account for the death of the boy, without calling in the aid of drowning.

The replies to, and observations made upon the first question, are in a great measure applicable to the second, whether in the event of any marks of violence appearing upon the body, these were inflicted before the submersion of the body, or happened from accidents attending it. The only additional remark which I will make on this point, refers to the state of the lungs, which, as I have already stated to you, are distended with air, when death is the result of strangulation or of hanging; but very little air is contained in them when a person has died by drowning. Dr. Paris, in his joint work with Mr. Fonblanque has stated, that "in relation to their gaseous contents, the lungs are the same in strangled as in drowned persons; for in both cases a quantity of air is forcibly

expelled from them before dissolution—an opinion which surprises me greatly, and which is directly opposed to the facts connected with strangulation. I would not have adverted to the error, however, in a work of inferior merit; but in one which stands so high as this does, and deservedly so, it is a matter of duty to point out every thing that is likely to mislead.

In determining whether the body found, was drowned by a murderer, or whether suicide was committed, or the drowning was accidental, what is termed the external circumstances of the case must be taken into account. Thus, if the marks of feet on the bank, indicating a struggle to have occurred are discovered; if the hand be clenched and grasping grass and other matters, there is reason for suspecting murder. It might be supposed that a body found drowned, with the hands and feet tied together, may confidently be regarded as a case of murder; but two cases at least are recorded, which display the impropriety of such an opinion being hastily delivered. One was the case of a guaging-instrument maker, who had been missing for some days, about the end of June, 1826. His body was discovered floating down the Thames; and when taken out, the wrists were found tied together and fastened to the knees, which were in like manner secured to each other. The cord employed for this purpose was proved to have been one that had hung from the top of his bedstead; and which, when he was ill some weeks before he drowned himself, he had employed in raising himself up in bed. He was a good swimmer, and it was supposed that he had tied himself in this manner before precipitating himself into the water, to prevent himself from swimming. There was sufficient evidence of this man's insanity, but none that he had thus tied himself; yet, on the presumption which I have stated, the coroner's jury properly, in my opinion, returned a verdict, "found drowned." In the second case, the evidence was still more conclusive than in the former. The man was reduced to great pecuniary distress. One day he took an affectionate farewell of his family, declaring that he would not return until he had procured some employment. On the following day he was taken out of the New River, with his hands and legs tied together. In his pocket was found a card of his address, and three-pence in money. He had five-pence when he left home, and it was supposed that he had expended the other two-pence in the purchase of the cord with which he was tied.

As illustrative of this part of our inquiry, I would refer to the reports of two surgeons, and of the colleges of surgeons and of physicians of Edinburgh, respecting the causes of the death of Sir James Standsfield, and the trial of Samuel Cowper, for the murder of Sarah Strut. (See Paris, Appendix, p. 227).

The first case exhibits an instance of parricide, which, for the honour of human nature, seldom occurs. Philip Standsfield, a son of Sir James Standsfield of New Milns, Scotland, a man of vicious and dissipated habits, had repeatedly sworn that he would take the life of his father; which, at length he accomplished by strangling the old man in his bed chamber, at the dead of night. He afterwards carried the body to some water, into which he threw it, in the expectation that it might be supposed Sir James had drowned himself, but the body floated in the morning; and, although it was taken out and interred, yet, suspicion having been excited, two surgeons were sent for from Edinburgh, by order of the king's advocate, Sir John Dalrymple, to examine the body. It was accordingly dug up and subjected to dissection.

The only other subject connected with our present inquiry to be noticed, is one of much importance in prosecuting evidence with respect to the time at which a case of death from drowning occurred, when no other evidence than the appearance of the body can be obtained to throw any light on the investigation. This can only be determined by the degree of putrefaction at which the body has arrived; and nothing is more fallacious than this ground of judgment. After a certain time, bodies that have been drowned, rise and float on the surface, owing to the extrication of gaseous matter during the progress of the putrefactive process; but no precise time is fixed for this result, which varies from many collateral circumstances. It is evident, however, that a body found floating, must have been under water for two days at least. The body of the celebrated Caraccioli, the Neapolitan admiral, who was hanged, and afterwards thrown into the sea, with shot attached to the feet, floated in thirteen days after it was committed to the deep; and, as it neared Lord Nelson's ship, on the deck of which the king of Sicily was walking, produced in the guilty monarch a yell of horror, and the expression, "he comes!—he comes!—vien! viene!" It does not at all follow that bodies, whether dead before being submerged, or those of persons drowned, should not float before putrefaction takes place; but in general they do not float until after two days have elapsed. When the water is not deep, and in a clear running stream, the body does not putrefy, but is converted into a substance resembling spermaceti—adipocere; and the period of time required to effect this change, has been made the subject of legal inquiry. (See Male, p. 239).

In summing up the whole of the evidence necessary to be adduced on trials of suspected murder, or suicide by drowning, many of the collateral circumstances are of great importance, even in those points in which a medical witness is likely to be examined. For instance, if a fracture of the skull were evident on a body found in the water, it might

become an important question whether it would have been produced by a person precipitating himself, or being precipitated from a height above the river, from which circumstantial evidence would lead to the assumption that he had fallen. In this case, not only the nature of the fracture, but the height of the spot from which the fall had taken place; the direction in which the blow was received; the difference of effect between that produced by a heavy body descending with the force of a blow upon the skull, and that caused by the descent of the body upon a resisting substance, as a point of rock for instance; and many other circumstances would require to be investigated and taken into account before a correct opinion could be delivered. But on many of the points of collateral evidence, I must refer you to the able opinion of my learned colleague, who will not only direct your attention to those most likely to suggest themselves to the mind of an acute barrister, in his cross-examination of a medical witness; but will put you upon your guard to avoid being entrapped by questions which would lead to unsettled physiological discussions, that only tend to throw ridicule upon the profession of medicine, and obstacles in the way of the strict administration of justice.

So much has been said on the subject of wounds and mutilations, that nothing remains but to point out the method of ascertaining, when sudden death occurs from wounds, whether these have been the effects of accident, or acts of suicide, or of homicide.

Some years ago a medical man left town to enjoy a few days' shooting in the country. No uneasiness was experienced by his family on his account; but before the time expired at which he had promised to return, intimation was brought that he had been found dead, on one side of a hedge, in a field; and that the body appeared as if it had lain there for some days. A coroner's inquest was held, but little satisfactory evidence was obtained, as doubts remain to this day whether his death was accidental or an act of suicide. The circumstance of no robbery having been committed, his watch and his purse being found on his person, set aside all idea of murder. I mention this anecdote to shew you the importance of such an inquiry; and it becomes particularly so in cases in which the life of the person is insured for the benefit of his family.

Under the idea that accident is the cause of death, every collateral circumstance must be taken into account: the situation and attitude of the body; the position of the instrument with which the wound is supposed to have been inflicted; the direction of the wound, and the part of the body in which it is situated. Thus in such a case as I have related of the medical gentleman, if the body and the gun had not been moved by those who found the body, it might have been as-

certained as to the fact of the death being accidental, as it is likely had it been so, the butt-end of the gun must have been employed to clear the passage of the hedge, and the body have fallen into the hedge, or been left on the side of it opposite to that on which the gun lay. If two men have been together, and one is shot, if the ball can be traced to have entered from below, and passed upwards, the probability will be that the gun was on the trail when it went off, and consequently that the death was accidental.

When suicide is doubted, the manner in which the wound must have been inflicted should be strictly investigated. Thus if a man is found with his throat cut, it should be determined whether the wound has been inflicted by the right or the left hand; for if the manner of the wound be such as cannot be readily produced with the left hand, and the person be nevertheless a left-handed man, it cannot be ascribed to suicide. It will be found that the depth of the wound is always least and most oblique on the side opposite to that of the hand which inflicted it. In Hargrave's State Trials is the case of a woman, Jane Norkott, who was found dead in her bed, with her throat cut, and a knife sticking in the floor near her. A verdict of *felo de se* was brought in by the coroner's jury; but suspicion having arisen respecting the cause of death, the body was disinterred, and some of her relations who slept in an adjoining room were put upon their trial for the murder. Many circumstances were proved which tended to implicate the prisoners; but the evidence was incomplete, until it came out, that on the left hand of this unfortunate woman the mark of a bloody left hand was observed, which could not of course be that of the deceased. Sir Nicholas Hyde, who was Chief Justice, made this remark, "How can you know the print of a right hand from that of the left in such a case?" The reply of the witness was extremely satisfactory. "My Lord," said he, "it is hard to describe; but if it please the honourable judge to put his left hand upon your left hand, you cannot possibly place your right hand in the same posture." The experiment was made, and the jury being convinced, as no satisfactory defence was set up, the party, with the exception of one, was condemned and executed. If fire-arms be employed, it is not likely that suicide has been the cause of death, if the ball be found to have entered from behind. It is of the utmost importance to ascertain whether the wound has been inflicted before or after death, and this may be done by the degree of hæmorrhage and other circumstances which I have already pointed out. Sir Edmondsbury Godfrey, during the pretended popish plots, in the reign of Charles the Second, was strangled on the 12th of October, 1677, in Somerset House. The body was concealed until the fourth day afterwards, when it was removed in a sedan chair

and thrown into a ditch. The murderers passed his own sword through him, to excite the belief that he had committed suicide; but on the evidence of two surgeons who examined the body (Messrs. Skillard and Cambridge), it was proved that the wound could not have been inflicted during the life of Sir Godfrey, as no blood was found at the wound or near the place, and none followed the sword on withdrawing it; and beside, the neck was dislocated, a mark an inch broad round, and the eyes bloodshot. The murder was discovered, and three men, of the name of Green, Hill, and Berry, tried for it, convicted, and executed. In such a case, it may be said that a fallacy might arise from blood flowing from a wound made after death; but in that case the blood does not coagulate, which is always the case with blood drawn during life. In Sir Everard Home's account of the supposed suicide of Selis, a servant of the Duke of Cumberland, who was reported to have attempted his master's life, one of the reasons given for supposing the wound on the throat to have been inflicted by his own hand is, that it was long and straight; "any struggle," says Sir Everard, "would have made it irregular." On this point, I must accord with the remark of Dr. Paris, "that this is really a refinement that I do not pretend to understand." If weapons be found near a dead body with wounds inflicted upon it, we must ascertain whether the wounds could have resulted from the use of these instruments. Thus in 1764 a citizen of Leige was found shot, and his own pistol lying near him; but on examining the ball which was extracted from the wound it was found too large ever to have entered that pistol; murder was therefore inferred, and the murderers were afterwards discovered. The wadding of the fire-arms employed has even led to the discovery of murder. In a case mentioned by the Lord Chancellor, in 1820, the wadding of the pistol was found to correspond with a torn letter in the possession of the murderer.

The determination of those bent on self-destruction is often extraordinary. (Here the lecturer related the story of Mr. Adams.)

In this instance there was no difficulty in determining the cause of death; but this is not always the case. In Hecker's Annales for 1826, a case is related of a Silesian butcher, who, whilst labouring under severe depression of spirits, surprised his wife in the very act of infidelity with one of his men. This discovery drove him to distraction, in which he endeavoured to kill himself by dashing his head against the wall, but not succeeding, he seized a cleaver, and struck himself repeatedly in the forehead with the edge of the instrument, until he fell down from the loss of blood, and the violent commotion of the brain. Now, independent of the frantic resolution displayed in this case, if the outrage had not taken place before witnesses,

the conclusion, in the absence of evidence, would have been, that the murder had been inflicted by the hands of another person, and in all probability suspicion would have fallen upon the adulterer. (With regard to the law of suicide, see Russell, p. 429).

With respect to the proofs deduced from collateral objects, such, for instance, as the indications of a struggle having happened, and remaining visible on the ground—the traces of footsteps near the place where the murder is supposed to be perpetrated—the absence of such traces—the nature of weapons found near the body—and the circumstances to be learnt from the examination of competent witnesses—these are matters much connected with the medical part of this course.

There can be little difficulty in determining the fact when persons have been accidentally or wilfully burnt to death; but questions may arise when no witnesses are present to testify to the manner in which the fire originated—whether the fire was the cause of death? Foderè mentions a case, in which several individuals were murdered with an axe, and the house in which they were, afterwards set on fire by the murderer. The medical man, whose duty it was to examine, reported them as simple instances of death by fire; but circumstances having occurred to excite suspicion, the bodies were taken up and carefully examined. It was proved that the fire had only scorched the bodies superficially, and that the marks of the wounds from the axe were distinctly visible; thence investigation was made, and the murderers detected.

I do not think it necessary to occupy your time with any speculations of mine on the subject of spontaneous combustion. You will find all the information you can desire on this part of our subject, in the *Philosophical Transactions* for 1745, in the *Dictionnaire de Sciences Medicales*, and in a work expressly on the subject, entitled *Essai sur les Combustions Humaines, produites par l'abus des liquers spirit*, by Jarre Aimé Lair, published at Paris in 1808. I have never seen any cases of this morbid condition of the body, yet I do not deny the possibility of the event; but it is so rare as scarcely to demand your attention. Nevertheless, Foderè asserts, that combustion has taken place, in which it was possibly spontaneous, and, yet, persons have been accused and condemned for the supposed murders.

Murder, or suicide, may be the result of starvation, consequently the symptoms of it should be familiar to the medical witness.

It is unnecessary to say that the life of the body cannot long be sustained under privation from food; although the period to which it may be protracted varies considerably, owing to circumstances connected with the age, constitution, and situation of the individuals subjected to it. I will first detail

to you the effects of starvation on the living body, antecedent to its termination in death; then the appearances presented by dissection of the body after death; and afterwards point out the causes which modify the results of either a forced or voluntary privation of food; and the difficulty of determining between starvation, from a mere examination of the symptoms, and some states of disease.

The first visible effect of starvation is emaciation and debility; but these do not display themselves for the three first days. The countenance, however, becomes pale, and the expression languid: the voice fails; the extremities become cold; the pulse sinks, and the muscles lose the power of responding to the will. An icy coldness often spreads over the body; and the pulse ceases to be felt; sleeplessness; palpitations at the heart alternate with headache and syncope; mild delirium supervenes; not unfrequently, however, if the wretched sufferers survive this state, a second series of symptoms present themselves; the pulse again becomes perceptible; palpitation of the heart alternates with syncope; the delirium rises to a degree little short in violence of that which characterises phrenitis; and the exhaustion consequent upon this flash of apparently reviving power, quickly extinguishes the vital spark in the wasted frame which it had previously almost ceased to animate.

Life, under such circumstances, is scarcely extinct ere a foetid, aerial odour exhales from the body; the eyes are red and open; the tongue and throat are dry, as if completely parched up. On opening the head, the brain displays something like increased vascularity, and serous effusions are found in the ventricles and between the membranes. In the thorax, the lungs seem shrunk, and as if withered; in the abdomen, the stomach is often reduced to one fourth of its natural size, and the intestines are found nearly empty; the gall-bladder is turgid with bile, and the duodenum and small intestines deeply imbued with it; whilst the blood-vessels are contracted, comparatively empty, and the blood nearly devoid of crassamentum. Sometimes the small intestines display marks of inflammation.

The most remarkable effects in the series which I have enumerated, are those displayed in the cerebral organs; and they demonstrate how closely the two extremes of abstinence and of excess resemble one another in their effects on the nervous energy. The symptoms during life, and the post mortem appearances displayed by dissection, leave little difficulty in recognizing this condition, and permitting a decisive opinion to be delivered: at the same time, from its simulation of phrenitis in the adult, and of hydrocephalus in children, care must be taken not to confound them.

In cases of spontaneous starvation, the cerebral symptoms are in a great measure

absent, the mental stimulus of stern resolution operating upon the brain in a manner sufficient to prevent the development of the delirium. There are few cases of voluntary abstinence on record. In the *Journal of Foreign Medicine*, No. v, is one described by the suicide himself, who lived eighteen days, and was found still alive but feeble, speechless, and insensible. He died immediately after having swallowed, with difficulty, the yolk of an egg in broth. In this instance, no cerebral symptoms seem to have displayed themselves. The most striking example of mental resolution warding these off, is in the history of Luc Antoine Viterbi, a Corsican, who was condemned to death as an accomplice in the assassination of Frediani, and voluntarily starved himself. The details are copied from the *Corsican Gazette* into the *London Medical and Physical Journal* for March, 1822, and from it into Dr. Paris' work on *Medical Jurisprudence*. Viterbi lived twenty days, merely gargling his mouth occasionally. On the 19th day, a slight pain at intervals affected his heart, and for the first time he felt a ringing in his ears; at noon his head became heavy; his sight, however, was perfect, and he conversed as usual, making some signs with his hands. An icy coldness, which had occurred several times before, again assailed his body; the shiverings were frequent and dreadful; and his loins, in particular, were seized with a stone-like coldness, which extended itself down his thighs. On the 20th, Viterbi determined no longer to moisten his mouth; and feeling the approach of death, he laid himself out, and added, "I am prepared to leave this world." Death, says the narrator, did not betray his hopes. On the 21st. Viterbi was no more.

It is probable that in both these cases, the small quantities of water, which in Viterbi's case was taken in the mouth, and in that of the other was applied to the surface, during the eighteen days of fasting (for the suicide was often soaked with rain), certainly tended to protract life. Dr. Paris justly attributes the preservation of Elizabeth Woodcock, who for the space of eight days, was buried under the snow, near Cambridge, to the fluid which she obtained by occasionally sucking the snow.

Children sooner die from starvation than adults; and in after years, the rapidity of this kind of death is proportioned to the youth and vigour of the body—a fact of some importance to be known, as questions may arise

respecting the right of survivorship, in the event of shipwreck, and two or more people being saved on a barren rock, and afterwards dying of famine. In the account of the awful death of Count Ugolino and his sons, given by Dante, the sons perished before the father, who survived till the eighth day of his imprisonment. On the same principles, women are able to bear abstinence longer than men.

It is thus obvious that the symptoms which mark starvation are sufficiently obvious; and it is a melancholy reflection, that many instances of it have been brought to light, as subjects of legal investigation. (1 East, P. C. 226; 1 Leach, C. C. 163; 2 Campbell's Reports, 650).

When a medical man is called to examine a case of this description, the first object in view is to ascertain whether the starvation be a case of suicide or of murder; and some data have been pointed out in the cases to which I have referred, in which the brain was examined for determining this point. Thus, if the appearances in the brain resemble those of extreme excitement, there is much reason for supposing that the starvation was involuntary, and of course a case of murder; but if no appearances of this description present themselves, we may conclude that it has been an act of suicide.

Before dismissing this subject, it is of importance to point out the management of such cases, when death does not ensue. The first object is to restore, if possible, the animal temperature, which is always alarmingly diminished, before a morsel of food be administered. This should be effected by means of moderately warm flannels, bladders filled with hot water, and such like, applied to the pit of the stomach, whilst, at the same time, assiduous frictions are applied to the surface. Food should then be administered of a fluid kind; and, even that which becomes solid in the stomach, such as milk, should be avoided. A little broth, thickened with any farinaceous matter, should be cautiously given at long intervals, and gradually augmented in quantity. Much care is also necessary to remove every source of irritation from the alimentary canal; and, therefore, the bowels should be daily relieved by enemata of barley water. By such a method of proceeding, the tone and powers of the first passages will be gradually restored, and the wretched patient again restored to life, if not to health and vigour of body.

A LECTURE

Delivered in Chelsea Garden, on Monday, 27th April, 1835;

BEING

INTRODUCTORY TO THE COURSE OF BOTANICAL DEMONSTRATIONS.

BY GILBERT T. BURNETT,

PROFESSOR OF BOTANY, IN KING'S COLLEGE, LONDON; TO THE MEDICO-BOTANICAL SOCIETY; AND TO THE SOCIETY OF APOTHECARIES.

GENTLEMEN—The last person a man should suffer to speak of him is himself; for whether his words be few or many, it is likely he will be blamed for having said both too little and too much. Still there are occasions, and the present appears to be one, in which such a risk should be encountered; and I could not reconcile the omission to my notions of propriety, were I to enter upon the duties of the office to which I have lately been elected, without publicly expressing my deep sense of the responsibility which attends the honour conferred upon me, and of returning my thanks to the Court of Assistants in that manner which I know will alone be acceptable to them, viz. by tendering an assurance that I shall be constantly engaged in attempting to further their desire of rendering this garden, in every possible way, conducive to the advancement of science.

Gentlemen—It is now about 20 years since I first followed to the fields that venerable and venerated old man, who held the office of Professor of Botany to the Society of Apothecaries for almost half a century. I can easily recal to mind the sensations of pleasure with which I listened to his peripatetic lessons as we wandered over hill and dale, and the feelings half of wonder, half of shame, that for so long I had neglected to examine minutely the plants daily trodden under foot, for so long had been wilfully purblind to the chief beauties of the creation—but this is a topic on which, however grateful, I must not now descant, and I have referred to it merely as affording an epoch whence to trace the revolutions which have so rapidly succeeded each other, and have so entirely changed the aspect of our science, that I cannot but do something more than suspect my much esteemed preceptor would find himself half a stranger in the provinces where then, none were so familiar as he.

Gentlemen—At the time to which I refer, the only Lectures on Botany delivered in London, were the lectures on this foundation—I might almost say in England; for those at our universities had fallen into neglect. At that time our various medical schools, all now so well provided with botanical teachers, were wholly unconscious of a lecturer on botany. It is true that occasional attempts were made both at St. Thomas's Hospital and by several private individuals, to institute courses of lectures, but they all without exception failed. Botany, although extolled and recommended as a branch of medical education, was not absolutely required, and the students were too few to allow the lectures to be continued. Hence, had it not been for the exertions of this society, in fostering botany through the dark ages of its neglect, this most important branch of science, which is so intimately connected with our profession, as almost to deserve to be ranked as part of its foundation, might have been severed from the study of medicine, and its cultivation have become obsolete among us.

Gentlemen—It may not be known to all now present, and therefore I may be permitted to mention the fact, that this was the third botanical garden established in England, and the oldest now in existence. Gerard's garden, which appears to have been the first, was in Holborn, but now its place knoweth it no more; and Tradescant's garden at South Lambeth, has long since fallen into decay: while the Chelsea Garden has alone been permanently supported; yet this has not been done without great exertions, and repeated sacrifices on the part of the members: of these an account will be found in Mr. Field's Memoirs of Chelsea Garden. The early celebrity which this garden attained, and the reputation that it established, is well marked by the visits made to it by illustrious foreigners, as *Hermann*, who was here in 1682, and who by exchange enriched the botanic garden at Leyden, with plants from this collection. It has also been from time to time spoken of by Evelyn and others, in terms of high commendation; and furthermore, it was in this garden and by its officers, that many of those discoveries and observations were made that have served so essentially to advance our science. Doody and Petiver, who assisted the celebrated Ray, and furnished him with such abundant materials, that their names occur in almost every few pages of his synopsis, were, the former the curator of this garden, and the latter the first demonstrator. Jussieu, speaking of Doody, calls him "*Inter Pharmacopoeios Londinensis, sui temporis Coryphæus*," and Ray thus affectionately mentions Petiver, whose botanical knowledge was well known, "*Jacobus Petiver, non postremæ notæ botanicus, mei amicissimus*." To these may be added, the well known names

Rand, Miller, Forsyth, Hudson, Curtis, Wheeler, and others, who have successively held the offices of curator and demonstrator, and have earned for themselves and this establishment, the credit that both they and it enjoy. Sherard, a member of our society, and an active member of the garden committee, must not be passed unmentioned, for it was he who not only fostered this establishment, but cultivated at Eltham, at his own expense, a choice collection of rare exotic plants, an account of which was published after his death, by Dillenius, in a work entitled the "*Hortus Elthamensis*." A love of science seems to have prevailed in Sherard's family, for while he was fostering botany here, his elder brother, Dr. William Sherard, endowed the Botanical Professorship in the University of Oxford. It may likewise be observed, in passing, that it was from this garden that Dr. Walker, the founder of the Botanic Garden in the University of Cambridge, sought and obtained his first curator, in the person of Charles Miller, younger son of the celebrated Philip Miller, who was well entitled to the commendations bestowed on him by his foreign cotemporaries who styled him "*Hortulanorum princeps*." Linnæus, however, seems to have even more worthily estimated him, and to have been inclined to salute him as a chief among botanists, as well as among gardeners; for, he says, of his great work, the *Gardener's Dictionary*, "*non erit Lexicon Hortulanorum, sed etiam Botanicorum*."

It would be easy to swell this record by naming other members of our society, who have distinguished themselves as botanists, or have been more or less intimately connected with these gardens, either as patrons or students, or both. Yet a prolonged detail would be tedious, and might appear almost egotistical, or least might seem to display too much of the "*esprit de corp*," which, although not an unworthy spirit, must not be too freely indulged. We will, therefore, turn to another topic, referring those who wish for further information, to the memoirs of Mr. Field, already mentioned, from which many of the preceding facts have been derived: only in conclusion, adding that it was here that Sir Joseph Banks is believed to have commenced his botanical studies, under the tuition of the venerable Philip Miller.

The first herborising or botanical excursion undertaken by authority of this society, of which there is any record, was in the year 1633, upwards of two hundred years ago; but how long previously the herborisings, which were then first formally instituted, had been made is unknown. These excursions, at first few in number, were subsequently increased, and became highly serviceable in the instruction of students. And they have now been carried on for about two centuries, until merged in the establishment of more extensive courses of instruction.

When no other lectures were delivered in London or its vicinity, the instruction afforded here was with great propriety altogether of an elementary kind; but, now that the elements of botany are taught, and taught so well, in so many schools in London, it does seem that this garden, and the abundant illustrations it contains, may be more advantageously employed in practically illustrating its general principles or theories, as taught in the schools, than in simply teaching the rudiments of botany, which from the very rules which regulate the admission of students, viz., the recommendation of their teachers, it is presumed have already been (in the majority of cases) elsewhere attained. Indeed, I cannot conceive it to have been ever the intention of the garden committee to invite the botanical lecturers of the metropolis to send the students of their respective classes to Chelsea merely for the purpose of hearing repeated, in other words, and by another voice, those principles and rudiments of the science which can be both taught and learned as well in the lecture room as in the garden. And in this opinion I am confirmed, not only by what has previously been done, but also by what is now being done here, viz., the rendering various parts of the garden more available for practical study. During this season a dozen beds have been prepared and planted to illustrate the natural system of arrangement; and, although not yet quite completed, they will be so very soon.

This is an alteration in the garden—an addition to its previous means of study and instruction—which I should have been proud to have presented you with as the first fruits of my official labours. But, alas! I was forestalled. I found the work ready to my hand; and I am bound to advertise you that the scheme originated with the garden committee during the interval that occurred between the resignation of my predecessor, Mr. Wheeler, and my election; and that the design has been carried into execution under the superintendence of Mr. David Don, so well and so honourably known to us all.

Such, gentlemen, being the case, I propose to render these garden lectures and demonstrations as practical as possible; as far as possible to render them illustrations of the principles of botany which you are taught in your respective schools; to make them, in fact, to botanical students, what clinical lectures are to the students of medicine and surgery. You go to the lecture rooms in your various schools, you hear descriptions of diseases, their symptoms, and their treatment; but your instruction is imperfect, if you do not follow up the theoretic doctrines you have heard in the theatre, by observation in the wards of an hospital; and simple observation in an hospital will be of little avail without clinical instruction is at the same time afforded. In botany the case is strictly parallel: it consists, like other sciences, of its theory and its practice. The general principles may

be taught in the schools, but it can be practically studied only in the garden and the fields. We will not call this garden a vegetable hospital, because, although our plants are often sickly, and too often, notwithstanding all our care, will die, yet we may affirm that what the hospital is to the students of medicine and surgery, this garden may become to the students of botany; viz., the place where they may see those things of which they have previously only heard; and test, by actual observation of nature, the doctrines which are taught by man. Here, too, as in an hospital, we shall lead you to the bed-sides, sometimes of our vegetable patients, but more frequently introduce you to some of the fairest objects in creation, in a state of health; and assist you to study their physiological as well as their pathological conditions: and, after such observations have been made in the garden, we shall assemble here to deliver our clinical lectures.

Such, gentlemen, is the plan I intend to pursue; but, as at present few plants, excepting those which Linnæus figuratively called *precie*, messengers, or early risers, have raised themselves from their wintry couches, and the majority are (to continue the use of his poetical language), still asleep, and have withdrawn their heads beneath their coverlid of earth, I propose to fill up that time which must elapse before they awake, by giving a few introductory lessons, which will familiarize the subject to those pupils who have not attended any botanical lectures before; and which may, also, be not without their use in shewing the more advanced student that the facts, and all the main doctrines of our science, are the same, wherever they may be learned, or wherever taught; however various may be the general views which different lecturers may take, and however diverse the extent to which they pursue the subject.

But, in giving you my view of botany and its subdivisions, I would not have any one suppose that I wish to enforce it on your attention as the best that has been delivered, or to recommend you to let it supersede those you have already learned; on such points each individual may entertain his own opinion; only he should take care not to form one before he is well acquainted with the subject, lest he mistake prejudice for conviction. I shall merely give it you as a scheme which I have found convenient for collecting and associating the various subordinate sciences of which botany consists, and which I consider integral parts, while others in general esteem them distinct though collateral studies.

It is a curious fact, that the conclusion or end of a science, philosophically considered, is always the part first known and pursued in practice. Indeed it is the value of a few facts often accidentally discovered, and long empirically practised, which encourages research into abstract principles, and ensures a reward to the labours of the student. What is the value of that science, asked Franklin, which is not applicable to some useful purpose? And the question of utility is the touchstone by which all sciences must be content to be tried, for by it they will ultimately be judged, by it they will be approved, or by it condemned.

The utility of botany I am not here called upon to shew: its value has been too long established and too generally acknowledged, to admit of any comment. What I wish to direct your attention to, is the fact that it was the uses of plants which first arrested human attention—that it was their value as food, as medicines, and in the arts, which led to the investigation of their structure and their functions, as well as to their diagnosis and systematic arrangements—subjects upon which immense labour has been bestowed; and this chiefly, and in the first place altogether, because of their pre-eminent utility.

Illustrations of this position are so numerous, that one is puzzled in the selection. A plant is found having a pleasing aspect, an agreeable smell and delicious flavour; and moreover when eaten, proves to be wholesome and nutritious as food. Another is met with, which to a casual observer seems to possess many of the same qualities; this however on being eaten, may prove to be unwholesome—or at least unfit for food. It may yet, however, be useful as a medicine, or it may be a deadly poison. In either case it is essential that plants having such different properties, should be distinguished, otherwise food would be eaten in dread, if not in danger, and medicine be taken without confidence, if not in fear. It is absolutely necessary, therefore, that distinctions should be sought; and this is the work of science—mere habit, or empirical observation, is unequal to the task. We have, in some of our excursions, met with *experienced* herb-gatherers, who have collected *myrrhis temulenta* instead of *conium*, and who have laughed at our ignorance, in attempting to convince them of their error. Such instances are continually occurring; our officers at the Hall will tell, you that countrymen labour up to town with heavy burdens of useless plants mistaken for officinal ones. The fatal accident which occurred at Woolwich, must be in the recollection of all, when a gang of hungry convicts employed to raise the river wall on the banks of the Thames, dug up some fleshy sweet-tasted roots, which short commons persuaded them to eat, and of seventeen persons who partook of this repast, the major part were made seriously ill, and several died. A similar accident I find reported in the papers of yesterday, by which two children were destroyed.

The uses of plants in the arts, as affording habitations and clothing, and as food, every one who by nature is naked and hungry, will readily allow. Our cotton and linen manufactures, and the duties raised for the service of the state, on malt, hops, sugar, tea,

coffee, and tobacco, are likewise so constantly urged on our attention, from their extreme importance, that a simple notice is alone required; but the value of plants as medicines, they who are, or have been sick, alone can feel, and they can only feel, they cannot tell their worth.

My estimate of physic, gentlemen, is very different now to what it was a twelvemonth or two years ago. I will not say that I then regarded it merely as a profession by which a livelihood was to be obtained. I knew, I perceived, I was convinced, that it removed or mitigated much bodily suffering, that it assisted in the re-establishment, or hastened the recovery of health, and thus if it could not always preserve life, it smoothed the passage to the grave. I well recollect, as it was one of my early cases, the unspeakable effusions of gratitude which a poor creature looked, who after suffering a martyrdom with scirrhus pylorus, obtained temporary ease by the application of a plaster of extract of belladonna; and in another very recent case, a lady who had cancer of the neck of the uterus, spreading also to the neighbouring parts, the only intervals of ease which she enjoyed for many months were those produced by the administration of the acetate of morphia. She used to call her medicine her *blessed pills*, and said that however excruciating her pains, shortly after she had taken the pills, a calm appeared to steal over her, her agonies were lessened, her tortured body seemed lulled to rest, and after lying for some time, often an hour or two in a state of what she described as heavenly tranquillity, she usually slept; but she slept only to wake again to misery, for day by day her pains returned, and regularly increased in force as the influence of the medicine wore off, so that she watched with intense anxiety the time when she was again to take her blessed pills. Circumstances such as these reconcile us to much that is irksome in the study, to much that is unpleasant in the duties of our profession; and if some patients are unthankful, the gratitude of others and the consciousness of benefits bestowed, become more than an equivalent. Hence, if of any one, it may truly be said of the medical practitioner, that when the ear hears him, it blesses him, and when the eye sees him, it gives witness unto him; because he delivers the poor that cries, and he that hath none to help him, therefore the blessing of him that was ready to perish shall come upon him. Yet gentlemen, even with these convictions it was not until I myself was ill, that I truly felt and confessed the value of medicine—I had previously formed far too low an estimate of its powers—I had little weighed in my mind the felicity which a cessation of pain produces, a cessation often effected by a single grain of opium, by one sixth of a grain of morphia. During convalescence I had little understood the tonic powers of cinchona and our other vegetable bitters, but on rising from a bed of sickness, the sensible accessions of strength, during its administration, and the perceptible influence of each successive dose is accompanied by a degree of pleasure, which you must be very ill before you can hope to enjoy.

But, gentlemen, with such instruments in our hands, how great is our responsibility for their proper use. Medicines are fearful weapons, for according as they are wielded they may liberate the sick from the thralldom of disease, or they may render incurable slight ailments, fetter the body with permanent complaints, or even worse, spread through families death, desolation, and woe.

A man presuming to practise medicine without a competent knowledge of the means at his disposal, and the best modes of their application, is not simply a dishonest man, for he does not, like the fraudulent trader, merely rob his fellow creatures of their property, but he injures their health, and perhaps destroys their life; and if a life be lost by an ignorant practitioner, which might have been saved by one well-informed, is such a death to be considered a natural death? Is it not rather one of the most cruel and cold-blooded kinds of murder?

If these things be so, can we wonder that the study of plants, whence our most valuable medicines are derived, should be considered an important and essential branch of medicine? Can we any longer be surprised at the labours, immense as they are, which have been bestowed on the systematic arrangement and specific distinctions of vegetables? For a long time all our medicines were derived from this kingdom, and even now, although some important ones are of mineral origin, the majority of the most valuable and useful are vegetables, such, for example, as opium, cinchona, rhubarb, aloes, jalap, colocynth, senna, ipecacuan, cinnamon, hemlock, belladonna, assafoetida, catechu, digitalis, myrrh, castor oil, sarsaparilla, tobacco, &c., &c.; and even iodine, which triumphs over scrofula, and threatens to conquer cancer, and even consumption, is the produce of a long-neglected plant—the *Alga inutilis* of the ancients. What a satire on the judgment of man, as to the utility of the productions of nature.

Time forbids me to dilate further on this branch of our science; but the uses of plants are so well known, that more ample illustrations are needless: each person will be able to levy them in hosts. To discover the properties of vegetables, and to distinguish the active from the inert, is the purpose or chief end of botanical studies, and the uses of plants as food, as medicines, and in the arts, are the subordinate branches of one great department of botany, hence called *Phytognosia*, or the doctrine of vegetable utilities.

As the characters by which plants may be distinguished from each other can only be de-

rived from their peculiarities of form; the necessity of obtaining accurate diagnoses has naturally led to an investigation of their structure, and hence has sprung that branch of the science called, of old, vegetable anatomy, but now, in general, termed organography—which includes the investigation both of their external forms and their internal organic structures. To this must be added researches into their chemical constitution, and into those laws which regulate the developments of their various parts. The study of the structure of plants, first undertaken for the purpose of deducing diagnostic signs, is in itself so pregnant with interest, that it well deserves, and often obtains, attention on its own account alone. These investigations have likewise not only answered the purpose for which they were instituted, but have opened several new fields of inquiry, and led to some most important and very unexpected results, *e. g.* not only have differential characters been obtained, by which the various species and genera of plants can be with tolerable ease and certainty distinguished from each other, so that dietetic, medicinal, and deleterious vegetables need no longer be mistaken for each other or confounded; but furthermore, it has been shown that plants, not specifically the same, if they have the same general structure, are possessed of the same general properties. On this discovery is built the doctrine of homomorphism, one of the most important advances made in modern botany; for, from the ascertained properties of a few known plants, the qualities may be safely predicated of multitudes that are unknown. Thus not only is it ascertained that strychnos, atropa, colchicum, and digitalis are poisonous vegetables, but it has become an axiom in botany, that all plants having equivalent structures are more or less noxious likewise. Again, we thus learn, not only that the coleworts, apples, grasses, mallows, beets, and many others are innocuous and nutritious, but that all their associates or natural allies are possessed of similar wholesome properties, and may be used as dietetic vegetables. Further illustrations of the importance of this doctrine are scarcely wanting—but a few may be given. Thus it is known that all the marantaceæ or arrow-roots are nutritious and insipid; the gingers and their allies, innocuous, but sapid and powerfully aromatic; the pines resinous and stimulating, while the cycasæ are mucilaginous and insipid, but affording nutritious fecula; the labiatæ, or mint tribes, innocuous, but aromatic; the gentians bitter; the convolvuluses cathartic; the succory group soporific; the artichokes and their allies bitter; the myrtles aromatic; the poppies and their associates more or less powerfully sedative; and the ranunculus tribes acrid and poisonous; and so forth.

Such knowledge cannot fail to be highly useful and important, and its practical applications are obvious—of these time will only allow me to offer two illustrations, and the following is selected because its termination was less serious than many that could be quoted. Beverley, in his History of Virginia, tells us that some soldiers, who were sent to James Town to quell the rebellion of Bacon, mistaking stramonium for a spinach herb, gathered some of its leaves in a very young state, and after boiling, ate plentifully of them; the effect of which, he adds, was a “very pleasant comedy; for they turned natural fools upon it for several days. One would blow up a feather into the air; another would dart straws at it with much fury; another, stark naked, was seen sitting up in a corner like a monkey, grinning and making mouths; a fourth would fondly kiss and paw his companions, and sneer in their faces with a countenance more antic than any in a Dutch droll. In this frantic condition they were confined, lest in their folly they should destroy themselves. A thousand simple tricks they played, but, after eleven days, returned to themselves again, not remembering anything that had passed.”

Beverley might call it “a very pleasant comedy,” but to be deprived of one's reason for eleven days, and to be during that time not only a fool, but in danger of destroying one's-self, could be anything but pleasant to the sufferers, however comic their antics might be to bystanders; and in other cases where this plant has been taken, death has ensued.

Such an accident could not have occurred if the surgeon of the regiment had possessed a very slight portion of botanical knowledge. It contrasts well with another case, in which a ship's crew, suffering much in health from the deprivation of vegetable food, touched at a place where there were found abundance of plants, but none of them of the kinds which they had been accustomed to eat; but the surgeon recognising in an unknown plant those essential characters of a natural order of known innocuous qualities, at once with confidence selected it for food, and thus restored the crew to health, avoiding, by the means of science, the misfortune of rendering his companions madmen for a fortnight, or of poisoning them, as occurred to the poor fellows at Woolwich.

There are certain groups of plants which form apparent exceptions to these general rules, such as the umbelliferæ, the artocarpæ, &c., but these exceptions, some of which may be attributable to the newness of the research, and the imperfections of our classifications, are no hindrances to the practical application of homomorphism, although they have been ignorantly thrown forward as objections; for it is obvious, that if certain forms are ascertained to indicate wholesome properties, and others deleterious ones, while a third series are known to be present in plants of uncertain or variable qualities, the first and second would be accepted or rejected with confidence, while the third would be regarded with suspicion, and danger avoided; hence the end or purpose of the inquiry is attained.

Beings so curiously and wonderfully made as plants—being of such surpassing beauty and variety in their external forms, and demonstrative of such astounding skill in their internal mechanism, cannot but have some important functions to perform; and the investigation of them is the province of vegetable physiology. The functions of plants, I need scarcely say, are most curious and important, not only with reference to their own well-being, but in an equal degree to both animals and men. Their influence upon the atmosphere and upon the soil are among the most extensive and important of their functions. The renovation of the air by plants, when rendered irrespirable by breathing or combustion, although at one time questioned, is a fact now indisputably established, and their influence on its humidity, and on the salubrity of the soil, is much greater than is usually conceived. That swampy aguish districts have been drained and rendered salubrious by the judicious planting of trees, and that the humidity and temperature of various countries, such especially as our own, and other parts of Europe, have been varied, and even the quantity of rain that falls, been lessened by the felling of woods and clearing extensive tracts of forest land, are truths too well known to be more than just adverted to. The influence exerted by plants in the conversion of inorganic into organic matter, is likewise another most important function, and one exclusively their own, for it is a power that animals do not possess; while the metamorphoses they effect in refuse matter, changing every sort of filth and ordure which is supplied to them in the form of manure, into substances fit for food or raiment, are no less strange than they are common. We are astonished at the chemist, and extol his skill for converting, by an expensive process, linen into sugar, wood into a sort of flour, starch into gum, and so forth—and rightly do we give way to wonder; but conversions similar, though much more perfect and extensive, are being wrought by every plant, even by the humblest weed that grows. They are constantly engaged in the manufacture, if we may so express ourselves, of flour, sugar, oil, resin, flax, cotton, and all the other numerous vegetable substances which are so conducive to our comfort, nay, so essential to our existence, from earth, air, and water—presenting us not only with new organic matter, derived by their agency from the mineral kingdom, but also renovating that which, having been fed on or otherwise used and spoiled by men and animals, they cast, with loathing, on the dunghill, and for the most part fail to recognise when returned to them as corn, and oil, as culinary vegetables, as delicious fruit, and as fragrant and beauteous flowers. The scientific culture of plants is founded on a knowledge of their structure and their functions, or it is a branch of vegetable physiology; and vast have been the improvements in both horticulture and agriculture, since empirical practice has in some measure been superseded by scientific principles. The system of assolements, or the rotation of crops, by which the produce of our land has been quadrupled, and the acclimation of plants with their hybridizations, by which the fruits and flowers of more southern regions are reconciled to our climate, are a few among the many examples which might be given of the benefits conferred by this science upon some of the most useful arts. The increase of food, and the fact of the more choice vegetables becoming cheap and common, cannot fail to have been observed by every one. Each year our markets and shops are supplied more abundantly and with more choice vegetables. Sea kale, for example, which a few years since was rare and costly, is now cheap and common. Coleworts, cauliflowers, and the various kinds of broccoli, are not only improved, but have become more plentiful and cheap; while the potato, second only to corn in its importance, if not altogether, as an esculent vegetable, the offspring of science, has been so much improved, varied, and multiplied by human skill and industry, and so much increased in value, as to be more indebted to its foster parents in Europe, than to the American savages by whom it was originally discovered. But here again inexorable time cuts short the thread of our discourse.

If plants in a state of health are so essential to our existence, and conduce so much to our comfort and our pleasure, it would surely be ungrateful in us to neglect them when diseased. Vegetable pathology forms, then, another subordinate branch of our science; and although the maladies of plants have not hitherto been studied so much and so successfully as those of men and animals, still we know enough of them to be able to perceive that they suffer from the attacks of various diseases, some of which we are enabled to relieve, and others which are incurable in the present state of our knowledge. Plants, perhaps, suffer more from invagination and the attacks of insects than from any other means; yet they are subject to other diseases, both of a sporadic and epidemic kind. Some of these even bear a similitude to animal disorders, and have, therefore, received similar names, of which Wildenow furnishes a catalogue. Thus, plants are affected with atrophy, tabes or consumption, anasarca or dropsy, hæmorrhage, lepra, verrucæ, or warts, chlorosis, icterus, ulcerations, common gangrene, and necrosis, or dry gangrene, besides various kinds of deformities, wounds, mutilations, &c. &c. They are likewise subject, especially the cacti, to a peculiar kind of sudden death, called by the French "*la mort*," by which, when affected, a branch or even a whole plant is as rapidly destroyed as the use of a limb is lost, or death produced in animals by apoplexy.

Plants, although they will bear judicious pruning, resent barbarous operations, and even

accidental injuries. In them, as in animals, contused wounds, especially contused and punctured wounds, are much more dangerous than incised ones; of this there is an example in the adjoining green-house. It is a splendid agave or American aloe; this, which is one of its leaves, was pierced last season with the ferrule of an umbrella by one of the visitors to the garden. The parenchymatous substance became diseased; it spiculated, and the mortification, which at first extended upwards, subsequently began to descend and travel so rapidly towards the base as to render amputation necessary. The operation was performed, but, as you will perceive on examining the plant, the mortification had previously extended in an insidious manner so far towards the centre that a fatal termination is to be feared. As an illustration of the vitality of plants, and their proneness to disease from injuries, no example could be more satisfactory; but I am sure I need not formally reprobate such wanton mischief. Experiments of all kinds are justifiable, but to destroy a noble plant like that, without any object to be attained, could only have been done through thoughtless ignorance, for I would not attribute it to any other motive.

The diseases of plants are often, although injurious to them, beneficial to man, while at other times their unhealthy conditions so far deprave and change the quality of their ordinary productions, as to render those which are usually wholesome and nutritious, either worthless, baneful, or even poisonous. The production of agalocum and the various kinds of galls and gums, are instances of vegetable disorders being serviceable to man, while the diseases of corn, such as the smut, canker, rust, &c., and especially the ergot, are familiar examples of the fearful havoc they make in our crops, the former rendering a harvest worthless, and the other converting our sustaining corn to poison. It must, however, be recollected that the ergot is, when properly administered, a most valuable medicine, and also that these apparently grievous evils are such only on a partial view; they are injuries only when particular instances are selected and isolated, for it is on all hands confessed that in the general economy of nature they are highly beneficial, as forming a part of the system of checks and counterchecks by which the balance is corrected when the strong overpower and would exterminate the weak, and preserve that equality which could not be otherwise maintained. To modify their influence, and protect ourselves from their injurious prevalence, is the duty of science, and the more the study of vegetable pathology is pursued, the greater will be the power we shall obtain of turning even these apparently malevolent incidents to our advantage.

(To be concluded in our next.)

Reviews.

Physiologie Medicale et Philosophique. Par Alm. Lepelletier de la Sarthe. 8vo. pp. 495. Paris. G. Balliere.

THIS system of physiology is to be completed in four volumes. The author has undergone immense labour for several years, and has classed in methodic order the vast materials on the works of preceding physiologists; he has examined the comprehensive systems of the indefatigable and illustrious Haller, and of contemporaneous authors, and replete with facts, he then devoted himself to teaching, and delivered courses of physiology in the French schools. In the present work, he offers the results of all his labours. He hopes it will be useful to his readers, by confirming them in the doctrines of vitalism, and preserving them from those theories which spring from the imagination, but which the judgment destroys. He divides his work into three parts; 1, prolegomena; 2, study of the functions of the living economy; 3, the completion of physiology. The first part comprehends all considerations relative to the

fundamental bases or general principles of physiology. The general study comprises bodies, properties, functions, and economies. The second part comprises the generalities of functions of the living organism, and the history of each function. The volume before us is devoted to these two parts.

There is a great similarity between this work and Tiedemann's Physiology, but our brethren have the advantage of possessing the latter in our vernacular language, owing to the valuable translation of our able and learned friends, Dr. Gully and Dr. Hunter Lane. We are happy to state that their translation has, as we predicted in our review of it, a large sale, and it well deserves it. There is, however, an astonishing identity in many parts of both productions, and in Dr. Fletcher's Lectures published in this Journal; and yet the three differ most widely on many points. The majority of our readers are so well acquainted with the doctrines and classifications of Tiedemann and Fletcher, that we shall now place those of Lepelletier before them. The great scope of the domain of physiology demands a full exposition.

our author's arrangement of the subject, and obliges us to give copious extracts.

"General Observations on Organic or Living Bodies, and Inorganic Bodies, or those not endowed with Life."

"All beings in the universe are divided by naturalists into two classes; 1, *celestial bodies*; 2, *sublunar or terrestrial bodies*.

"The terrestrial bodies are composed of air, earth, and the water, with all the material beings contained in them; and the latter are divided into two orders; 1, *organic bodies*; 2, *inorganic bodies*. The *organic bodies* are all those which are composed of organs, whose union forms the different parts or systems, the functions of which preserve the individuals, repair the losses, and perpetuate their species. These are divided into *vegetables* and *animals*.

"*Vegetables* possess nutritive and generative functions; they have only very partial motion, and never general locomotion. *Animals*, in general, including man, not only possess the functions of nutrition and generation, but many other relations, and a complete power of locomotion, or moving from place to place.

"Inorganic bodies are fossils or minerals, fluids, and gases.

"It is not as yet determined whether imponderable substances, as light, heat, electricity, and magnetism, have a separate existence, or are only manifestations of the activity of certain ponderable bodies.

"Animals in general are guided by instinct only, and do not possess individual intelligence or mind.

"The special object, however, of our study is man, who, by the superiority of his organization as well as by his reason, an attribute peculiar to his species, is placed immeasurably beyond irrational beings.

"The whole of these bodies, organic and inorganic, the mutual connection of their phenomena, the reciprocal equilibrium of the different laws that govern them, form *nature*, *natural economy*; and this with the *celestial economy* united, constitute all *that infinity* which is called universe.

"The external configuration and internal aggregation of organic beings and inorganic substances are widely different."

M. Lepelletier gives a most minute description of the distinctive marks between organic and inorganic bodies; but as these have been so graphically and comprehensively enumerated by Dr. Fletcher in a former number, we omit them on the present occasion.

We have next a comparison of the composition of organised and inorganised bodies, which will be perused with deep interest by those attached to the study of physiology.

"All organic bodies are composed of fluids

and solids; they possess but little consistency and rigidity when first formed, and all are soft and flexible, either throughout, or in a great number of their parts. The consistence and rigidity vary according to age.

"Inorganic bodies, on the contrary, which are entirely composed of solid parts, are remarkable for their great rigidity; their parts do not differ in consistence, neither does their rigidity vary with the duration of their existence.

"The solid parts of organised beings originate from fluid. Every animal and even plant originate from a fluid in the midst of which they are formed.

"Fluids are also incessantly furnishing the materials for the solids, as water, chyle, and blood.

"Organic bodies are covered with a skin or bark, pierced by different openings to admit the absorption of substances from without, and to expel substances from within. Minerals and other inorganic bodies have no such covering.

"There is a reciprocity of action between the different parts of organised bodies, so that the greater number of the more complex of them cannot be divided, without being deprived of existence.

"All organic beings derive materials from surrounding bodies; they attract the constituent principles of the air, water, and food, which they introduce into their own structure for its nourishment.

"No change whatever occurs in inorganic bodies; the permanency of forms of crystals, for example, proves their composition to be in a state of repose."

The accuracy of the preceding comparisons cannot fail to be admitted by every intelligent reader. The axioms are so simple that every one can comprehend them. Indeed, the author excels for the fidelity of his descriptions, and the classic beauty of his style. Every sentence is replete with information. He proceeds as follows:—

"Material Composition of Organic and Inorganic Bodies."—There are important differences between the chemical mixture or composition in the two groupes of bodies.

"The number of elements which enter into the composition of a plant or an animal is smaller, being nineteen, while there are fifty-two in the other kingdom. (Fiedemann, *Op. Cit.*)

"There are in the vegetable kingdom, starch, vegetable albumen, gluten, gum, sugar, &c., which are composed of carbon, oxygen, and hydrogen; and in the animal kingdom, we find gluten, albumen, fibrin, gelatin, mucus caseign, &c., which are composed of the three elements or gases, oxygen, hydrogen, and carbon, with nitrogen.

"All organic and almost all inorganic bodies are composed of simple materials or

elements, variously combined with each other, and which may be separated by chemical experiments. When we examine and compare the chemical constituents of organic and inorganic bodies, we recognise the greatest differences between them. Thus, in the vegetable kingdom, we find starch, albumen, gum, sugar, &c.; and in the animal kingdom, albumen, fibrin, gelatin, mucus, &c. These are termed by chemists the immediate or proper constituents of organized bodies; or simple organic compounds. On submitting these substances to further chemical analysis, we find them composed of other principles which cannot be further decomposed; and on this account they are denominated elements. There are in animals, oxygen, hydrogen, carbon, and nitrogen; and in vegetables, oxygen, carbon, and hydrogen; and in some few cases a small quantity of nitrogen. Besides these, there are non-metallic substances, metallic alkaline, earthy, and ponderous metals. There are also the imponderable substances, light, heat, galvanism, magnetism, and electricity. It will immediately appear, that organic bodies do not differ from inorganic, with regard to elementary matters. But great differences exist with regard to the number of elements which enter into the organic combinations, and the manner in which they are united.

"It will also appear, that the number of elements that compose organic bodies, is much less considerable than that of the elements of the inorganic kingdom. All simple substances, therefore, do not enter into the composition of organic bodies.

"But although the elements of organic bodies are comparatively few, nevertheless, the composition of a living body, a plant, or an animal, is much more complicated than that of an inorganic body—a fact which Kiemeier has noticed in his lectures on general zoology.

"Organic substances are composed of three or four, and occasionally of more elements. Thus, vegetable sugar, starch, and mucus, are composed of carbon, oxygen, and hydrogen; and animal substances, of fibrin, albumen, mucus, &c., which are composed of oxygen, hydrogen, and carbon, with nitrogen. The ternary or quaternary combinations of these four elements, in proportions varying *ad infinitum*, form the immediate products of organised bodies—a fact clearly proved by the researches and experiments of Thénard, Gay Lussac, Berzelius Prout, Thomson, Berard, Saussure, Ure, and others.

"Inorganic bodies, on the contrary, are proved by Berzelius to be binary combinations, that is, resulting from the union of two elements alone, or as combinations of two binary compound bodies; or lastly, as combinations of a binary compound with a simple element. Thus, oxygen with hydrogen forms water; with sulphur, phosphorus, nitrogen, and carbon, it forms sulphuric,

phosphoric, nitric, and carbonic acids; combined with calcium, sodium, and potassium, it forms lime, soda, and potash; chlorine united with hydrogen forms the hydrochloric or muriatic acid, and nitrogen combined with hydrogen forms ammonia. All these compounds are therefore, only double binary compounds. Organic compounds are readily decomposed by chemical operations, but they cannot be reproduced, like those of inorganic compounds. Chemists have separated the elements of vegetable constituents, as starch, fibrin, gluten, &c.; but no one as yet has decomposed them in all their parts; the same result has been observed with regard to all the fluids and solids of living bodies. It is therefore reasonable to conclude, that the composition of living or organised bodies is not the result of chemical affinity or union alone, but dependent on the power peculiar to such bodies—the vital power.

"The elements of inorganic bodies are not disposed to change or unite with other substances; while those of organic bodies have a constant tendency to do so.

"There is another difference between organic or living, and inorganic or inert bodies, as regards their chemical composition and configuration, it is this—that the first, although, they resemble each other most closely in their composition, nevertheless, present a much greater diversity in their forms. Thus, what an immense variety of forms the vegetable and animal kingdoms exhibit, notwithstanding the inconsiderable number of elements which constitute living bodies in general. It is well known that the component parts of the different organs of living beings, differ from each other in a remarkable degree, as to chemical composition and configuration. Witness the illimitable diversities in plants and animals. Inorganic bodies, on the contrary, are remarkable, with few exceptions, for their great similarity of form and crystallization when their chemical composition is identical. It therefore follows, that there must be in organic or living bodies a peculiar power totally different from chemical affinities, which determines the configurations or forms of bodies not endued with life; and the influence of which produces the great diversity which organic forms of a similar chemical composition exhibit. It therefore follows, from the preceding acknowledged facts, that there are vast differences between organic and inorganic bodies.

"Let us next adduce further proofs of the validity of this conclusion. To effect this, we must notice the chemical composition of all the bodies in the universe, with which we are acquainted; we must examine the classifications of naturalists, and institute a comparison between organic and inorganic substances; between vegetables and animals, and between animals and man."

We have now enabled our readers to form

their own opinions on the execution of this great work, and have adduced ample attestation of its comprehensiveness. To those who feel interested in comparative and human physiology we strongly recommend the English version of Tiedemann; and if we may consistently, the elaborate lectures of Dr. Fletcher in our own pages.

—o—

A NEW PRACTICAL FORMULARY

OF HOSPITALS, OR A

Collection of Formulae of the Civil and Military Hospitals of France, Germany, Italy, Great Britain and Ireland, &c., containing the Indication of the Doses in which simple Substances, magistral and official Preparations of the Codex are administered, the use of New Medicines, and general receipts on the art of prescribing. By M. EDWARDS, M. D., and P. VAVASSEUR, M. D., of the Hospitals of Paris—1834. Translated and augmented by M. RYAN, M. D. &c. &c.

(Continued from p. 439.)

Potion of the Hydro-sulphate of Antimony.
H. Militaires.

Rx. Antimonii hydro-sulphatis, gr. j;
Gummi tragacanthæ, gr. x;
Aque fontanæ, ʒ ix.

Fiat haustus.

As an expectorant.

Emulsion of the Hydro-sulphate of Antimony.
H. of Italy.

Rx. Hydro-sulphatis antimonii, gr. iv;
Mellis despumati, ʒ j;
Emulsionis simplicis, ℥j.

Misce. Cochl. amp. pro dosi.

Marmalade Expectorate de Zanetti.

Rx. Antimonii hydro-sulphatis, gr. iv;
Mannæ, ʒ vj;
Olei amygdalæ dulcis,
Syrupi scillæ,
—— polygalæ, ā ā ʒ ij.

Misce. Capiat cochl. min. secundâ quâque horâ.

BROWN SULPHURET OF ANTIMONY.

It possesses the same properties as the hydro-sulphate of antimony, and is employed in the same manner. It is not much used in France; but in England it is preferred to that medicine.

INTERNALLY. The same doses as the hydro-sulphate.

Antirheumatic Powder. H. of Germ.

Rx. Sulphuris antimoniatifusci, gr. j;
Pulveris glycyrrhizæ, gr. x.

Fiat pulvis.

Pectoral Pills. H. of Germ.

Rx. Antimonii sulphurettifusci, ʒ.
Gummi ammoniaci,
Extracti glycyrrhizæ, ā ā ʒ

Fiat massa, in pilulas granorum ij distri-
buenda, ex quibus sumat v—x quotidie.

Pectoral Pills. H. of Germ.

Rx. Antim. hydro-sulphatis, 3ss;
Gum. ammoniaci,
Extr. glycyrrhizæ, ā ā ʒ ss.

In pilulas gr. ij. divide, ex his sumantur
quinque vel decem quotidie.

Looch Pectoral. H. of Germ.

Rx. Sulphatisantimoniatifusci, gr. iv;
Mucilaginis acaciæ,
Mellis purificati, ā ā ʒ j.

Misce. Cochl. amp. pro dosi.

SULPHATE OF ANTIMONY.

Formerly employed as an emetic, exci-
tant and diaphoretic; but at the present day
it is scarcely ever prescribed, except in some
cases of scrofulous swellings and cutaneous
diseases.

INTERNALLY. Gr. xij—ʒj and even ʒj,
in suspension in an emulsion, or in pills.

Tablettes Antimoniâles de Kunkel. P. No. iv
—x daily.

OXIDE OF ANTIMONY AND ANTIMONIC
ACID.

M. Trousseau considers these the most
powerful antiphlogistics and counter-stimu-
lants. He assures us that he has found them
most efficacious in inflammatory affections
of the chest. [Later writers have declared
them to be useless. T.]

INTERNALLY. ʒj—iv, in emulsion or
pills in 24 hours.

The other preparations of antimony, such
as powder of Algaroth, glass of antimony,
diaphoretic antimony, &c., are scarcely ever
employed at the present day.

IPECACUANNA.

In small doses it produces vomiting and
sometimes alvine evacuations; but it also
possesses excitant and tonic properties,
which have a special action on the pulmo-
nary organs.

It is generally used to produce vomiting;
it is less certain, as an emetic, than the tar-
trate of antimony, but less irritating than
that medicine. Its use is much recom-
mended in the treatment of dysentery, croup,
and puerperal peritonitis, after the intensity
of the inflammatory symptoms has been di-
minished by blood-letting. It is also used
in very small doses to excite the action of
the stomach, and to stimulate the mucous
membrane of the bronchiæ in certain cases
of pulmonary catarrh, whooping cough, &c.

INTERNALLY. *Powder.* As an emetic, gr.
xv—xxx, in half a glass of tepid water.

As a stimulant, gr. i—vj.

Potion émetique avec l'ipecacuanha. P. (ʒi
aq. ʒ ix.; syr. ʒ j.) To be taken at three
doses, every quarter of an hour.

Potion d'expectoration composée. P. A spoon-

—tic, ʒ ss, every
—tant and dia-

phoretic, from gut. xx—xl, several times a day.

Syrup. P. ʒ ss—ij.

Pastilles d'ipécacuanha. P. No. iv—x.
Ipecac. ʒ iv, sach. ʒ xx. Muc. tragacanth. q. s.

An Emetic Powder. H. of Germ.

Rx. Pulveris ipecacuanhæ,
Sacchari, ā ā ʒj.

Divide in chartulas iv, de quibus sumat unam quartā quaque parte horæ, donec emesis supervenerit.

Powder of Ipecacuanha and Rhubarb. H. of England.

Rx. Pulveris ipecacuanhæ, ʒj;
—— rhei, ʒ ij.

Misce. The dose is gr. x—xx as an emeto-cathartic, and gr. iv—vj twice or thrice a day, as a diaphoretic.

The *poudre éméto-cathartique* of the Hôt. D. very much resembles the above. It is composed of ipecacuanha, ʒj, and rhubarb, gr. xij, which is given at one dose as an emeto-cathartic, and in divided doses as an excitant of the digestive tube.

Expectorant Powder. Hôt. D.

Rx. Pulveris ipecacuanhæ, ʒj;
—— scillæ, gr. xij.

Divide in chartulas xij quarum, sumat unam secundā vel tertiā quaque horā.

Pilules Nauséuses. H. of Italy.

Rx. Pulveris ipecacuanhæ, gr. vj;
Succi sambuci, q. s.

Fiant pilulæ vi, de quibus sumat unam secundā quaque horā.

Boluses of Ipecacuanha. H. de la Mat.

Rx. Pulveris ipecacuanhæ, gr. xvij—xxiv;
Mellis despumati, q. s.

Divide in bolos tres, capiat unum singulis semihoris.

As an emetic.

An Astringent Bolus. H. de Montp.

Rx. Pulveris ipecacuanhæ, gr. iʒ;
—— aluminis, gr. vj;
Syrupi papaveris, q. s.

Fiat bolus.

Employed in chronic diarrhœa.

Infusion of Ipecacuanha. H. of Germ.

Rx. Ipecacuanhæ contusæ, ʒ ij;
Aquæ, ʒ iv.

Boil till reduced to a half, and strain. Boil the residue twice in the same quantity of water, and add the three colatures together. It should be taken at three doses in dysentery.

[The compound powder of ipecacuanha or Dover's powder is a much better remedy in such cases. T.]

Infusion of Ipecacuanha. H. de Montp.

Rx. Ipecacuanhæ contusæ, gr. xv;
Corticis aurantii, ʒj;
Aquæ, ʒ vj;
Syrupi florum aurantii, ʒj.

Fiat infusium capiat cochl. amp. ex cyatho aquæ.

Before each repast, as a stimulant and stomatic.

Emetic Potion. H. des Ven.

Rx. Pulveris ipecacuanhæ, gr. xij;
Aquæ destillatæ, ʒ iv.

Fiat haustus.

Looch anisé avec le Sirop d'Ipécacuanha. H. des Ven.

Rx. Syrupi ipecacuanhæ, ʒj;
Linctus anisi, ʒ iv.

Misce.

Given to infants, to remove mucosities of the intestinal canal.

[The wine of ipecacuanha is preferable to the antimonial in bronchial diseases of infants, because the latter is too stimulating, more especially as most children labour under more or less gastro-intestinal irritation. The following syrups are highly beneficial in the catarrhal and bronchial affections of children.

Rx. Syrupi simplicis, ʒ xj;
Vini ipecacuanhæ,

Dosis ʒj urgente tussi.

In spasmodic cough or pneumonia, one minim of hydrocyanic acid and xx—xxx of comp. tinct. of camphor, may be added. In violent cases of pneumonia, when the usual remedies had failed, I have repeatedly prescribed for infants from a year and a half to two years of age, two drops of Scheele's acid in the above syrup, with decided advantage. A teaspoonful was given every half hour or hour, according to the urgency of symptoms. Dr. Marshall Hall and Dr. Elliotson prefer ipecacuanha to tartarized antimony in bronchitis. Dr. Sheridan and Dr. Osborne of Dublin have lauded this medicine in hæmoptysis. T.]

EMETINE.

The active principle of ipecacuanha, which is employed as an emetic, in the same cases as that medicine; its action is much more violent, consequently its use requires great prudence.

Subst incomp. The infusion of galls, &c.

INTERNALLY. Gr. ʒ—dissolved, or in pills.

Syrup of Emetine. F. de M. (Emetine, gr. iv.; common syrup, ʒi. Each drachm contains gr. 1-32 of emetine). ʒ ij—iv.

Emetic Potion. Magendie.

Rx. Emetinæ puræ, (solutæ in acido nitrico, q. s.) gr. i;
Infusi florum tilisæ, ʒ iij;
Syrupi albæ, ʒj.

Misce. Sumatur cochleare modicum quartā quā que horā ad emesin.

Lozenges of Emetine. Magendie.

Rx. Emetinæ puræ, gr. viij;
Sacchari, ʒ iv.

Fiant trochisci, gr. ix, capiat j, singulā horā.

Employed in *hooping cough*, *chronic pulmonary catarrh*, *chronic diarrhoea*, &c. (Each lozenge contains about gr. 1-45th of emetine).

COLOURED OR IMPURE EMETINE is also employed in the same cases; but as it is much less active it is generally administered in doses four times as strong. We should bear in recollection which of these two substances is employed.

Emetic Mixture. Magendie.

Rx. Emetinæ coloratæ, gr. iv.;
Infusi florum aurantii, ℥ ij;
Syrupi florum aurantii, ℥ ss.

Misce. Sumatur cochleare modicum singulâ semihorâ.

Lozenges of Coloured Emetine. Magendie.

Rx. Emetinæ coloratæ, gr. xxxij;
Sacchari purificati, ℥ ij.

Divide in trochiscos granorum, xvij.

The dose is one for children, and three or four for adults. Each lozenge contains 3-11ths of a grain of the emetine.

The *Sirop d'emetine coloree*, Magendie differs only from that of pure emetine in containing gr. xvj of emetine, to Oj of common syrup. It may be used with advantage instead of the sirop of ipecacuanha.

[Violine or emetine procured from the root of the *viola odorata*, is recommended by M. Magendie in diarrhoea. Doses gr. vj—xij. T.]

ASARABACCA.

A very energetic excitent, violent emetic, and sternutatory in nervous head ache. Not much employed at the present day.

INTERNALLY. Root. Powder, ℥j—3j.

Infusion. 3j—ij to Oij of water or wine.

Leaves. Powder. Gr. xij—℥ij.

Poudre sternutatoire, or de St. Ange. P. Pini, j of asarabacca, marjoram betony, flowers of may-lilly

Teintre. P. Gutt. xx—xxx. Not much used.

[Squill, sulphate of zinc, sulphate of copper, mustard seed and chamomile are also employed as emetics. The doses are described under the respective heads.—T.]

CHAPTER XIII.

MEDICINES GENERALLY EMPLOYED AS PURGATIVES.

A—DRASTICS.

COLOCYNTH.

In large doses, a violent irritant of the stomach and rectum; in small doses it is a very energetic drastic purgative. Its irritating influence on the rectum may be communicated to the uterus, and increase menstruation. Colocynth may be employed with advantage in passive dropsies, and when

it is necessary to produce a powerful action on the large intestines. In such cases, it should be mixed with eight or ten parts of an insoluble and inert powder, to diminish its violent action on the stomach.

Subst. Incomp. The fixed alkalies, the sulphate of iron, the nitrate of silver, the acetate of lead, &c.

INTERNALLY. Powder. Gr. iv—xi and even to ℥j, mixed with the powder of gum, or some other inert powder.

Extract. P. Grs. iv—xij, in pills, combined with calomel or some other purgative.

Purgative Bolus. H. of Italy.

Rx. Extracti colocynthidis, gr. ij;
Mellis despumati,
Pulveris glycyrrhizæ, ā ā q. s.

Fiat bolus.

Powder of Colocynth. H. of Germ.

Rx. Pulveris colocynthidis, gr. j to iij;
——— gummi acaciæ,
——— glycyrrhizæ,
Sacchari, ā ā gr. v.

Fiat pulvis catharticus.

Pills of Colocynth and Calomel. H. of Eng.

Rx. Extracti colocynthidis, 3j;
Hydrargyri submuriatis, gr. xvij.

Fiant pilulæ viij, ex quibus capiat unam, ad quatuor quotidie.

Decoction of Colocynth. H. of Germ.

Rx. Colocynthidis, 3ij;
Aquæ, Oj.

Coque per duodecimam horæ partem, cola et adde,

Etheris sulphurici, 3ij;
Syrupi corticis aurantii, ℥ ij.

Fiat potio cujus capiat cochleare bis vel ter in die.

In dropsies.

EXTERNALLY.

Irritating Suppository. H. of Germ.

Rx. Pulveris colocynthidis, 3ss;
Sodæ muriatis, 3j;
Mellis, ℥j.

Misce.

To be introduced in the rectum.

Purgative Pommade. H. de Montp.

Rx. Pulveris colocynthidis, 3j;
Adipis preparatæ, ℥j.

Fiat unguentum.

Used in frictions on the abdomen, in 3ij doses.

CROTON OIL.

In small doses, it produces alvine evacuations more or less abundant; in larger ones it irritates, in a violent manner, the mucous membrane of the intestines. It is used with advantage in obstinate cases of constipation, when the other drastics have proved ineffectual; when it is necessary to obtain prompt results, or when there exists an obstacle to the employment of an ordinary purgative, as is sometimes the case in tetanus.

nus, mania, apoplexy, &c. M. Andral found it efficacious in obstinate head-aches, asthma, dropsies, &c. It is also employed in the treatment of plumbers' colic. Very good effects have been obtained from its use in frictions, in cases in which tartarized antimony is used, but this acts more quickly, as in cases of chronic rheumatism, and tumours of the articulations, &c. The very violent action of this oil requires the greatest attention on the part of the practitioner.

INTERNALLY. Gut. j—iv and more, in ʒss of syrup, or in pills of bread.

Saxon d'huile de Croton. F. de M. (Croton oil, 2 parts; solution of caustic soda, 1 part). Gr. ij—iv, with syrup or in pills.

Cathartic Mixture.

Rx. Olei tigllii, gut. ij;
Mucilaginis acaciæ, ʒj;
Sacchari purific., q. s.

Fiat mistura.

To be taken in two, at some hours of interval.

Oleo-saccharat de Croton Tigllum. H. of Germany.

Rx. Olei tigllii, gut. j;
Micæ panis ʒj.

Divide into 8 packets, of which one should be taken every hour until purging is produced.

[Two or four drops may be added to the extract of colocynth with calomel, in cases of obstinate constipation. T.]

Purgative Pills of Croton Oil. H. of Italy.

Rx. Olei tigllii, gut. j;
Micæ panis, q. s.

Fiat pilula.

EXTERNALLY. In frictions, gut. iv on the umbilicus, as a purgative,

[It suddenly reddens the skin, and is advantageously added to the antimonial ointment, when this has failed. See *Antimony*. T.]

OIL OF SPURGE (EUPHORBIA LATHYRIS).

A very energetic purgative, which may replace with advantage croton oil, because its action is much less violent, and always very certain.

INTERNALLY. From gut. vj—x in an emulsion or in pills.

Purgative Lozenges. Bally.

Rx. Ol. euphorbiæ lathyris, m xl;
Chocolati pulv. ʒj;
Sacchari pur. ʒss;
Amyli pulv. gr. xij.

Divide in pastillos gr. ix.

One may be given to infants, and two or three to adults. A very convenient purgative.

Potion with the Oil of Spurge.

Rx. Olei euphorb. lathyris, gut. viij;
Pulveris acaciæ, ʒj;
Sacchari, ʒij;
Aquæ destillatæ, ʒiij.

Fiat potio, cujus capiat cochleare omni horâ donec alvus soluta sit.

CAMBOGE.

A very energetic drastic purgative, which frequently produces colic and purging, and in too large doses it inflames the stomach and the intestines. Nevertheless, it is employed with advantage when it is necessary to cause a powerful derivative in certain cases of dropsy and chronic cutaneous affections. It is frequently used by English practitioners; but not much employed in France. It may also be administered as an anthelmintic. The Italians consider it as a powerful counter-stimulant.

INTERNALLY. Powder. From grs. ij—vj, in pills or in an emulsive potion.

Powder of Camboge. H. of England.

Rx. Cambogiæ, gr. iij;
Sacchari, ʒj.

Fiat pulvis singulâ tertia quâque horâ sumendus, donec alvus responderit.

Bolus of Camboge. H. of England.

Rx. Cambogiæ, gr. x;
Potassæ tartratis, gr. xx;
Pulveris zingiberis, gr. iij;
Syrupi simplicis, q. s.

Fiat bolus.

Drastic Pills. H. of Italy.

Rx. Guttæ gambæ, gr. xij;
Succi sambuci,
Pulveris glycyrrhizæ, ā ā q. s.

Fiat pilulæ vj, quarum capiat unam tertis horis.

MEADOW SAFFRON.

In small doses it acts as a sedative, in more modified ones it is an energetic purgative, and at the same time a diuretic; in large doses it is a violent irritant of the gastro-intestinal mucous membrane. It is employed as a drastic in hydrothorax, anasarca, violent rheumatic pains. It is also used in small doses, to calm the pains in gout, &c. It is not much used in France; but in England it is very much employed.

[Sir C. Scudamore thinks it too freely used. T.]

INTERNALLY. Powder, from gr. j—iv, in pills.

Teinture. P. Gut. xv—xxv, in a potion.

Teinture de Colchique de Darmstrong. P. Gut. x ad xx in a potion.

Wine. P. ʒj—ʒss, and more progressively.

Oxymel. P. ʒij—ʒj, progressively, twice a day, in a mucilaginous mixture.

Honey. P. ʒss—j and more.

[The liquor colchici of Battley, may be given in doses, from m v—xx daily. T.]

Diuretic Mixture. H. of Germ.

Rx. Oxymellis colchici,
Ammonisæ acetatis, ā ā ʒij;
Aquæ destillatæ petroselinii ʒvj.

Fiat potio, cujus capiat cochleare, secundâ quâque hora.

Anti-arthritic Mixture. H. of America.

Rx. Vini colchici, 3 ij;
 Magnesiae subcarbonatis, 3 j;
 Aquae destillatae cinchonae, ā ā
 3 iij.

Fat mistura cujus capiat cochl. ampl. itertiā horā.

[Sir Charles Scudamore prescribes from m xx—xc of acetum colchici, combined with sulphate and carbonate of magnesia. Essay, April 1835. T.]

VERATRINE.

The active principle of colchicum, &c., which acts in large doses in the same manner as the most energetic irritating poisons in small doses; it is employed as a drastic purgative. Its action is very prompt. As an external application, it appears to be useful in the treatment of gout, anasarca, chronic rheumatism, and other cases in which the tincture of colchicum is recommended.

[Recommended in neuralgiae, but found to fail. T.]

INTERNALLY. As a purgative, gr. 1-12th to ½, in pills.

Alcool de vératrine. F. de M. (Veratrine, gr. iv; alcohol, 3 j). Gut. x ad xxv, in a potion.

Pills of Veratrine. Magendie.

Rx. Veratrinæ, gr. ½;
 Gummi acaciæ, ʒj;
 Syrupi gummi, q. s.

Divide in pilulas vi, quarum capiat unam ad tres in die.

These pills replace with advantage those of Bacher. Each of them contains 1-12th of a grain of veratrine.

In anasarca, dropsy, &c.

EXTERNALLY.

Alcool de Veratrine. F. de M.

Veratrine gr. iv, alcohol 3 j. Dose m x—xxv in a draught. Used in frictions.

Pommade of Veratrine. Magendie.

Rx. Veratrinæ, gr. iv;
 Adipis, 3 j.

Fiat unguentum.

M. In frictions, in cases of anasarca, gout, &c.

[Sabadilline is not preferable to veratrine, according to Magendie. T.]

SULPHATE OF VERATRINE.

It possesses the same action, and is used in the same manner as veratrine.

INTERNALLY.

Solution de Vératrine. F. de M. (Sulphate of veratrine, gr. j; distilled water, 3 ij). 3 j—iv, in a potion. The preparation replaces with advantage the *Eau Médicinale de Husson*.

BLACK HELLEBORE.

One of the most violent drastic purgatives. Not much used at the present day. Nevertheless, sometimes employed in dropsies and certain diseases of the skin. Its use requires great prudence.

INTERNALLY. Powder, gr. x—ʒj, in pills.

Infusion. 3 ij in ʒij of boiling water, of which 3 j should be given every four hours.

Extract of Hellebore. P. Gr. iv—x in pills.

Tonic Pills de Bacher. P. Gr. j—ij daily.

Tincture. P. Gut. xx—3 ss, and even to j, progressively, in a proper vehicle.

The WHITE, GREEN, and FETID HELLEBORE, act in nearly the same manner. They are not used at present.

ELATERIUM.

A very violent drastic purge, even in small doses. Formerly used in the treatment of ascites and dropsies in general. Its use requires great care.

[The extract may be given to children under three years of age, labouring under dropsy, in doses of one sixteenth to one twelfth of a grain, combined with calomel, &c. T.]

INTERNALLY. Powder, gr. ½, every hour until purging is produced, either in pills or suspended in an emulsion. The dose ought never to be carried higher than gr. vj.

Compound Powder of Elaterium. H. of Eng.

Rx. Extracti elaterii, gr. iv;
 Potassæ tartratis, ʒv;
 Pulveris zingiberis, ʒj.

Dosis gr. v. ad xx. (30 grains contain 1 gr. of elaterium.)

[Compound Powder of Elaterium. Ryan.]

Rx. Extracti elaterii, gr. i;
 Hydrarg. submur. gr. xij;
 Pulv. cinnam. comp., ʒj;
 Sacchari purific., 3 ss.

Tere intime et divide in ch. xij, quarum capiat unam ter in die.

I have repeatedly prescribed this powder for children of five years of age affected with anasarca, ascites, and even hydrothorax, after scarlatina, with success. The dose must be diminished if the bowels act too freely. T.]

ALOES.

In small doses, a bitter tonic; in large ones, an energetic purgative; but its effects are not manifest for some time after its administration, and it acts principally on the large intestines. It is employed with advantage in cases of habitual constipation, arising from atony of the intestinal canal, in jaundice, chlorosis, scrofulous affections, hypochondriasis, and, in general, every time that a slight purgative effect is wished to be produced, and secondly, a tonic effect. It is given to persons predisposed to cerebral congestion, on account of its action on the rectum; which may be also extended to the uterus, and it is sometimes used to excite the flow of the menses. It ought not to be administered to persons affected with hemorrhoids. It is also recommended

as an anthelmintic; but it cannot be depended on.

INTERNALLY. *Powder.* As a tonic, gr. j—iv.

As a purgative, grs. vi—℥j.

Pills of Aloes and Soap. P. Grs. x—xv.

Pills of Rufus. P. As a cathartic, ℥j—ij.

As a stimulant, grs. x—℥j.

Pills of Aloes and Guaiac. P. Gr. vj—xij.

Pilules Bénites de Fuller. P. No. ij, twice a day.

Pilules Hydragogues de Bontius. P. From gr. xij—xviiij.

Compound Electuary of Aloes. P. ℥j—3j.

Opiate Méésentérique. P. 3ss—ij.

Aqueous Extract. P. Gr. vj—xij, in pills.

Tincture. P. Gut. x—3ss, in an appropriate potion.

Compound Tincture of Aloes. P. 3j—iv.

Compound Powder of Aloes. H. of Eng.

Rx. Alōes spicati, ℥iv;

Cinnamomi, 3j.

Doses gr. x ad ℥j.

Compound Aloetic Pills. H. of England.

Rx. Alōes spicati, 3ss;

Extracti gentianæ, 3ij;

Olei carui, ℥j;

Syrupi auranti, q. s.

Fiat massa.

The dose, gr. x—xv daily.

Emmenagogue Boluses. H. of Italy.

Rx. Extracti alōes, gr. viij;

———— sabinæ, gr. vj;

Pulveris glycyrrhizæ, q. s.

Divide in bolos vi de quibus, capiat unum tertia quaque hora.

Aloetic Pills. H. des Ven.

Rx. Alōes spicati, 3j;

Pulveris rhei,

Sulphatis potassæ, ā ā 3iv;

Syrupi chichorii, q. s.

Divide in pilulas, gr. vi, de quibus, capiat duas vel tres in die.

As a purgative.

Laxative Electuary. H. of Italy.

Rx. Extracti alōes, gr. viij;

Potassæ supertartratis, 3ij;

Mellis, q. s.

Misce, pro una dosi.

Tincture of Aloes and Myrrh. H. Militaires.

Rx. Tincturæ alōes,

———— myrrhæ, ā ā, p. e.

Misce.

Dosis ℥j ad 3j bis vel ter in die.

As a stomachic and excitant.

Aloetic Mixture. H. of Germ.

Rx. Extracti alōes,

———— myrrhæ, ā ā 3j;

Potassæ supertartratis, 3ss;

Aque menthæ piperitæ, 3vj.

Fiat potio, cujus capiat cochleare mane nocteque.

To excite the hemorrhoidal flux.

EXTERNALLY.

Anthelmintic Suppositorium. Swediaur.

Rx. Alōes spicati, 3ss;

Sodæ muriatis, 3ij;

Farinæ, 3ij;

Mellis, q. s.

Fiat suppositorium.

[The compound decoction and tincture of aloes are favourite medicines with many practitioners. The first is often combined with the compound iron mixture. Aloes is the chief ingredient in the popular aperient called pill of cochises (cochées). These and other aloetic pills are injurious during uterine gestation. T.]

JALAP.

In moderate doses jalap is a purgative, whose action is principally carried to the small intestines; in large doses it is a strong irritant of the gastro-intestinal mucous membrane. It is a medicine very much employed on account of its energetic action, and its low price. It is used in costiveness, mania, worms, and as a hydragogue in dropsies. It is generally united with some other purgative [as calomel, supertartrate of potass, and a drop of essential or some aromatic oil should be added to prevent griping. T.]

INTERNALLY. *Root. Powder.* Gr. xij—3ss, in pills, or suspended in an emulsion.

Cathartic Powder. P. Gr. xviiij—℥j.

Compound Tincture of Jalap. P. ℥j—3j, in an emollient vehicle.

This is much stronger than the British preparation.

Syrup of Jalap. P. 3ij—3ss.

Resin. Powder. Gr. ij—x, in pills, or better, suspended in an emulsive potion. Not so much used as the root. It gripes violently.

Purgative Emulsion. P. A spoonful at a dose.

Savon de Jalap. Resin of jalap, 8 parts, almond soap, 16 parts, alcohol, q. s. P. Gr. x—xv, in pills.

Anthelmintic Powder. Hdt. P.

Rx. Pulveris jalapæ, gr. xxx;

———— rhei, gr. vj;

Hydrargyri submuriatis, gr. ij.

Divide in pulveres duas, capiat unam singulis horis.

Purgative Powder. H. de la Mat.

Rx. Pulveris jalapæ, gr. ij;

———— rhei,

———— cinnamomi, ā ā gr. i.

Fiat pulvis.

Given to children as a purgative.

Purgative Powder with the Essential Oil of Orange.

Rx. Pulveris jalapæ, 3iv;

Potassæ tartratis, 3j;

Sacchari, 3ijss;

Olei aurantii, 3ss.

Make an alco-saccharat, to which add q.

first the salt of potassa, and then the jalap. The dose is ʒ ij—iij in Oj of orange water. It is a very agreeable purgative.

Cathartic Boluses. H. Militaires.

Rx. Pulveris jalapæ, gr. xx;
 ——— scammonii, gr. viij;
 Mellis, q. s.

Fiant boli iv.

Purgative Pills. H. of Italy.

Rx. Pulveris jalapæ,
 Sacchari, ā ā ʒj;
 Pulveris rhei, gr. xxx;
 Syrupi chichorii, q. s.

Divide in pilulas xxiv, quarum capiat iv ad viij pro dosi.

Purgative Biscuits. H. of Montp.

Rx. Pulveris jalapæ, ʒj;
 Farinæ, ʒj;
 Ova, No. ij;
 Sacchari, ʒj.

Make into three biscuits. A very commodious purgative for children.

Purgative Jelly. H. of Germ.

Rx. Pulv. jalapæ, ʒss;
 Gelatin. mali cydonii, ʒiv;
 Alcoholis, ʒvj.

A very agreeable purgative.—Dose, ʒj.

Jalap Potion. H. de la Ch.

Rx. Pulveris jalapæ, ʒss;
 Decocti chichorii, ʒiv.

Misce.

To be taken in two doses.

Purgative Emulsion. H. Militaires.

Rx. Pulveris jalapæ, gr. vi;
 Emulsionis amygdal., ʒvj.

Misce.

Purgative Potion. Hôt. D.

Rx. Tincturæ jalapæ comp., ʒj;
 Syrupi rhamni, ʒss;
 Decocti chichorii, ʒiv.

Fiat potio.

Employed in the treatment of certain dropsies.

Purgative Potion, or Medecine Commune. H. des Vén.

Rx. Pulveris jalapæ, gr. xxx;
 Sulphatis sodæ, ʒv;
 Syrupi mellis, ʒj;
 Decocti chichorii ferventis, ʒvi.

Misce.

To be taken at several doses.

[The compound powder of jalap, combined with calomel, squill, and digitalis, is a valuable remedy in dropsies. T.]

SCAMMONY.

A very energetic drastic purgative, whose action is very prompt. It is employed in small doses, in obstinate cases of constipation, caused by atony of the intestinal canal, and especially in passive dropsies; and also to produce abundant alvine evacuation.

INTERNALLY. Powder. Gr. j—vj, and gradually increased to xij and xv.

Purgative Emulsion. P. ʒij—iv.

Tablettes de Scammonée et de Séné composées. P. ʒj—ij.

Teinture. P. ʒj—3j, in a potion.

Sirop. P. ʒj—iv, in a potion.

Electuaire Diaphœnix. P. ʒss—ij.

Compound Powder of Scammony. H. of England.

Rx. Pulveris scammonii,
 Extracti jalapæ, ā ā gr. x;
 Pulveris zingiberis, gr. iij.

Divide in chartulas iv, quarum capiat duas vel tres quotidie.

Powder of Scammony and Calomel. H. of England.

Rx. Pulveris scammonii, ʒj;
 Hydrargyri submuriatis,
 Sacchari, ā ā ʒss.

Fiant chartulæ xxviij, de quibus sumat unam vel duas quotidie.

Purgative Powder. H. of Eng.

Rx. Pulveris scammoniae, gr. v;

——— rhei, gr. xv;

Ammoniae subcarbonatis, gr. vj.

Misce.

To be taken at a dose.

Purgative Oil. Swédiaur.

Rx. Scammonii, ʒj;
 Olei amygdalarum, ʒj.

Dissolve by a gentle heat. The dose is ʒss and more, in an emulsion. It is a gentle purgative.

Purgative Electuary. H. of Germ.

Rx. Scammonii,
 Zingiberis, ā ā ʒss;
 Olei caryophyll., gr. xij;
 Syrupi corticis aurantii, q. s.

Misce.

The dose is ʒj—ij.

TURBITH (CONVOLVULUS TURPETHUM).

It has the same action, and is used in the same cases as the preceding substance. It is scarcely ever used at the present day.

INTERNALLY. Powder. P. Gr. x—ʒj.

Decoction. ʒj—ij in ℥j of water. A glassful should be taken at intervals, until purging is produced.

SENNA.

When administered in large doses it powerfully irritates the gastro-intestinal mucous membrane; in moderate doses it is an energetic cathartic, and one very frequently employed. It is not often administered alone, but generally combined with some mild purgative, such as the neutral alkalies, tamarinds, manna, &c. It is customary, in England, to join with it some aromatic substance, such as ginger, carraway, cardamom, cinnamon, &c., to obviate the griping it frequently produces; a practice which is very advantageous.

[This is essentially necessary in cases of children. T.]

(To be continued.)

**The London Medical
AND
Surgical Journal.**
Saturday, May 9th, 1835.

**NEW REGULATIONS OF THE RHABAR-
BARIANS.**

THE new regulations issued by the Rhabarbarians will be very differently viewed by opposite parties in the profession; one regarding them with complaisance, as conferring additional respectability on the Company—the other deprecating them, as tyrannical to the medical student. We cannot say that we agree with either. Taking the regulations simply as a further provision for the good education of medical practitioners, we think they are entitled to praise; and we give it heartily, well pleased at finding an opportunity of commending where we generally find room only for censure. It is but justice to the Rhabarbarians to admit, that the course of education prescribed by them is far superior to that insisted on by either of the London Colleges. Why then are we incessantly denouncing the Apothecaries' Company as the most odious and contemptible of medical institutions? We answer, because notwithstanding the improvements it has effected in medical education, it is still based on the degradation of the profession; its very existence is interwoven with the worst of the many evils that beset the general practitioner; its main object is to perpetuate that union of a liberal profession and a paltry trade, which lowers medical practitioners in the eyes of the public, which engenders a vile subordination of one class of the profession to another, and drowns the free and generous spirit of science in the low arts of a sordid and barely honest species of traffic.

Again, while we give the Company full credit for their attempts to extend the acquirements of their licentiates, we must protest against the members of that company as competent judges

of the qualifications of candidates. The examiners are frequently men who have received their own education behind a druggist's counter, who are obliged to learn their lesson for the occasion, and who are precisely as fit to conduct a medical examination, as we are to teach Sanscrit.

Lastly, we protest against the intolerable insolence of a set of illiterate tradesmen pretending to examine graduates in medicine, and members of colleges. It is much the same thing as if men in orders, even though Doctors in Divinity, were compelled to pass an examination before a board of parish clerks, ere they were permitted to accept a living, or to enter a pulpit.

Now we will give the Rhabarbarians a piece of advice—not in irony, but in good will; and we assure them they will be obliged to follow it, some day or other, whether they like it or not. Either let them cease to be a medical body altogether, and, restricting themselves to pharmacy, supply the public with a sufficient number of well educated *pharmaciens*; or let them become a medical body in good earnest; with a view to which, we would recommend them to have an auction without loss of time, at the emporium in Union Street, and sell off all the jalap, prometheans, pink-saucers, tooth-brushes, and other useful and ornamental articles to the highest bidder, strongly dissuading all their alumni from ever dealing in the like wares.

If, in addition to all this, they would include surgery in their otherwise very respectable *curriculum*, their diploma would be decidedly the most valuable that is given in London. They might thus, perhaps, have the honour of forming the nucleus of the One Faculty which must ere long be established; and they would, at all events, attain a decided ascendancy over the twelfth century men—the monkish physicians of Pall Mall, and the barber-surgeons of Lincoln's Inn.

PARISH JOBBING AGAIN.

To the Editor of the London Medical and Surgical Journal.

SIR—Belonging to a Society containing amongst the rest a few members of the medical profession, your journal is one of the works taken in; and although not professional myself, I generally run through its pages, to see if it contains any general article, when I found one, in the number for last week, page 408, headed "Parish jobbing," and was so forcibly struck with the justice of your observations, and the degrading manner in which parochial elections are carried on, as well as the party-political feeling now displayed, that I am induced to forward you another instance thereof, first assuring you that I am not at all interested for or prejudiced against the two individuals concerned, but actuated purely from a desire to see the profession and all professional appointments conducted with justice and impartiality, as well as to render a just tribute to an ill-used and highly talented, although a young member of the profession.

The late Mr. C. W. Wright held the appointment of surgeon-apothecary to the large parish of St. Pancras for some years (testimonials from the College and Hall being indispensable necessities for the situation), and when Mr. Dillon, the surgeon, resigned, he became a candidate for this higher office—natural enough, for every man wishes to better his condition in life. He was opposed by several candidates, and among the rest Mr. Delisser, who at that time, although in private practice, was not a licentiate of the Apothecaries' Company; but by some means or other, the select vestry presumed he was qualified, or he forgot his certificate, and they took it for granted that he had passed; be that as it may, he was allowed to stand at the election, but was unsuccessful; Mr. Wright was elected, and things went on smooth. Now comes the point I wish to allude to particularly.

Mr. Wright had a pupil, Mr. Henry Bird, of Kentish Town, who to my certain knowledge, from opportunities I then had of witnessing his unremitting attention, was both skilful, assiduous, and a well-disposed young man. He took advantage of the opportunities that were afforded him in the practice of the infirmary, containing two hundred beds, with a lying-in ward and infant nursery, under the instruction of that able physician Dr. Roots, and many thousands of out patients annually, and where in conjunction with attending his lectures first at St. Bartholomew's Hospital, and afterwards at the London University, he spent the whole of eight years; from these opportunities it may be presumed he acquired a good practical knowledge of his profession.

I have made this remark, not as a puff,

but merely to show that the above, in conjunction with his diploma from the College and Hall, proved his capability to undertake any situation. The select vestry were so satisfied with his conduct and abilities, that they appointed him resident medical officer to the Cholera Hospital, which office he filled with credit to himself, and benefit to the parishioners at large; as testimonials from Government and the Board of Health testify.

Mr. Wright, about a year and a half or two years ago, being attacked with consumption, found it impossible to attend to his duties, which Mr. Bird kindly undertook for him, and which he performed until the death of the former, last autumn.

Before the body was quite cold, Mr. Delisser, a non-resident in the parish, had his circulars out, and commenced canvassing for the situation. Mr. Bird wrote to the directors, announcing the death, and his intention to apply personally in proper time, thinking they would have the decency to defer making any arrangements until the funeral had taken place, and offering, with their permission, to continue the duties until his successor was appointed, which they desired him to do; and although they knew Mr. Bird had to make arrangements for the funeral, to attend the duties of the office, and was residing at the deceased's house, the board, for private motives, actually fixed the day of election close upon the day of the funeral, without even giving him any notice thereof; and only a few days previous to the election was he aware of it, and was then obliged to forego all personal respect to his deceased friend, and to commence his canvass without delay.

On the day of nomination there were five candidates, who were all examined as to their testimonials, and were all found correct, although Mr. Delisser, from some cause or other, did not produce his certificate from the Hall; however they all stood the election, and the question was asked, "Were all the candidates aware that they must be prepared to reside in the parish?" All answered "Yes." Party feeling ran high at this time; the other candidates divided Mr. Bird's interest, and Mr. Delisser was elected.

I thought Mr. Bird exceedingly ill-used, and was determined to see if Mr. Delisser was a licentiate of the Apothecaries' Hall, where I went, and found he had lately qualified, having at all previous elections deceived them as to the possession of the necessary qualifications.

During his election he stated that Mr. Bird was too young, when actually the latter was the older qualified practitioner of the two.

But Mr. Editor, this was easy to be accounted for: Mr. Murphy, the Pancras radical, has a tail at the vestry, who are obliged to vote as this rejected candidate for the borough of Marylebone orders, and Mr. Delisser was a friend of Mr. Murphy's, and was on the hustings at his unsuccessful trial

for a would-be M. P., hollowing out "Murphy for Marylebone;" and for this reason Mr. Murphy ordered his tail to vote for his friend. Now this is not all; Mr. Delisser has a surgery in the parish, but he still resides out of it; and although some months have elapsed since the appointment, not one of the vestry have yet thought fit to raise a word on the subject.

This I consider as one of the now-too-common acts of injustice to persons, from political motives, that ever came before the public; and I am only acting fairly in sending them to you, and trust you will lay them before the public. I remain sir, a well wisher to the profession.

LONDINENSIS.

SAINT PANCRAS, MIDDLESEX.

Day of 183

SIR,

You are requested to attend

of Agent
To MR. DELISSER, Surgeon, No. 1, Woburn Place, Russell Square.

N. B. All patients capable of going abroad, must attend on the surgeon in person, between 9 and 11 in the morning, and take with them cups and bottles for their medicines; and those incapable of attending must send for the same at the time before mentioned*.

OBSERVATIONS ON VERSION.

To the Editor of the London Medical and Surgical Journal.

SIR—It is a rule laid down by the majority of writers on midwifery, in breech or foot presentations, that as soon as the former part has passed the os externum, we should gently turn the back of the child towards the abdomen of the mother. This is the general

* Here is another example of gross parish jobbing. A surgeon, non-resident in the parish, is elected in preference to many residents, and especially to a gentleman who performed the duties of parish surgeon during the illness of the late surgeon, with satisfaction to the vestry, and the greatest credit to himself. The vestry of St. Pancras ought to be ashamed of themselves. If any tradesman amongst them, for example, Mr. Murphy, who we believe is a coal merchant, or any butcher, grocer, &c. was excluded by his brother vestrymen from supplying his wares to the workhouse, and an individual from a neighbouring parish preferred, such excluded person would be most vociferous about the manner he had been treated, but he cannot see why a surgeon should feel like himself. Such is the vestry wisdom of St. Pancras.—ED.

direction, or if I misinterpret, it is because it is laid down so vaguely that it is very likely to lead to error in practice.

The rule appears to me incorrect, for at the moment the breech is expelled, I presume the head is situated above the brim of the pelvis, and if we then turn the child as directed, we shall place the chin upon the promontary of the sacrum, the occiput upon the pubis, or the reverse. The shoulders too will be put in an unfavourable position for expulsion, being placed transversely to each of the tubera ischii. In cases where the head has passed the outlet, and some little delay has occurred in the passing of the shoulders, I have more than once attempted to place them in the most favourable position, by turning the head, when I have found nature essaying the turn in an opposite direction, and perseverance on my part would have thwarted her intention. From this fact, I infer that in presentations of the lower extremities, to place the back of the child (if practicable) towards the pubis, immediately the breech has passed the os externum, is to place the head and shoulders in the most unfavourable posture for passing the parts in which they are about respectively to be engaged; or if the attempt fail, to interrupt the efforts which nature is making to turn the body in an opposite direction, thus prolonging the labour, and rendering the chance of saving the child much less.

It appears to me that authors on the practice of midwifery only intended to inculcate the propriety of giving the body of the child, in its descent, a certain bias or inclination, as it were, to turn in a proper way at the time the shoulders pass the outlet; which may be right: but I am convinced that generally the rule has been laid down so vaguely, that were it followed to the letter, we should (nolens volens) immediately the breech is expelled, turn the back of the child towards the pubis, and the consequences would be, I believe, what are stated above.

The importance of the subject is the only excuse for sending this paper; and allow me to add, the hope of drawing some instructive remarks from you, or some one of your able correspondents. I am sir, yours &c.,

JOHN C. W. DYER.

Foreign Medicine.

Luxation of the Knee.

BARON LARREY addressed the following reflections on this accident to the Academie de Medecine at its sitting, April 14th. He first remarked upon the anatomical circumstances which render the knee joint so firm, and particularly insisted on the crucial ligaments, which he compared to the cross hands that keep the equilibrium of the body of a vehicle upon the carriage. Luxation, nevertheless, does sometimes take place. The first kind is extremely rare, if indeed it

exists at all, because the articular surfaces of the bones forming the joint are so extensive that it is almost impossible they should altogether lose their mutual connection, without the laceration of the principal ligaments; such a luxation would demand immediate amputation, so great would be the constitutional derangement consequent on it. The incomplete luxation is not so serious, and the extent of mischief will be proportionate to that of the displacement of the bone and the idiosyncrasy of the patient; the crucial ligaments are however necessarily ruptured. In other respects, such luxations are easily recognized and reduced: but every effort must be made to reduce the inflammatory symptoms as quickly as possible.

For this purpose, the leg must be speedily reduced and placed in a strictly straight posture: cupping immediately practised around the knee, which is afterwards to be enveloped in thin compresses steeped in a tonic glutinous fluid, such as white of egg beaten up with wine or camphorated vinegar, and the whole supported by a bandage somewhat tightly drawn. The immovable apparatus (such we presume as is used in fractures of the neck of the femur) is then applied and maintained until an ankylosis of the knee takes place. This is absolutely necessary to the perfect cure of the patient; for without it he would be liable to lose his balance on the slightest deviation from the straight line—the crucial ligaments meantime never uniting. Leeches and emollient remedies applied after the reduction are apt to favour the swelling, and accelerate the inflammation and suppuration of the circumjacent white tissues, whereas compression assists resolution and precludes such consequences.

Several incomplete luxations, treated at the Hôpital du Gros-Caillou, and at the Hôtel des Invalides, prove the necessity of establishing this ankylosis in all cases. One individual, Charles Hubert, aged 62, who had an incomplete and scarcely visible dislocation, being unwilling to submit to the application of immovable apparatus during the whole period required for ankylosis, is now unable to walk without crutches. Had this apparatus been applied in Benjamin Constant's case, the chronic inflammation which fixed in his knee, and contributed not a little to his death, might have been avoided.

M. Larrey does not believe in the dislocation behind, although this is the most easily effected. Complete luxation is impossible, without transverse fracture of the knee-pan, rupture of the tendon of the knee-pan and the tendons of the flexor muscles of the leg, or fracture of the bony projections to which they are affixed. The deformity in incomplete dislocation is frightful; flexion of the leg on the thigh is impossible, unless the tendon of the patella has been broken.

The dislocation of the tibia, anterior to the femoral condyles, is much more difficult,

and even impossible, on account of the disposition of the parts entering into the formation of the joints to each other. Lateral incomplete luxations are most frequent; but M. Larrey is not aware of any well grounded instances of complete luxation in that direction—and the reasons for which are obvious.

—o—

Case of Hydrocephalus, in which the Fluid was withdrawn by Operation. By S. S. Allison, M. D.

ON the 23d June 1834, I was requested to visit Robert Cunningham, aged 5 months, son of a fisherman residing in Prestonpans. He had from the period of his birth inclined his head to a side, but appeared in perfect health in other respects, till about three months ago, when it was observed that his head was swollen, and more especially at certain spots; that he was affected with restlessness, frequent fits of crying, rolling of the eyes, cough, and emaciation.

The head, properly so called, is of enormous size, and sinks the small and emaciated face into striking insignificance. Its circumference is $20\frac{1}{2}$ inches, and a line drawn from ear to ear measures $12\frac{1}{2}$ inches. The parietal bones are far asunder, and between them on pressing, a sensation is felt as of water under the scalp, and the right side of the forehead is more prominent than the left.

The eyes appear to project more than usual; part of the sclerotic tunic of the upper surface of the balls is constantly visible, and the pupils are quite sensible to light. He takes little food, is almost constantly awake, and, from the increasing emaciation, and from the present rapid progress of the disease, it is obvious that death must soon be the result unless speedily checked.

To prevent all misapprehension, it may be mentioned, that fits, vomiting, and other symptoms that often attend *hydrocephalus*, have at no period been observed.

Calomel and compound powder of jalap have been ordered in small doses; and the propriety of withdrawing the fluid by an operation has been suggested to the parents, as the only measure in the present state of medicine that affords any chance of recovery.

24th. Bowels are open, and he appears altogether more at ease than for some time previous. Medicine to be continued.

26th. This day about 1 P.M. in presence of my partner, Mr. Cunningham, surgeon in Ormiston, and the friends of the child, the head was again measured, and found to correspond with the dimensions formerly given. The point of a small cylindrical trocar was then rested on the right side of the anterior fontanelle, and gently introduced into the cavity of the head, in a direction obliquely forward and outward. When the trocar had penetrated about half an inch, water appeared at the canula, and the stilette was withdrawn, to give egress to the fluid, which immediately ran off in a stream with considerable force and

rapidity. As the fluid escaped, the bones sunk under the hands, and the scalp, before tense, became loose and folded upon itself. The fluid was still flowing, though with less rapidity, when it was deemed prudent to close the wound, lest any bad effects should follow the sudden diminution of pressure on the brain. Adhesive plaster was applied over the wound, and the bones and scalp were retained firmly in their situation by a bandage and cap.

During the operation he did not cry much more than usual. He was laid in his cradle; quiet was enjoined; cow's milk diluted with water was ordered to constitute his diet; and wine and other spirituous liquors were prohibited.

10 P. M. He is reported to have been restless, and to have vomited a little, but he is free from fever, and has not been affected with fits and startings. Upon wine being again prohibited, occasion was taken to inquire if any had been given, when it was acknowledged by the mother that a small quantity had been administered "out of a cup" because, she added, he appeared faint.

27th. Since last report he has not been more restless than before the operation, and has not vomited, although a disposition to it has been observed. The eyes move freely, are certainly less prominent than before, and less of the sclerotic tunic is observable. The pulse is natural; the pupils sensible; the bowels are open, and the secretion of urine natural.

Upon measuring the fluid taken from the head, it amounted to nine ounces, two drachms, fluid measure, and, adding to that, for what was lost during the operation, and what issued from the wound shortly afterwards, two ounces, which appears a moderate allowance, the whole fluid evacuated may be estimated at eleven ounces. The fluid is transparent and almost colourless, having only a slight green tint, scarcely observable.

28th, noon. He has been very quiet since last report, and has slept three hours during the night, a longer period of uninterrupted sleep than he has enjoyed since the commencement of the complaint. The eyes are bright, active, and sensible to light, pulse 120; skin cool and tongue moist; he has had three natural evacuations from the bowels; has taken greedily some milk and water; and coughs little. The bandages and pillows are wet with fluid which has issued from the wound, the amount of which it is difficult to specify; but five ounces must be a moderate computation. The head is much smaller than before the operation, and is very uneven on the surface, with the folding of the scalp. Its dimensions were taken, but are lost.

29th, noon. At an early hour this morning he became very restless, vomited, cried much, and was affected with rigidity of one of the arms. The pulse is strong, and about 140; the tongue white and dry, and frequent-

ly protruded beyond the lips; bowels continue open; swallows milk and water greedily, and sucks the nipple occasionally. No more water has issued from the head, and its dimensions are as follow:—Circumference of head, 18 inches; from ear to ear over the crown of the head, $11\frac{1}{4}$ inches. The eyes move incessantly in the orbit, and the pupils are very sensible. A leech to be applied to the temple, and a blister to the *occiput*.

8 P. M. He continued very restless, tossed his arms and legs, and the tongue was protruded at short intervals till about 6 o'clock, when he became quiet. The eyes are less active, and the pupils contract upon exposure to the light; the pulse considerably quicker than at noon, and the bowels continue open.

30th. Soon after last report he again became restless; while the limbs were convulsed, and the tongue protruded. These symptoms continued to recur at short intervals till 4. A. M., when death took place.

July 1st. This day, in presence of my partner Mr. Cunningham, the head was examined. It appeared about the same size as when last measured, and the same feeling of fluctuation, that was experienced previous to the operation, was again felt. Previous to exposing the brain to view, an opening was made through the anterior *fontanelle* with the point of a scalpel, through which there immediately issued about ten ounces of fluid slightly tinged with blood. No trace of inflammatory action could be detected on the scalp in the vicinity of the wound, nor at the corresponding parts of the brain and its membranes. In the lateral ventricle of the right side was found a small quantity,—about half an ounce—of a white opaque fluid, and in the left fully more, and of a colour inclining to yellow, and altogether much resembling a mixture of purulent fluid and water, with albuminous flakes. The walls of the lateral ventricles were rather unusually soft, but, on the whole, did not present marks of great disorganization. The base of the brain presented no appreciable signs of disease, and the nerves proceeding therefrom appeared perfectly sound.

Feeling satisfied that my treatment of this case was justified by its circumstances, and that it was proper to make an attempt for the life of the patient, I publish the details, to give a practical demonstration of my belief in the opinion, that it is not from the knowledge of successful events only, but also of the unsuccessful, that a right estimate is to be obtained of the value of our measures.

The operation was undertaken under the impression that the fluid was exterior to the brain; that the lateral ventricles were free from water; and that their walls, and indeed, the whole cerebral mass, were very little, if at all, disorganized; an opinion substantiated by the state of the parts on examination after death. It is in such a case,

and in such only, that the evacuation of the fluid seems calculated to afford any chance of cure, and in which, therefore, it would be prudent to practise it. When there is merely a collection of fluid on the exterior of the brain, it appears as likely that recovery would follow its removal, as the evacuation of the water in the forms of hydrothorax, unconnected with organic disease, were it not for the greater delicacy and importance of the structures affected by the operation.

Anasarca is sometimes the effect of a derangement of the functions of the vascular system, totally unconnected with any organic lesion; and it will perhaps be allowed, that at least some cases of external *hydrocephalus* also owe their origin to functional derangement of the vascular system of the membranes covering the brain. Since such forms of anasarca are often cured, there is good reason to believe that the said forms of *hydrocephalus* might be as often cured, were it not for the danger of the operation necessary for the evacuation of the fluid in the meantime. The correction of the fault of the vascular system to which anasarca owes its origin, prevents the further effusion of fluid in the cellular tissue; and may not the same correction prevent a further effusion from the membranous coverings of the brain?

The principal danger to be apprehended from the operation is inflammation of the brain and its coverings. Yet I am not aware that it has existed in the majority of those cases in which death has followed this measure; and it is known, that at least two patients have ultimately survived its performance, one of which was treated by Dr. Conquest of London, and the other by Mr. Russel of Aberdeen.

That such inflammation was the cause of death in this case, I admit, from consideration of the symptoms shortly before dissolution, and from the appearance of fluid with albuminous flakes in the lateral ventricles, along with a slight softening of their walls, observed at the examination. But to conclude, from its supervention in any particular case, that the operation should never be performed, is not less unwarrantable than to infer, that, because *phlebitis*, *peritonitis*, and *phrenitis* sometimes follow the operations of bleeding, lithotomy, and trepanning the *cranium*, these operations should be discontinued.

Hospital Reports.

NORTH LONDON HOSPITAL.

Lithotomy.

HENRY SHORE, aged 27, was admitted, April 30, under the care of Mr. Liston. He has been suffering from stone in the bladder for the last five or six years. During August last, the symptoms having become

much aggravated, he was induced to apply for relief to one of the London Hospitals, where lithotripsy was performed without success. The operation was attended with great suffering, without producing any sort of benefit. Since that period the symptoms have been unabated in severity; and he was willing to submit to any operation to remove them.

On the 2nd of May Mr. Liston proceeded to operate. The curved staff having been introduced, and the presence of the stone detected, the patient was secured in the usual manner. The bladder was reached, and the prostate divided, as far as necessary, by the second incision; the forceps was then introduced, and the stone removed with ease, having been first turned by the fore-finger of the left hand to the position most favourable for its extraction. A gum elastic tube was then introduced through the wound into the bladder, and retained by strips of oiled silk, tied to a bandage applied round the loins. The patient did not evince the slightest feeling of pain, except during the introduction of the staff. There was scarcely any blood lost in the operation; but a few ounces afterwards: the urine came through the tube quite clear, about three hours after the operation. The tube was removed the next morning. The patient is doing well, says, "he is happy, being free from pain." There seems to be no constitutional disturbance. He says he did not suffer any pain in comparison with what he endured when lithotripsy was performed. The stone was two inches and a half long, and one and a half broad, of the uric acid species, and exceedingly hard; it bore marks of the lithotrite, and on the depressions made by that instrument, was a deposit of the phosphate of lime. The stone was removed in forty-five seconds, from the first touch of the knife. The theatre was crowded with pupils and practitioners.

Mr. Liston was assisted by Mr. Quain, Mr. Duncan, and Mr. Rowland.

Seasons for Conception.

It is a common belief that the spring is the period in which conception most readily takes place. This idea, grounded doubtlessly, as regards man, on some roughly-sketched analogy between him and the lower animals, receives confirmation, however, from careful statistical investigations. Villermé, Quételet, and others, have by these means found that in the order of comparative frequency of conceptions, the months of the year stand thus: May, June, April, July, February, March, December, January, August, November, September, October. Hence the quarter including April, May, and June is most rife in conceptions. In these months also, according to the registers of crime, the greatest number of rapes and attempts at violation are made.

NEW REGULATIONS OF THE APOTHECARIES' COMPANY.

THE following new regulations have been just issued by the Apothecaries, a copy of which reached us too late for insertion in our last:—

Every candidate for a certificate to practise as an apothecary, will be required to produce testimonials—

* Of having served an apprenticeship of not less than five years to an apothecary;

† Of having attained the full age of twenty-one years;

‡ And of good moral conduct.

Students whose attendance on lectures shall commence on or after the 1st of October, 1835, will also be required to produce proof of having attended, during three Winter and two Summer sessions, lectures in the following order, and medical practice from the commencement of the second, to the termination of the third Winter Session.

The Winter medical session is to be understood as commencing on the 1st of October, and terminating in the middle of April, with a recess of fourteen days at Christmas: the Summer session as commencing on the 1st of May, and ending on the 31st of July.

First Winter Session.

Chemistry.

Anatomy and physiology.

Anatomical demonstrations.

Materia medica and therapeutics.

First Summer Session.

Botany; and such other branches of study as may improve the student's general education.

Second Winter Session.

Anatomy and physiology.

Anatomical demonstrations.

Dissections.

Principles and practice of medicine.

Medical practice of an hospital.

* No gentleman practising as an apothecary in England or Wales can give his apprentice a legal title to examination, unless he is himself legally qualified to practise as an apothecary, either by having been in practice prior to or on the 1st of August, 1815, or by having received a certificate of his qualification from the Court of Examiners. An apprenticeship for not less than five years to surgeons practising as apothecaries in Scotland and Ireland, gives to the apprentice a title to be admitted to examination.

† As evidence of age, a copy of the baptismal register will be required in every case where it can possibly be procured.

‡ A testimonial of moral character from the gentleman to whom the candidate has been an apprentice, will always be more satisfactory than from any other person.

Second Summer Session.

Botany, if not attended during the first Summer session.

Midwifery and diseases of women and children.

Forensic medicine.

Medical practice of an hospital.

Third Winter Session.

Dissections.

Principles and practice of medicine.

Midwifery, with attendance on cases.

Medical practice of an hospital or dispensary.

The student is required to attend the medical practice of a recognised hospital, from the commencement of the second Winter to the termination of the second Summer session, and from that time to the end of the third Winter session, at an hospital, or recognised dispensary.

The sessional course of instruction in each respective subject of study, is to consist of not less than the following number of lectures, viz.:—

One hundred on chemistry.

One hundred on materia medica and therapeutics.

One hundred on the principles and practice of medicine.

Sixty on midwifery, and the diseases of women and children.

Fifty on forensic medicine.

Fifty on botany.

The number of lectures on anatomy and physiology, and of anatomical demonstrations, must be in conformity with the regulations of the Royal College of Surgeons of London, on these subjects.

The lectures required in each course respectively, must be given on separate days.

Students, when they present themselves for examination, must bring testimonials of having received instruction in practical chemistry during their attendance upon the lectures on chemistry, materia medica, or forensic medicine; and also of having attended a full course of clinical lectures, and such instruction in morbid anatomy as may be afforded them during their attendance at an hospital.

Every student will be required to produce proof of having dissected the whole of the body once at least.

That the lecturer on the principles and practice of medicine must be, if he lectures in London, or within seven miles thereof, a Fellow, candidate, or licentiate of the Royal College of Physicians of London; and if he lectures beyond seven miles from London, and should not be thus qualified, he must be a graduated Doctor of Medicine of a British university of four years' standing (unless previously to his graduation he had been for four years a licentiate of this court).

That the lecturer on *materia medica* and therapeutics must be a fellow, candidate, or licentiate of the Royal College of Physicians of London; a graduated doctor of medicine of a British university of four years' standing (unless previously to his graduation he had been for the same length of time a licentiate of this court), or he must be a licentiate of this court of four years' standing.

That the lecturer on anatomy and physiology must either be recognised by the Royal College of Surgeons of London, or must be a member of that college of four years' standing.

That the demonstrator of anatomy must either be recognised by the Royal College of Surgeons of London, or must be a member of that college.

The only other important changes in this batch of regulations are, that every hospital must contain 100 beds; be situated in a city or town in which there is a school of medicine, and be attended, if in London, by two physicians of the London College; and if in the country by such, or graduated doctors of medicine of a British university; and also by a legally qualified Apothecary. The same rule applies to dispensaries. Lastly, the examination in Latin may be obtained at the commencement of the first winter session by those who commence next October; or by those already registered, by giving notice to the beadle.

The examination on the practice of medicine embraces diseases of pregnancy, the puerperal state, and also those of children.—Surgery and obstetrics are excluded.

Students who commenced during former sessions, must comply with the regulations existing at the time. Students may attend lectures during their apprenticeships, and may apply for examination at the age of twenty-one years.

The winter session to commence on the 1st of October, and terminate in the middle of April, with a recess of fourteen days at Christmas. The summer to commence May the 1st, and terminate July 31st.

DEATH OF DR. HOOPER.

THIS celebrated physician expired at his lodgings in Bentinck-street, Manchester-square, on Wednesday last, the 6th inst., after a short illness, which he bore with Christian patience. He took up his residence in town for the purpose of being near his medical attendants. He was ill about three weeks, and his disease was urinary abscess. Few physicians acquired such eminence as Dr. Hooper. His various works were most favourably received and translated into the foreign languages. His *Anatomists'*, *Physicians'*, and *Surgeons' Vademecum*, and *Medical Dictionary*, passed through several editions, and had perhaps the greatest circulation of any of our medical works.

We were informed, while editing the last

and present edition of his *Physicians' Vademecum* of 1833, that 20,000 copies of the work had been sold. His works have conferred essential benefits on science and humanity.

Dr. Hooper had retired for some years past from practice, and resided at Stanmore Cottage. Few were more respected for amenity of manners and sincerity of friendship; and few will be more sincerely regretted by a large circle of private friends and professional acquaintances. His age was fifty-six years.

The editor of this journal has to deplore the loss of a very valuable friend in Dr. Hooper, a loss the more deeply to be felt, as he was honoured with that eminent physician's valuable acquaintance without the slightest solicitation. Dr. Ryan had been requested by the proprietors to revise the last edition of Dr. Hooper's *Physicians' Vademecum*, a duty he discharged to the best of his ability; and it was most gratifying to his feelings to receive the kind acknowledgment from Dr. Hooper of his approbation and friendship. The last act of his professional life was to recommend Dr. Ryan to be intrusted with the re-editing of his *Medical Dictionary*, another unsolicited favour; the last, alas! he can ever receive from so great an ornament of his profession.

LITERARY INTELLIGENCE.

IN a few days will be published, *A New Practical Formulary, or Conspectus of Prescriptions of the Civil and Military Hospitals of France, England, Germany, Italy, America, &c. &c.*, including the *Formularies* of MM. Magendie, Lugol, Dupuytren, Alibert, &c., and of the most eminent Physicians and Surgeons, in Medicine, Surgery, and Obstetrics; with an Account of the Doses of all new and ordinary Medicines, Rules for Prescribing, &c. Translated from the Second French Edition of MM. Milne Edwards, and Vavasseur, and considerably augmented by M. Ryan, M. D., &c.

CORRESPONDENTS.

J. F. C.—The article will appear in our next.

The paper on Purgatives is too late for this number.

One of the Class—We cannot answer the question, though we are almost certain we might in the affirmative.

A Constant Reader—The trickery is unworthy of the member of the College or Hall, though it is unfortunately too common. Were we to insert these handbills, &c., we should be expected to place many others before our readers.

Londinensis—The candour and readiness to comply with our request, convince us of the authenticity of this statement, and we therefore insert it.

THE

London Medical and Surgical Journal.

No. 172.

SATURDAY, MAY 16, 1835.

VOL. VII.

A LECTURE

Delivered in Chelsea Garden, on Monday, 27th April, 1835;

BEING

INTRODUCTORY TO THE COURSE OF BOTANICAL DEMONSTRATIONS.

BY GILBERT T. BURNETT,

PROFESSOR OF BOTANY, IN KING'S COLLEGE, LONDON; TO THE MEDICO-BOTANICAL
SOCIETY; AND TO THE SOCIETY OF APOTHECARIES.

(Concluded.)

THE physical conditions under which plants exist and are found in relation to other organic beings, or in the world at large, such as their geographical and local distribution, the geological position of the remains of the ancient flora of the globe, and various other collateral inquiries, form that branch of the science called vegetable statistics.

These are all novel fields of investigation, and our knowledge of them, at present, in a somewhat rudimentary state: yet enough is already known to convince us of their commanding interest and importance. The habits of mankind, their modes of life, and even their civil condition, is often greatly influenced by the vegetation of the countries they inhabit; and if the energies of the mind may be increased or diminished by the strength and the healthiness of the body, the effects of food must be far from trifling; indeed, it is well known that its influence is great. Thus, certain lines may be drawn through various parts of the globe, separating regions in which either pasturage and corn, or the vine and olive, or other vegetables chiefly flourish—and these lines will be found to separate the beer-drinking from the wine-drinking nations; and the countries in which the people consume, on the one hand, vegetable oil, as in Italy, Sicily, and Greece, from those, on the other, in which animal oil or butter supplies its place. Similar demarcations may be drawn between the fish-eating, the meat-eating, and the rice-eating nations; and the civil condition and mental capacities of the Esquimaux, the inhabitants of temperate and southern Europe, and the effeminate nations of the East, need merely to be mentioned to shew their contrast.

The topographical distribution of plants is no less interesting than the study of their geographical range. Thus, in the first place, they often indicate the healthiness or insalubrity of the districts in which they are found; even the nature of the soil may be judged of by the indigenous vegetation, and the conditions of the atmosphere; and the variations of climate may often be calculated more correctly by the plants found growing without protection, than by any other mode of observation. The preference exhibited by certain plants for certain soils is a most wise provision of nature. Thus, species with long tap roots, such as thistles, docks, &c., prefer clayey soils, which they penetrate, underdrain, and render fertile. Plants with long, creeping and fibrous roots, such as the mat-grasses, will grow only in sand; and by the interlacing of their fibres it is that the undulating sand-hills become bound as it were in a living net, and mould prevented from being wholly washed from the sides of mountains, and the banks thrown up from the sea hindered from deluging the plains. A sand-flood is indeed a fearful visitation—Egypt is a terrible example of its destructive power—and even in our own country there are many lamentable instances of the ruin it occasions; the shores of Suffolk, near Downham, where the sand-flood has travelled inland upwards of five miles within a century, and those of the eastern side of Scotland, may be cited as examples; and the devastation would have been much greater on every point, had not its ruthless course been restrained by the mat-grasses and other adjuvant vegetables. To select one instance from many, of the protective power of these plants, we may refer to the town of Hull. All persons acquainted with its situation, and

cognizant of the force of the tides in the German Ocean, are agreed, that were it not for Spurn-point, which protects the town from the full and direct influence of the devastating waves, that the very site on which Hull stands would long since have been washed away, and the land in its vicinity have been a shoal beneath the sea. Now, Spurn-point is a sand-bank, at first fixed, and still retained, by the interweaving roots of mat-grass, of which I have had specimens brought to me of 20 and 30 feet long, and many have been at various times dug out of much greater length.

The discovery of the symbols or semblances of plants in the various strata of the globe, such as in lime-stone, sand, chalk, and especially in coal, where they are most abundant, has opened another new field of investigation to the botanist, and forms that branch of our science called fossil, or rather geological botany. On the first discovery of these fossils, much difference of opinion prevailed as to their nature and origin, some persons believing them to be petrified vegetables, or plants turned into stone; while others considered that they never had been plants at all, and that their vegetable similitude, although great, was illusive. Chateaubriand, perhaps led away by the vain speculations of some of his countrymen, even went so far as to suggest that they were evidences of the abortive attempts of nature to produce plants, and that, before true and perfect vegetables were formed, many models were spoiled and cast away, or rather that many attempts failed before the desired object was achieved. This opinion is manifestly absurd; and the former one, although not quite correct, is a much nearer approximation to the truth; for modern investigators have proved these fossils to be, without doubt, either the remains of vegetables which once existed on this earth, or the impressions of plants, the substance of which has decayed and been removed, and the vacuity filled by subsequent depositions of earthy or stony matter.

I cannot venture now to do more than hint at the riches of this mine of investigation, which, though but lately opened, has been diligently worked; and the facts thus unearthed, although often mysterious, and frequently, no doubt, misunderstood, yet have already revealed many circumstances respecting the ancient history of the world, and indicate discoveries to be made, far more extensive and important. By these means there have been already ascertained the general characters of the several floras existing at different and distant epochs; also the probable condition of the atmosphere in various eras; the changes which have occurred in the climate of several parts of the globe, as well as the mutations to which the countries themselves have been subject—many large tracts of land having undoubtedly been the beds of former seas, and the summits of the everlasting hills shewn to have been once in the bosom of the deep.

Although other branches of our science are more pleasing, there is none that to me appears to possess so grand, so sublime a character as this. It opens a road by which the mind may safely travel through the ages of past time; it places within our reach the memorials of epochs long since forgotten, and these fossils, thus carefully preserved and laid up by nature, as, to use a weak similitude, the builders of our palaces and temples place coins in the foundation stones, become irrefragable evidence of transactions unrecorded, and which would otherwise have for ever been unknown; and furthermore, while thus assisting to complete the natural history of the world, it is constantly affording collateral proofs of the correctness of the sacred history of creation.

If, as I have stated, the only sure and efficient distinctive characters of plants can be derived from a knowledge of their structure, how vague must have been those schemes of arrangement which were attempted before any such knowledge was obtained; and against what stupendous difficulties and disadvantages did those systematic writers labour, who engaged in this work before organography, or indeed any branch of vegetable physics, was cultivated as a science. It is strange that they achieved what they did—not surprising that they did no more; their numerous approximations to the truth are more strange than the errors into which they were betrayed. At the present day we stand on vantage ground; but we should recollect that modern discoveries are often the discoveries as much of the age as of the individual; for, had not the materials been furnished by our predecessors, we should have been unable both to have wrought in the quarry and to have raised the structure.

We must here cut short our illustrations of the physical conditions of the vegetable kingdom, the study of which will furnish the *principles of botany*, and constitute that branch of our science called Vegetable Physics.

The third great department of botany includes a consideration of the language and other means by which plants may be represented or described; the systems or methods by which they may, for various purposes, be most conveniently arranged—whether for the intent of shewing their natural affinities, to distinguish them from each other, and find them with readiness, or for the uses to which they are applicable; and, thirdly, of the historical details—whether natural, experimental, or traditional, of our science. This department, once considered as the chief portion, and, by many, the whole of botany, although it is in truth but one of three great branches, is that to which the older botanists almost entirely turned their attention; indeed, so exclusively, for a long period, were system and language studied, that the other topics I have alluded to, such as the uses of plants, their structure,

functions, chemical constitution, geographical and geological distribution, &c., &c., were either altogether neglected, or only considered as collateral sciences; and it has not been without difficulty that we have been enabled to reclaim them from the grasp of the comparative anatomist and physiologist, the geographer, the geologist, and the chemist.

This, once the most prominent branch, and that chiefly studied, has, since the admission of the others, been perhaps rather too much neglected: it certainly possesses less commanding interest than the study of the uses of plants, and a less absorbing one than researches into their physical conditions. Still, notwithstanding the outcries of the ignorant against the hard words of botany, and the lamentations of the idle, at the changes which the onward progress of science render necessary in our systematic arrangements, this department will be found not to let those go away unrewarded or discontented, who enter on its study with the true spirit of philosophic devotion.

With regard to the various systems of botanical arrangement, there are two kinds or classes which deserve our especial attention; first, those methods which endeavour to associate plants according to the most obvious natural affinities; and secondly, those which merely furnish an index by which plants may be discovered and distinguished from each other, and for this purpose are designedly artificial in their construction. Those plans which distribute plants according to their properties and uses we shall pass over in silence—they are of much use in pharmacology, dietetics, agriculture, &c., but are serviceable only for special purposes. Of the artificial systems, the Linnæan is, by one consent—or at least with scarcely a dissentient voice—pronounced to be the best; but then it is useful only as an index, and those persons who would confine their studies to this system only, will find themselves grievously crippled in their progress.

As to the various modifications of the natural system which have been proposed, there is no such common agreement—almost every botanist of note having devised a scheme of his own; yet, although these differ in some points, they all more or less agree in many most important, nay, in most of the more important particulars. In the first place, there is little difference as to the acknowledgment of species and genera, and no very important schisms as to the groups of genera called ultimate orders, tribes, families, or types; and these in truth are the only groups in which it is essential that there should be any general accordance. The collection of these families or types into larger and larger groups, is expedient for facilitating an acquisition of their characters, but is not essential for the study of the groups themselves, which some authorities, indeed, prefer to consider as isolated and independent orders, or bind them together by a very loose and slender cord.

The agreement in the primary subdivisions of the vegetable kingdom is, however, known to be as general as in the ultimate ones, and this forms a strong argument in favour of its truth. I need scarcely add, that I refer to the distribution of plants into flowerless or acotyledonous, flowering and monocotyledonous, and flowering and dicotyledonous—which terms, adopted by Jussieu, are equivalent, or nearly so, to the cellular, endogenous, or inside growers, and the exogenous, or outside growers, of De Candolle. This three-fold distribution of the vegetable kingdom having been adopted by Jussieu, in his justly celebrated system, he has often been carelessly referred to as its author; but, although he did much to propagate the doctrine, it claims a much earlier date. Thus, Linnæus gives a table of his primary and secondary subdivisions of the vegetable kingdom, in which the same triadic form prevails, and even the same terms are used. It was, however, with Ray, among the moderns, that this triple distribution originated, and whose tabular conspectus differs only in a few trifling points from those of Linnæus and Jussieu. He primarily distinguishes plants into flowerless and flowering; which groups are equivalent to the acotyledonous and cotyledonous sections of Linnæus and Jussieu, and the cellular and vascular ones of De Candolle, and other modern writers. And he then immediately subdivides the flowering tribes into mono- and di-cotyledons, thus not only anticipating both Linnæus and Jussieu in the scheme of distribution, but also in the very names, which probably they both adopted from him, and never dreamt of claiming for them any originality. Previous to the time of Ray, various attempts had been made to associate plants in natural groups, as may be seen on referring to the Herbals of Parkinson, Dodoens, and others, especially to the works of Lobel and Pena; and many of the natural orders of these old writers were introduced into their systems by Ray, Linnæus, and Jussieu, and maintain their position even to the present day.

But this three-fold distribution may claim a much earlier origin, a much higher antiquity, for it is the distribution which appears to have prevailed in the earliest ages of the world, as traces of it may be found in the very beginning of the oldest records we possess, viz. in the book of Genesis. And, as I have elsewhere observed, it is a most remarkable fact, that in a work written in so early an age, almost before the birth of botany as a science, a work, be it remembered, not on natural history, nor written by a naturalist, but in which, if any references to plants occur, the mention is incidental, yet, that in such a work, and written at such a time, the classification of plants now generally adopted, and only of late universally received, should have been not obscurely hinted, but clearly and explicitly described.

It is curious that a system, which it has taken centuries to mature, and which successive

botanists have laboured age after age to advance to perfection, should be identical with that adopted by Moses, and from which for so many thousand years naturalists had wandered more and more, and to which their return was wholly unpremeditated, as the identity was not recognized until after the return was made.

The vegetable kingdom, it is well known, is now divided by common consent into three great regions; their names and synonymes, *A-*, *Mono-*, and *Di-cotyledons*, or *Exogenæ*, *Endogenæ*, and *Cellulares*, &c. &c., as well as their distinctive characters, are so familiar to most persons, that, even to repeat them sounds truistical. These primary divisions were called by Linnæus, from their port and habit, *Plantæ*, *Fruges*, and *Cryptogama*, as well as di-, mono-, and a-cotyledons, and have by others been termed, with more especial reference to their fruit or reproductive organs, *SEED-bearing*, *GRAIN-bearing*, and *SPORE-bearing* or seedless plants, which are merely English versions of Agardh's *SEMINIFERÆ*, *GRANIFERÆ*, &c. The lower series, including all the cryptogamic vegetables, even the ferns, have been considered seedless, because they are reproduced either by portions separated from their general mass, or by small grumous masses called spores, which have more resemblance to buds than seeds, which germinate from no fixed points, and which are destitute of an embryo, the essential organ of a grain or seed. Hence these, which include all the flowerless tribes, are called *Exembryonæ*, i. e. seedless plants, by Richard.

The second series, including the grasses, sedges, rushes, lilies, palms, &c. although furnished with flowers, and bearing seeds having perfect embryos, have this embryo but one-lobed, i. e. mono-cotyledonous, and such unilobate seeds are most frequently, as in all the grasses, rushes, and many other plants, invested only with a tight obscure pericarp, so that they have been considered naked, and called *grains*, to distinguish them from other seeds which have a loose and fleshy, and often eatable pericarp, such as the apple, the orange, and the plum, which, for the sake of distinction, have been termed fruits. Now these *seedless* or *spore-bearing*, *grain* or simple *seed-bearing*, and these *seed-vesselled* or *fruit-bearing* plants, which have just been shewn to be equivalent to the acotyledons, monocotyledons, and dicotyledons of Linnæus, Jussieu, and all modern botanists, are at the same time most peculiarly coincident with the three primary divisions hinted at by Moses. In the Book of Genesis we read that it was in the third epoch or day that vegetables were created. In our vulgate the account runs thus: "God said, let the earth bring forth *grass* (*DESHE*), and the *herb* (*ÆSHEB*) yielding *seed*, and the *fruit-tree* (*ETZ*) yielding *fruit* after his kind, whose *seed* is in itself, upon the earth, and it was so." "And the earth brought forth *grass* (*DESHE*), and the *herb* (*ÆSHEB*) yielding *seed* after his kind; and the *tree* (*ETZ*) yielding *fruit*, whose *seed* was in itself, after his kind." The words *etz* or *otz*, and *æseb* or *æsheb*, have been very well rendered by "*herb yielding seed*," and "*tree yielding fruit whose seed is in itself*;" but the translation of *deshe* or *deshe* is far less happy; in the text it is rendered "*grass*," in the margin "*tender grass*," and this marginal note renders it probable that some difficulty occurred, or that some doubt was entertained of the strict propriety of the version. "In the terms *tree* and *herb* we find, as the anonymous writer already referred to observes, a recognition of a remarkable natural distinction among the vegetable tribes; and this very circumstance would lead us to infer that the first term (which has obviously presented a difficulty to our translators, since they have given two interpretations of it), is intended to express some class or tribe of the vegetable kingdom, as naturally distinguished from herbs and trees as they are from one another. The term in question (*deshe*) is a noun from a verb, of which, from Joel ii. 22, we learn the meaning is *to spring*, *to shoot*, *to vegetate*, "Be not afraid, ye beasts of the field, for the pastures of the wilderness *do spring*" (*dasheu*). In the 11th verse under consideration, we find both the verb and the noun, for the words translated. "*Let the earth bring forth*," are *tadeshe haaretz*, which, in accordance with the obvious sense in Joel, would be better rendered, "*Let the earth shoot out*." From this meaning of the verb, then, the noun would signify the *springing* or *shooting plant*, and, as used here, in contradistinction to both herbs and trees bearing seeds, it is surely not recommending any forced interpretation to suggest, that it is meant to express that class of vegetables which are by botanists recognised as being naturally distinguished by the obscurity of their means of reproduction," plants which are called seedless both by the learned and the simple, and which the earth does literally *shoot out*, whence indeed the idea of their equivocal or fortuitous generation sprang.

This version is corroborated by the fact that *deshe* is not the Hebrew word for *grass*. The term for *grass*, the common food for cattle, is *chatzir*, which the lexicographers have shewn to be derived from its tubular structure. Thus, in Job xl. 15, we read, "he eateth *grass* (*chatzir*) as an ox;" and, Psalm civ. 14, "he causeth *grass* to grow for the cattle." In several passages, besides this of Genesis, we find *deshe* contradistinguished from both *æseb* and *chatzir*, as in Deut. xxx. 2. "As the small rain upon the *tender herb* (*deshe*), and as the showers upon the *grass* (*æseb*); and, Psalm xxxvii. 2, "They shall soon be cut down as the *grass* (*chatzir*), and wither like the *green herb*" (*deshe*); and, 2 Kings xix. 26, "They were as the *green herb* (*deshe*), as the *grass* (*chatzir*) on the house-tops." These quotations shew the want of uniformity with which the English translators have rendered these terms, and go to support the sense we would assign to it. And, furthermore, they prove that the *deshe* or *tender herb* of the Hebrews was something very different from *grass*, their

chatzir, and naturally contradistinguished from their *aseb* and *etz*, which, comprising all seed-bearing and fruit-bearing plants, the only others which their *deshe* could signify are the seedless ones."

Much more, gentlemen, might be added in further illustration of the interesting discoveries with which even this, the least promising subdivision of our science, abounds; but time warns me to conclude, and I will not neglect the admonition. Yet, in reflecting for a moment on the topics we have so cursorily discussed, I cannot but be convinced that so few are the facts and so meagre the details which I have been enabled to include in this inaugural address, that I am almost fearful of the effects of so rude a sketch. From such scanty, almost isolated memoranda, how imperfect must be the ideas conveyed of the vastness, the perfection, and the importance of that science which they were designed to illustrate and explain. But, even short as they have been, their length will prevent me now collecting their several radii into a common focus, and giving you a general view of the distribution of this department of botany. That conspectus I must reserve for the following lecture, and will only, in conclusion, beg you not to condemn the science as unworthy your attention, merely because its advocate is weak.

Note.—I have just learned that the *œnanthe crocata*, which occasioned the fatal accident at Woolwich, mentioned in the early part of this lecture, was mistaken for celery, and recommended by one of the convicts to his yoke-fellows as an excellent vegetable. I am glad of the opportunity this note affords of correcting an error into which some of my friends have fallen, by supposing I intended to insinuate that the convicts are improperly restricted in their diet, and that many were forced by hunger to eat this poisonous plant. The lecture having been given extemporaneously, I cannot recal to mind the exact words made use of; but it was the simple, yet important fact of the mistake having been made, and its melancholy results, that I desired to quote as illustrations of my argument.—G. T. B.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN,
*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XXXV.

*Nævus Maternus—Congenitæ Notæ—Envies
Maller-Mahl—Mothers' Marks—Spilus
or Mole—Ecchymoses—Tumefaction of the
Scalp—Abscesses in different Parts—Tu-
mours—Contusions on different Parts—
Elongation of the Head of the New-born
Infant.*

GENTLEMEN—I have still to describe some other congenital diseases of the skin, to which I wish to direct your attention.

Nævus Maternus, Congenitæ Notæ, Envies Maller-mahl, Spilus, Mothers' Marks.—Marks on the skin form a transition between vices of conformation and inflammatory diseases of the integuments. The various congenital marks, moles, excrescences, and discolorations, have been indiscriminately classed together under the name of *nævi*. They may be divided, however, into two classes—congenital alterations of the pigment, and vascular hypertrophy, or productions on the skin. The first class is caused by disease in the rete mucosum, in which the vascular network deposits the materials of the pigment; while the second class depends on the vascular net-work itself. This distinction was established by the researches of Callisen, Breschet, Bateman, Abernethy, John Bell, Wardrop, Martinet, and Rayer.

The pigmentary *nævi* cannot appear on the surface of the skin of the embryo before the third month of its growth, as the pigment does not exist before this period, for it is about the half term of intra-uterine gestation that the skin receives the greatest abundance of blood, and acquires its organization. M. Billard observed twenty embryos under the above age, and not one presented a congenital mark; but he modestly states, that a greater number of observations are wanted to confirm or overthrow his opinion.

M. Breschet ascribes *nævi* to an alteration of the skin, or to an abnormal development of the sanguineous capillaries, arterial or venous vessels, or a dilatation, relaxation, varicose or aneurismal state of these vessels. (*Dict. de Med., Art. Nævus.*) He also considers that the mucous body and pigment are affected in certain cases.

The different tissues which compose the integuments are so intimately connected, that disease in one may readily involve another. Thus the bulbs and hair develop with the cutaneous vascular net-work; hence brown or reddish spots are covered with coloured hair on different parts of the body. It is also possible that the cutaneous vascular net-work (capillaries) and the capillary body of the skin, may undergo alterations independently of the pilary or capillary system; and hence we often see brownish or violaceous spots with or without hair.

In fine, a simple alteration of the colour of the pigment, without apparent tumefaction, may take place, and then we observe yellow, red, brown, violet, dark, and other coloured spots on the face, trunk, and limbs. These last alone merit, according to Billard, the name of pigmentary spots; as those

which are salliant or projecting and covered with hairs, indicate an alteration in some other of the tissues which constitute the skin.

The congenital affections of the pigment, which the ancients termed *spili* or moles, present an infinity of varieties of form, magnitude, colour, and structure, and are observed in different instances on almost every part of the surface of the body. They generally appear on the face, which is explained by the development and activity of the sanguineous capillary system of that part. Some are superficial, or stain-like spots, and appear to consist of a partial thickening of the rete mucosum, sometimes of a yellow, yellowish brown, rose, red, livid, blue, or black colour. They generally remain stationary after birth, do not shew any morbid tendency, and should not be interfered with, as the effects of excision or caustics often leave more disagreeable appearances than the original marks. These, like many other congenital anomalies, are at first true diseases, but gradually become the natural state of the parts on which they are situated. Operations are only necessary in the vascular species, which I shall now describe.

Vascular Nævi.—These present a reddish colour, and an elevation more or less considerable. They consist of enlarged and contorted or varicose veins, which J. L. Petit named sanguineous fungi, and small aneurisms. They differ, however, from aneurism by anastomosis, in this—that they can exist without the communication between an artery and a vein, and do not offer to the touch those pulsations and murmurs peculiar to these aneurisms. In either case these elevated marks of the skin, caused by aneurismal dilatation of the small subcutaneous vessels, may, after birth, enlarge, ulcerate, and give rise to a fatal hæmorrhage, so that we must, as the age and health of the infant permit, arrest their progress and completely remove them.

Vascular nævi are sometimes spread more or less extensively over the surface; they occasionally cover the whole of one extremity, or one-half of the trunk of the body, and they are elevated into prominences of various forms and sizes. They are generally of a purplish red colour, varying in intensity according as the collection of blood-vessels is near the surface. There are two species of them:—1. Vascular cutaneous nævi, or nævi flammei, which are characterised by one or several violet-coloured patches, which assume a darker colour under the influence of all causes that accelerate the motion of the blood, as violent exercise, remaining long in a warm apartment, the heat of the bed, the use of strong warm drinks, stimulating aliment, affections of the mind, and the erethism of menstruation. Some are ovoid, pediculated, and formed by a true erectile tissue. These are red and granulated, and have been compared to cherries, raspberries, currants,

grapes, &c.; others are flat upon a broad base; some are vivid at and after birth, but gradually fade and disappear; some remain stationary through life, while others grow and extend soon after birth, or from accidental causes, and acquire a considerable size, when they readily burst, and produce an impetuous and profuse hæmorrhage, which, if not destructive to life, is highly injurious to health*. Lastly, they sometimes enlarge to a great size, then remain stationary, or gradually diminish and disappear. At other times they present the characters of erectile tumours, and sometimes terminate in cancer.

These vascular enlargements sometimes exist in deep-seated parts. They may occupy the whole surface of the cheek, according to Abernethy, and any external part of the body, according to John Bell.

When accidentally inflamed or ulcerated, they cicatrize with difficulty.

The mode of formation of these connate deformities is equally inexplicable as other anomalous and monstrous productions of nature; "but it would," says M. Martinet, "be insulting to the understanding of the reader, to waste one word in refutation of the vulgar hypothesis, which ascribes them to the mental emotions of the mother—an hypothesis totally irreconcilable with the established principles of physiology, and with the demonstrable nature of the connexion between the foetus and the parent, as well as with all sober observation." (*Manual of Pathology*). The vulgar opinion here denounced is, however, still entertained by a few medical practitioners, and by a vast number of women; and this has led me to expose its absurdity in my work on Obstetrics; because the fears of a pregnant woman will indirectly injure herself as well as the infant in her womb; and as these are groundless, so far as marks and deformities are concerned, I hoped to do good by dissipating them.

It has been already stated, that whatever expedites the circulation of the blood, as corporeal or mental exertion, warmth, warm drinks, &c., increase the redness of nævi. It is for this reason that they are redder in spring and summer, not from sympathy with ripening fruits, but from the more copious afflux or determination of blood to the skin, in consequence of the increase of atmospheric temperature.

Subcutaneous vascular nævi, described by Petit, Latta, Lassus, and Mr. Wardrop (*Med. Chir. Trans.*, vol. ix. p. 109), are more frequently developed on the face than any other region. Their size is diminished by pressure, and increased by crying, &c.; and they have no distinct pulsation like aneurism by anastomosis. They sometimes enlarge to

* This discharge has become vicarious in women, and returned in place of the regular menstrual evacuation. (Boyer; J. Bell. *Op. Cit.*)

a great size, and at other times remain stationary. They may inflame, ulcerate, and burst, and then cause profuse hæmorrhage. On dissection they are found to consist of a number of small cells, through which are distributed a large number of arteries and veins. When small, Mr. Wardrop caused inflammation and ulceration with success; but others prefer excision. When large, Mr. Wardrop advises to tie the artery which supplies the tumour, and then use the knife or caustic. The carotid artery has been tied for nævus of the cheek, and when the disease exists on a finger, or any part of a limb, some have resorted to amputation.

When the cutaneous vascular nævi are superficial without elevation, which would render them liable to accidental rupture, and without any tendency to enlarge or spread, there is no valid reason for attempting to remove them. If they enlarge, on the contrary, then remedial means are necessary; Mr. Abernethy considered there was a degree of inflammatory action in the vessels surrounding these tumours, and he therefore thought that a constant sedative application on these vessels, by means of cold, would be beneficial. He used refrigerants and compression. He applied folded linen, and ordered it to be kept constantly wet. This plan, though simple, succeeded in several instances in repressing these growths, and caused them to shrink and disappear. (*Surgical Works*, vol. 2). Professor Boyer ordered compression with the finger on a nævus of the upper lip for several hours every day, which caused it to disappear; and washed the tumour with a weak solution of alum. (*Traité de Malad. Chirurg.*) But Bateman judiciously remarked, that this compression was sometimes made with difficulty, was painful, and often inefficacious. Fabricius, Hildanus, J. L. Petit, and John Bell, recommended the extirpation of the tumour by means of a cutting instrument; and the last has most ably explained the grounds of this precept, by describing the real nature of these excrescences, as well as the sources of failure and danger when they are simply cut into or opened by caustic. Mr. White, of the Westminster Hospital, and Mr. Lawrence, passed a needle with a double ligature under the base of the tumour, tied it on each side, so as completely to destroy the part, by cutting off the supply of blood. (*Med. Chir. Trans.* vol. 13).

Mr. Hodgson proposed to vaccinate the tumour in different parts of its surface, so that a coalescence of the adhesive inflammation consequent to each vesicle might completely obliterate the nævous tissues. I have frequently tried this plan when the nævus was small, with success. The object is to produce an effusion of lymph in their structure, and thus obliterate their vessels. Others recommend various caustics, nitric acid, a combination of lime with soap (Callisen), chloride of

lime (Hanke), &c. when the nævus is small; and many cases have been removed from the use of these remedies. These were suggested by the facts, that accidental ulceration, or sloughing, destroyed a great portion of the tumour, and excited such inflammation as consolidated the rest of it. Great caution is necessary, lest a vessel of any size be opened by the caustic, which might cause fatal hæmorrhage.

As nævi are often stationary until the age of puberty, and as young infants are bad subjects for painful operations, it is considered the safest and best practice to avoid harsh measures, unless the tumour increases in size. Milder means should of course be employed in the first instance.

Diseases of the skin not inflammatory, developed during, or after birth.—These include local and general congestions, petechiæ, and some alterations of colour.

Ecchymosis.—The term ecchymosis is applied to the red, violet, or greenish-coloured mark, produced by a blow or other external injury, and caused by blood effused or infiltrated in organised tissues. This appearance may be observed on any part of the body of a new-born infant, and is the usual result of a difficult labour. It is most commonly observed on those parts which are most subject to pressure, such as the head and neck; and few first-born infants come into the world without more or less ecchymosis of the hairy scalp, and often considerable swelling. This is generally observed when the mother is young, or advanced in life; and when the child is large and the mother under the middle size. I have seen infants born with ecchymosis on almost every part of the body, the result of falls or blows on the abdomen of the mother during the last months of pregnancy. Injuries of this description are said not only to cause ecchymosis, but fractures, and even kill the infant in the womb; but I have never seen fractures result from them. It is important not to confound congenital nævi, or those which are caused by pressure during labour, or by instruments, with those which are produced by some criminal attempt to promote abortion, or to destroy the life of the infant before birth. The medical witness should consult some work on jurisprudence, on contusions, wounds, &c., lest he commit an error which might produce fatal consequences.

The treatment of ecchymosis or blackness, is very simple. Resolution or absorption generally takes place spontaneously. Nevertheless, if there is much swelling of the integuments, it will be advisable to use cold lotions, such as vinegar or spirits and water, Goulard's extract, or vegeto water, as it was formerly called. A tablespoonful of vinegar, or any kind of ardent spirit diluted with half a pint of water, will form an excellent lotion, which if applied constantly by wetting a piece of linen with it, or moistening the latter with it as often as it dries, will generally remove

ecchymosis. But unless in bad cases, any of these applications is unnecessary. In general the swelling and blackness disappear of themselves. In some cases there is considerable swelling of the back or sides of the scalp, accompanied by blackness, and this is called by British writers—

Tumefaction of the Scalp, and by the French *Tumeur du cuir Chevelu*. This tumour is caused by the pressure of the bones, or soft parts of the parent on the head of the infant during parturition, which interrupts the circulation of the blood through a certain portion of the scalp, generally the back part or sides; the blood accumulates in the cellular tissue between the skin and pericranium, and sometimes is effused or extravasated, forming a kind of *tegumentary apoplexy*, and sometimes apoplexy of the brain. This kind of tumour is of rare occurrence, but when it does happen, and proves fatal, blood is found in a fluid state, the surrounding parts are of a violet red, as well as the bones themselves, which have imbibed the fluid. The scalp is red, violet, or blackish externally.

There may, however, be considerable tumefaction of the scalp, without extravasation of blood, but arising from infiltration of this fluid or its serum. The edges of these tumours are so well defined, that a practitioner who saw a case for the first time, might suppose that the bone was wanting or depressed by fracture, or even that the infant had a large tumour attached to its head, or a double head. I was requested about four years ago to visit an infant, who was supposed to have a second head imperfectly developed, but the tumefaction arose from infiltration of blood*. These tumours were designated differently by various authors.

The terms *abscessus capitis neonatorum*, *hæmatoma*, *hæmatoma capitis*, *cephalæmatoma necnatorum*, *ecchymoma capitis*, *tumour cranii sanguineus*, were used by Levret, Smellie, J. P. Franck, Paletta, Nægelé, and others. In this kind of tumour the blood is not simply effused under the skin, but between the pericranium and the bones; and according to numerous observers, the effusion results from a rupture of the venous branches before their opening into the sinuses. According to others, it is caused by a separation of the outer table of the skull. Some practitioners state that this tumour is not caused by a slow or difficult labour, but happens as frequently when the labour is rapid. According to my own experience, I must say that I have never observed this tumour after an easy or natural labour.

The period of the disappearance of ecchymosis and tumefaction of the scalp must vary according to the extent of the disease. I

have known both disappear in three or four days, and other cases continue for two and three weeks. The constant application of the cold lotions above mentioned, when treating of simple ecchymosis, or even cold water, will generally excite the absorbent vessels, and effect the removal of the tumour. Mothers and nurses are fearful that the constant application of cold to the head of a new-born infant will cause bad effects, but this is an error, as no danger whatever is to be apprehended. Nurses generally rub the tumour with some kind of ardent spirit, which is a safe practice, provided the cuticle is unbroken.

When blood is effused on the cranium or in the brain, the disease is often fatal, as dissections have proved. Siebold relates in the thirteenth volume of Richter's *Bibliotheca*, a case in which he effected the resolution of large tumours by applying compresses, wetted with an aromatic decoction mixed with a solution of muriate of ammonia. These were no more than cold lotions.

The disease should be treated on the ordinary principles of surgery; and therefore, if benefit is not derived from cold applications, if the child is sleeping incessantly, or comatose, there is compression of the brain, and a longitudinal incision should be made into the tumour, to evacuate the effused blood, when absorption cannot be otherwise effected.

Capuron and Billard advise this practice, which accords with the standard precepts of surgery; and I should not hesitate to employ it, if all other means, after a fair trial, had failed. Compresses and cold lotions should be applied after the evacuation of the effused blood; and in general the wound heals very kindly. Dr. Burns passes over this disease very lightly, and says that the application of brandy will remove it. Others have written largely upon it, as a disease worthy of great attention; and with these I fully agree, though in general tumours of the scalp disappear very speedily by ordinary remedies. M. Capuron has judiciously observed, that we ought not to confound these tumours with encephalocoele or hernia of the brain; and Dr. Nægelé has remarked, that the latter is generally situated over the posterior fontanelle or occiput. The former is situated on the parietal protuberances or summit of the occiput; but the diagnosis will be easily formed, by reflecting on the appearance of the tumours and the species of labour. It will also be easy to distinguish tumours formed by œdema, or serous infiltration, from the sanguineous kind. The following works on the latter will be perused with advantage. *Paletta, Exercitat. Patholog. Milan, 1820; Car. Zeller, de Cephalæmatomate, seu Sanguineo Cranii Tumore recens natorum*, (Præs. Nægelé) Heideberg, 1822; Ant. Her. Haller, *De Tumore Capitis Sanguineo Neonatorum, Dissert. Dorpat, 1824; G. C. L. Brandau, Ecchymomata Capitis Recens Natorum*, Marbourg, 1824; G. F. Hære, *De Tumore*

* Levret mentions a case in which the practitioner supposed there was depressed fracture of the skull.

Cranii recens Natorum Sanguineo et Externo et Interno, Berlin, 1824; J. D. Strewé, *De Cephalæmatomate seu Sanguineo Cranii Tumore Externo recens Natorum*, Giessen, 1824; Billard, *Traité de Maladies des Enfants*, Paris, 1833.

Different Tumours on the Body.—Sometimes tumours containing either blood, serosity, or pus, are found on the body of the fœtus, and which were not formed by pressure upon it during its passage through the pelvis. At other times they present all the characters of encysted, steatomatous, and lardaceous tumours, &c. They are developed, during intra-uterine life, either on the chest, neck, back, shoulders, or on the head; and for which reason they are called, though erroneously, external hydrocephalus; a remarkable case of which appeared in the *Journal de Sciences et Institutions Médicales*, t. ix. p. 260. M. Chaussier found, in the middle of one of these tumours, situated at the iliac region, a kind of oblong cartilaginous growth, which rose from the crest of the os innominatum. Care should be taken not to open these tumours before proper means have been tried to remove by absorption the fluid which they contain, or before the infant has acquired sufficient strength to resist the inflammation of the walls of these sacs, and the suppuration which follows, when their immediate reunion cannot be effected.

Contusions and Bruises on New-born Infants.—These lesions may be observed after a natural labour; but they are most commonly met with when manual or instrumental operations have been performed. In the first case, the pressure of the bones or soft parts, or genital aperture, or the rude examinations of the obstetrician, or the malposition of the infant, or a deformed or contracted pelvis, may induce them. When the infant presents in an unnatural position, it must be subjected to considerable pressure, as in transverse and facial presentations, and also when the head advances in a wrong position.

But contusions and bruises are most common after operations when the hands or instruments are applied with more or less force over the head, legs, breech, abdomen, chest, neck, or face of the infant, as in version; or in using the forceps, lever, or blunt hook, the two first on the head, and the last on the groins or axillæ, by which wounds and fractures may also be inflicted, unless the practitioner be a scientific and cautious operator.

Contusions and bruises on new-born infants are reddish, brownish, or blackish, either with or without laceration of the cuticle; they inflame and may terminate by resolution, suppuration, or gangrene. Those of the head are in general most dangerous, on account of their contiguity to the brain. Those of the chest and abdomen may also prove dangerous, when the heart, lungs, liver, spleen, or bowels are injured.

Contusions, bruises, ecchymoses, when

slight, generally disappear without any treatment, or by cold applications, as already mentioned. But when the cellular tissue and flesh have been violently contused, it will be necessary to employ antiphlogistic remedies, leeches over the affected parts, warm emollient poultices, to allay the pain and encourage the bleeding; and if suppuration declares itself, it is to be treated on the ordinary principles. If gangrene appears, we must endeavour to limit its progress, and have recourse to tonics and antiseptics, quinine, wine, &c., with lotions of alcohol, dilute nitric acid, &c.; and after the separation of the sloughs, accelerate cicatrization by means of the usual remedies.

Among the external diseases which are congenite, are certain changes in the form of the head, certain solutions of the substance or continuity of bones. These, though not strictly cutaneous affections, are closely allied to them, and may be noticed after contusions and bruises. They are elongations of the head, and dislocations and fractures.

As dislocations and fractures are to be treated on the ordinary principles of surgery, they need not be described in this place.

Elongation of the Head of New-born Infants.

—This deformity is caused in natural labours, when the head presents, when it is disproportionately large, as compared to the outlet of the pelvis, or when there is rigidity, and resistance of the sexual parts, as in very young or aged women, who are in labour for the first time, and especially if there has been a premature escape of the waters or amniotic fluid. In this last case, the labour will be tedious; the head of the infant will be prematurely forced into the pelvis and neck of the womb, long before nature intended; it does not descend like a soft wedge, as in natural parturition, it is moulded to the passage, is contracted from one parietal protuberance to the other, or from side to side, while it is elongated from the occiput to the chin. This form can readily happen, as nature has wisely left the bones of the head imperfectly ossified, so that they may be readily compressed, or lap over each other, which is a great advantage in natural and preternatural or difficult labours. This elongation of the head may take place to a certain extent without injury to the brain; but when it is considerable, the brain is violently compressed, and congested, and apoplexy or convulsions, in consequence of the irritation of the origin of the nerves, or sudden death, may be the consequence. When the elongation is very great, the infant is born dead, the face is black or purple, and the brain is congested, or contains effused blood. Thence it is that the first infants of a majority of women under the age of sixteen, or over thirty-six years, are generally born dead.

It is therefore manifest, that an infant cannot be born without danger, when its head is elongated. Many, however, are born

alive in this condition; and what is still more remarkable, nature will often remove the deformity. Nurses, however, are seldom disposed to allow her, but mould the head after their own fashion, by compressing it between the palms of their hands,¹ and run the risk of injuring the brain, which has recently escaped from fatal mischief. If pressure be made at all, it should be very slight, and directed by a medical practitioner. In these cases, the infant may be born with apoplexy, asphyxia, or apparently dead, or still-born, or extremely weak and feeble. The first is so intimately connected with the last disease, that it deserves notice in this place; the second will be described in the lectures on diseases of the respiratory organs.

Apoplexy of New-born Infants.—When an infant is born apoplectic, it appears as if dead, it is deprived of sense and motion, but its countenance does not present the pallidity of death; the lips are everted, the eyelids red, bluish, and injected, and the eyes almost beyond their sockets, and its face blackish, livid, and swollen. This disease is always produced by compression of the brain, whether by means of the bones of the skull, by narrowness or resistance of the bones of the mother, or by contraction, or thickening of the neck of the womb, vagina, or genital fissure, by the application of the forceps or lever, so that the vessels of the brain are distended by the blood which is accumulated in the head.

This also happens when the umbilical cord or navel-string is twisted round the neck, trunk, body, or limbs of the infant, or when it is compressed by the parts of the mother: under any of these circumstances, the blood cannot return from the head. M. Capuron ably illustrates this point. He remarks, “suppose the infant ceases to respire freely after birth, and after the ligature of the umbilical cord, do we not then observe that it falls into apoplexy, unless we come speedily to its succour? What has this ligature done? precisely the same thing as compression during labour. The one and the other cause apoplexy, by making the blood flow towards the brain; by the first, blood cannot circulate in the lungs of the infant, and by the second, it cannot return to the placenta, which is regarded with reason as the physiological lung of the fœtus.”

On opening the bodies of new-born infants, destroyed by apoplexy, we observe the same appearances as in adults—effusions of blood or serum in the head, under the membranes, or in the ventricles of the brain.

The prevention of apoplexy in infants will be effected by obviating the difficulties above stated, by a scientific practice of obstetrics. The practice in each of the circumstances mentioned, is fully described in all modern works on this branch of medicine, and is foreign to my present subject.

There is one precaution so indispensably

necessary, that I must mention it: and that is, to cut the navel string as soon as the head is born, when it is twisted round the neck, unless it can be loosened, or unless the labour is rapid and natural. If the cord be pressed on for a minute or two, the pulsation of its arteries cease, and the infant will be born apparently dead, but it may be resuscitated. This section is not less necessary after the birth or complete expulsion of the trunk; and as I have known many infants destroyed by neglecting to perform it, I shall allow M. Capuron to comment on this fatal omission. “Every accoucheur, who has then the imprudence to tie the cord, or to wait to cut it until the infant has respired, or uttered some cries, will give a proof of ignorance, and deserves by it to be accused of infanticide. The principle indications here are to reanimate the obstructed circulation, and to excite respiration. To effect this, we bleed the infant by cutting the cord, and by applying leeches behind the ears. We thus disgorge the vessels of the head, and the brain will no longer be compressed. If this evacuation is not sufficient, we plunge the infant into a hot-bath, to which we add some stimulant liquor, as wine, brandy, vinegar, &c. to excite the general sensibility; we rub the whole vertebral column (or spine) with warm cloths, as Legallois has ingeniously proved that the principle of vitality or life which influences the heart resides in the spinal marrow; and finally, to use all means proper to excite the first respiration, as in asphyxia of new-born infants.”

In such cases we may abstract from one to four ounces of blood from the navel string. The face, neck, and spine should be rubbed with brandy or any ardent spirit, as by this means the respiratory nerves of the face and spine will be excited, and inspiration induced. It is upon this principle that sprinkling cold water on the face is good, and that frictions of camphorated liniment with opium, or stimulating liniments applied to the same parts, very speedily relieve and cure hooping cough.”

These directions are excellent, but it is necessary to state, that while the infant is in the hot bath, it ought to be in the sitting posture, and cold should be applied to its head, or the bath will do more harm than good. Unless we use this precaution, we increase the determination of blood to the brain, which we are most anxious to diminish. We may either pour a small stream of cold water from a teapot or small jug on the head, or apply a thin cap or napkin, wetted with cold water, and then continue the affusion. This is not blowing “hot and cold at the same time;” as we equalise the circulation in the body and limbs by the bath, while we diminish it in the head by the constant application of cold. The affusion of cold water may be continued for five or ten minutes, while the infant is in the bath, and is essential in all cases of cerebral congestion and convulsions or other

diseases when the head is affected. It is also used with the best effects in fever, when the head is affected, and it may be repeated three or four times, at the interval of a quarter or half hour, until the face becomes pale, the countenance assumes a more natural appearance, or in other words until the congestion of blood in the brain is diminished.

—o—

A NEW PRACTICAL FORMULARY OF HOSPITALS, OR A

Collection of Formulæ of the Civil and Military Hospitals of France, Germany, Italy, Great Britain and Ireland, &c., containing the Indication of the Doses in which simple Substances, magistral and officinal Preparations of the Codex are administered, the use of New Medicines, and general precepts on the art of prescribing. By M. EDWARDS, M. D., and P. VAVASSEUR, M.D., of the Hospitals of Paris—1834. Translated and augmented by M. RYAN, M. D. &c. &c.

SENNA—(continued from p. 472.)

Subst. incomp. The strong acids, alkaline carbonates, lime water, tartarized antimony, &c.

INTERNALLY. *Powder.* From \mathfrak{Dj} — $3j$. Not much used.

Infusion. $3ij$ — iv to $3viij$ of boiling water, which should be taken at 3 or 4 doses.

The *Infusion of Senna* of the Hot. D. and de la Ch. contain $3ij$ of senna to Oij of water.

Poudre Antiarthritique Purgative. P. Gr. xij — \mathfrak{Dj} , and even more.

Common Purgative Potion. P. $3ij$ — iv .

Lenitive Electuary. P. $3iv$ — $3j$.

Aqueous and Alcoholic Extracts. P. Gr. xij — \mathfrak{Dj} . Not often employed.

Sirop of Senna, or Compound Sirop of Apples. P. $3ss$ — j , and even more.

Compound Powder of Senna. H. of Eng.

Rx. Sennæ foliorum,
Potassæ supertartratis, $\bar{a} \bar{a}$ $3ij$;
Scammoniae, $3ss$;
Zingiberis, $3ij$.

Fiat pulvis.

The dose is \mathfrak{Dj} — $3j$.

Compound Infusion of Senna. H. of Eng.

Rx. Sennæ foliorum, $3iss$;
Zingiberis radiciis, $3j$;
Aquæ ferventis, Oj.

Macera per horam unam et cola.

The dose is $3j$ — ij , as a laxative.

Infusion of Senna with Lemon Juice. H. of Germ.

Rx. Sennæ foliorum, $3vj$;
Aquæ ferventis, Oss.

Decoque per horam, cola et adde,
Succi limonis, $3ss$.

A small cupful to be taken at intervals, until purging is produced.

Decoction of Prunes with Senna. H. of Germ.

Rx. Sennæ foliorum, $3j$;
Pruni domesticæ, \mathfrak{lbss} ;
Aquæ, \mathfrak{lbij} .

Macerate for 12 hours, and strain.

A small cupful at a dose, as a laxative.

Purgative Potion. Hot. D.

Rx. Sennæ foliorum, $3ij$;
Sodæ sulphatis, $3iv$;
Aquæ, $3iv$;
Pulveris jalapæ, gr. xxv .

Fiat potio.

To be taken in two doses.

In another *Purgative Potion* of the same hospital, the jalap is replaced by $3j$ of the syrup of buckthorn.

Compound Senna Mixture. H. of Eng.

Rx. Sennæ foliorum,
Menthæ viridis, $\bar{a} \bar{a}$ $3j$;
Aquæ ferventis, Oij.

Coque, cola et adde,

Magnesiæ sulphatis, $3vj$.

The dose is $3ij$ — iv .

EXTERNALLY. In enema, $3ss$ to Oij of water.

Purgative Enema. H. des Vén.

Rx. Sennæ foliorum, $3iv$;
Decocti lini, Oj.

Infuse and strain.

Purgative Enema. H. de la Ch.

Rx. Sennæ foliorum, $3ss$;
Aquæ, Oj.

Macera, cola et adde,

Sodæ sulphatis, $3ss$;

Vini antimonialis, $3iv$.

Fiat enema.

Employed in Plumbers' colic. It is by this enema that the treatment of this disease is commenced.

Enema of Senna. H. de la Ch.

Rx. Sennæ foliorum, $3ij$;
Aquæ ferventis, Oj.

Macera et cola.

Laxative Enema. Hot. D.

Rx. Fol. sennæ, $3ss$;
Spec. emollient. $3ij$;
Sulphatis sodæ, $3ij$;
Aquæ ferventis, q. s.

Infuse and strain.

RHUBARB.

In small doses an astringent; but in large ones a purgative and a tonic. It is employed with great success in debility of the stomach, anorexia, diarrhoea, and in general in all cases in which a gentle purgative is recommended. It is a medicine very much used in a great variety of cases, too numerous to mention here, and is a very proper one for children.

Subst. incomp. Strong acids, lime water, the sulphates of iron and zinc, tartrate of antimony, the sublimate, the astringent infusions, &c.

INTERNALLY. Powder. As a tonic, gr. vj—xij. As a purgative, ℥j—3 ss, and even more.

Tablettes de Rhubarbe. P. No. iv to xij daily, as a stomachic.

Extract. P. ℥j—3 j.

Sirop. P. 3 ss—j, in a potion.

Sirop de Chicorée Composée. P. 3 i—ij.

Compound Powder of Rhubarb. H. of Eng.

℞. Pulveris rhei,
Potassæ subcarbonatis, ā ā 3 j;
Colombæ, 3 ij.

Dosis gr. x—xx bis vel ter in die.

Powder of Rhubarb and Magnesia. H. of England.

℞. Pulveris rhei, 3 i;
Magnesia, 3 ij.

Dosis gr. x—℥i quotidie.

Powder of Rhubarb and Calomel. H. of Eng.

℞. Pulveris rhei, 3 iv;
Hydrargyri submuriatis,
Pulveris zingiberis, ā ā 3 i.

Fiat pulvis cujus capiat gr. x—℥i pro dose.

[Rhubarb combined with calomel or hyd. c. creta, in alterative doses, is an excellent medicine for children. I have given the formulæ in the article *Mercury*. T.]

Compound Stomachic Pill. Ryan.

℞. Pil. rhei comp., 3 i;
—hydrargyri, ℥ss;
Strychninæ, gr. i.

Fiant pil. xv—i bis vel ter in die.

Boluses of Rhubarb. H. Militaires.

℞. Pulveris rhei, gr. xij;
Sulphatis sodæ, ℥i.

Fiant boli ij.

Bols Fondants. H. of Italy.

℞. Pulveris rhei, 3 i;
Saponis amygdalæ, 3 iss;
Succi sambuci, q. s.

Divide in bolos viij quorum capiat unam secundâ quâque horâ.

Infusion of Rhubarb. Hot. D.

℞. Rhei pulveris, 3 i;
Aquæ ferventis, Oij.

Macara et cola.

A small cupful to be taken at intervals, as a tonic and slight purgative.

Bitter Infusion of Rhubarb. H. of Germ.

℞. Rhei radicis concisæ, 3 iij;
Corticis aurantii, 3 ss;
Aquæ menthæ piperitæ, 3 iv.

Macara, cola et adjice,
Extracti gentianæ, 3 i.

To be taken during the day.

Purgative Potion. H. de Montp.

℞. Pulveris rhei, gr. xij;
Decocti chichorii, 3 iij;
Syrupi ejusdem 3 i.

Fiat potio, cujus capiat cochleare pro dosi. For children.

Potion of Rhubarb and Manna. H. Militaires.

℞. Pulveris rhei, 3 ss;

Aquæ, 3 iv.

Coque paulisper, cola et adde,

Mannæ, 3 ij.

To be taken at several doses.

BUCKTHORN.

A very energetic purgative, which should be administered to none but persons of a robust constitution. It is employed in dropsy, and as a vermifuge.

INTERNALLY. Berries entire and fresh. No. x—xx.

Decoction. No. xx—xxx in Oij of water.

The Juice expressed and fermented. P. 3 ij—iv.

Extract or Rob de Nerprun. P. ℥i—3 iss.

Sirop. P. 3 ij—3 i, and even more, in a purgative potion.

Purgative Potion. Hot. D.

℞. Syrupi rhamni, 3 i;
Tincturæ jalapæ comp., 3 ss;
Decocti chichorii, 3 iv.

Fiat potio.

To be taken at two or three doses, in dropsy.

Cathartic Potion. H. de Paris.

℞. Syrupi rhamni, 3 i;
Decocti pruni domestic. 3 iv.

Misce.

To be taken at two doses.

WHITE AGARIC.

A very violent purgative, but scarcely employed at present, on account of its uncertain action. It is sometimes used in cases of passive dropsies.

INTERNALLY. Powder. Gr. vi—xij, in pills.

Extract. P. Gr. ss—iv, in pills, generally united with some other purgative.

HEDGE HYSSOP acts as a drastic. It is not much employed at present*. The dose is, in *Powder*, gr. x—xxx, and, in *Decoction*, from that quantity to 3 ij in 3 viij in water.

BRYONY, applied externally, produces a rubefacient effect; when administered internally it acts as a drastic. The dose is, in *Powder*, gr. xii—℥i, and, in *Decoction*, from 3 ss to j in Oij of water.

Fecule Médicinale de Bryone. P. Gr. xij—3 ss.

B—SALINE PURGATIVES.

SULPHATE OF SODA. (Glauber's Salt.)

A mild purgative. It is employed in all cases in which it is necessary to induce alvine evacuations without producing general excitation, especially in febrile and inflammatory affections, jaundice, diseases of the skin, &c. When administered in doses too feeble for a cathartic, it acts as a diuretic.

* It has been administered with success in delirium tremens.—(See *London Medical and Surgical Journal* for January, 1832).

[The sulphate of magnesia or Epsom salts is now preferred to the above. The sulphate of soda, is still however, a popular remedy. T.]

Subst. incomp. The salts of barytes, &c.

INTERNALLY. As a cathartic, ℥j—Oj of water.

As a diuretic, ℥j—℥iv, with a third of nitre, in Oj of water, to be taken during the day.

Apozeme purgatif. P. To be taken in the morning, at several doses.

Tisan royale. P. Taken in the morning.

Purgative Potion. Hôt. D.

Rx. Sennæ foliorum, ℥ij;

Aquæ ferventis, ℥iv.

Macera, cola et adjice.

Sodæ sulphatis, ℥ss;

Syrupi rhamni, ℥j.

Fiat mistura.

To be taken in three doses.

The Ordinary purgative potion of the H. de S. Ant. contains only ℥iij of the sulphate.

Purgative Potion. H. of Germ.

Rx. Sodæ sulphatis, ℥j;

Sacchari, ℥ss;

Succi limonis, ℥jss;

Decocti gruti, Oj.

Dosis cyathus, singulis horis.

EXTERNALLY.

Purgative Enema. H. des Enf.

Rx. Sennæ foliorum, ℥ss;

Aquæ ferventis, Oj.

Macera, cola et adde,

Sodæ sulphatis, ℥ss.

Fiat enema.

The Purgative Enema of the H. de St. Ant. contains likewise ℥iv of honey.

Purgative Enema. H. de la Mat.

Rx. Sennæ foliorum, ℥ij;

Decocti lini ferventis, Oij;

Macera, cola et adjice,

Sodæ sulphatis, ℥ss.

Misce.

Lotion used in Porrigo. Swediaur.

Rx. Sulphatis sodæ, ℥vj;

Saponis amygdalæ, ℥iij;

Aquæ calcis, ℥xviij;

Spiritus rectificati, ℥vj.

Fiat lotio.

SULPHATE OF MAGNESIA.

It possesses the same properties as the sulphate of soda, and is administered in the same manner. It is a medicine very much employed.

Subst. incomp. The muriate of barytes, lime, ammonia, the subcarbonates of potassa, soda, &c.

INTERNALLY. ℥ij—℥jss in Oj of an aqueous vehicle, to be taken at two or three doses.

Compound Saline Powder.

Rx. Magnesiae sulphatis,

Sodæ muriatis, ā ā partes, iv;

— sulphatis, partes iij.

M. A tea-spoonful to be taken in a pint of water.

Purgative Powder. H. of America.

Rx. Magnesiae sulphatis,

Pulveris cinchonæ, ā ā ℥vj.

Divide in chartulas iv, quarum capiat unam secundā quāque horā.

Compound Purgative Potion. H. of Eng.

Rx. Magnesiae sulphatis, ℥iij;

Aquæ menthæ piperitæ, ℥ij;

Tincturæ jalapæ, ℥j;

Acidi nitrici, gut. x.

Fiat haustus.

Eau de Trêvez.

Rx. Sulphatis magnesiae, ℥j;

Antimonii tartratis, gr. ss;

Aquæ, Oij.

Cyathus omni horā capiendus donec alvus responderit.

Ferruginous Saline Mixture. H. of Eng.

Rx. Sulphatis magnesiae,

— sodæ, ā ā ℥v;

— ferri, gr. ij;

Aquæ ferventis, Oij.

Dosis ℥iv—viij bis in die.

EXTERNALLY.

Purgative Enema. H. of Germ.

Rx. Magnesiae sulphatis, ℥ss;

Olei lini, ℥iss;

Decocti anthemidis, ℥vj.

Misce.

SULPHATE OF POTASSA.

An active purgative; principally employed in small doses to diminish the secretion of milk after parturition, and in chronic diseases of the liver, &c.

INTERNALLY. As a purgative, ℥ss—j, in solution. As an antilactic, gr. x—℥j, in a powder, or dissolved in an acid vehicle.

Compound Digestive Powder. H. of Germ.

Rx. Potassæ sulphatis, ℥iv;

Pulveris rhei, ℥i.

Divide in chartulas x, quarum capiat unam vel duas quotidie.

[This was very commonly employed in fevers, and during the puerperal state, by the practitioners of the last century. T.]

Acid Mixture. H. of Germ.

Rx. Potassæ sulphatis, ℥ss;

Decocti hordei, Oij.

Solve et adjice,

Oxymellis simplicis, ℥j;

Aceti, ℥jss.

As a refrigerant. A small cupful at a time.

Potion Fondante. H. of Italy.

Rx. Potassæ sulphatis, ℥iij;

Infusi rhei, ℥vi.

M. A spoonful at a dose, as an antilactic.

CREAM OF TARTAR.

In small doses, this preparation of potassa is a temperant, in large ones it is a laxative

of a less disagreeable taste than other saline purgatives. It is very much employed.

Subst. Incomp. The sulphates of lime, and strong acids.

INTERNALLY. As a temperant, ʒ ij—iv in Oj of water, sweetened with sugar. [A small quantity of ginger or orange is added. This is the drink called imperial acid, and is employed in febrile and dropsical diseases. T.]

As a purgative, ʒ j—iv, in an electuary, or ʒ j dissolved in ʒ vj—viij of water.

Crema de Tartre Soluble. P. In the same doses.

A Laxative Temperant Powder. H. of Germ.

Rx. Potassæ supertartratis, ʒ iiij;
Potassæ nitratis, ʒ iiij;
Sacchari, ʒ iv.

Dosis ʒ j ad ij, omne mane ex cyatho lactis.

Compound Electuary of Sulphur. H. of Eng.

Rx. Potassæ supertartratis, ʒ iv;
Sulphuris, ʒ i;
Theriaceæ, ʒ iiij.

Dosis cochl. min. quotidie vel bis in die. [A favourite remedy in piles. Ginger or aromatic powder should be added. T.]

Lozenges of Cream of Tartar and Manna.

H. of Germ.

Rx. Potassæ supertartratis, ʒ ss;
Mannæ, ʒ iv;
Aquæ, ʒ x.

M. Boil to a proper consistence, and make into two lozenges.

Used as a laxative for children.

Solution of Cream of Tartar. H. of Germ.

Rx. Potassæ supertartratis, ʒ iiij—vj;
Aquæ ferventis, Oij.

Solve et adjice,

Syrupi rubi idæi, ʒ ij.

Misce.

To be taken during the day, as a laxative temperant.

The Limonade de Crema de Tartre of the H. de la Ch. only differs from the preceding preparation in the dose of the cream of tartar being increased to ʒ ij, and in containing no syrup.

Purgative Potion. H. of Italy.

Rx. Potassæ supertartratis,
Pulpæ tamarindi, ā ā ʒ j;
Aquæ, ʒ viij.

M. To be taken in two doses.

Imperial Ptisan. H. of Germ.

Rx. Potassæ supertartratis, ʒ ss;
Corticis aurantii, ʒ iiij;
Aquæ ferventis, Ovj.

Macera et cola.

A small cupful at a dose.

NEUTRAL TARTRATE OF POTASSA.

A gentle purgative, whose action is similar to that of the preceding preparations. It is employed in the same cases and in the same manner.

Subst. Incomp. All the acids, lime water, the muriate of barytes, &c.

INTERNALLY. ʒ ij—ʒ i, in an aqueous vehicle.

Laxative Drink.

Rx. Potassæ tartratis, ʒ ss.

Infusi chichorii intybi, Oij.

Solve et adjice.

Mellis, q. s.

Fiat mistura, cujus capiat cyathum vinosum sæpe in die.

TARTRATE OF POTASSA AND SODA

Possesses the same action and use as the preceding substances.

Subst. Incomp. The same as for the tartrate of potassa.

INTERNALLY. ʒ j—jss in an aqueous vehicle.

Powder of Fordyce.

Rx. Tartratis potassæ et sodæ, gr. x;
Pulveris rhei, gr. vj.

Divide in chartulas duas, capiat unam omni mane.

For children.

Saline Purgative Potion. H. de la Mat.

Rx. Tartratis et potassæ sodæ, ʒ vj;
Antimonii tartarizati, gr. i;
Aquæ florum aurantii, ʒ ij;
Syrupi mellis, ʒ i;
Aquæ, ʒ ij.

Fiat potio, dosis cochl. mag. tertiis horis ad alvi solutionem.

SUB-PHOSPHATE OF SODA.

A very gentle purgative; much employed on account of its tastelessness, and in the same cases as the preceding substances.

Subst. Incomp. Sulphuric, nitric, and hydrochloric acids, lime, magnesia, &c.

INTERNALLY. ʒ j—ij, in herb broth.

[It is also added to animal broth, instead of muriate of soda, when patients are delicate. T.]

Laxative Potion. H. of Germ.

Rx. Sodæ phosphatis,
Syrupi althææ, ā ā ʒ ss;
Aquæ, ʒ iv.

Misce.

To be taken in four doses, one every hour.

CALCINED MAGNESIA.

In large doses a gentle purgative; in small ones an ant-acid and absorbent. It is very much employed in cases of acidity of the stomach, dyspepsia, &c. Very useful in cases of poison by acids.

INTERNALLY. As a purgative, ʒ ij—ʒ ss. As an ant-acid, gr. vj—ʒj. As an antidote of concentrated acids, ʒ ij—iv, often repeated, diluted with water.

Absorbent Powder. P. Gr. xij—ʒij.

Tablettes de Magnésie. P. No. iv—vj.

Tablettes de Magnésie et de Cachou. P. No. iv—vj.

Absorbent Powder. H. de la Mat.

R_x. Magnesiae, gr. xvj;
Pulveris cinnamomi, gr. ij.
Divide in chartulas ij, in die sumendas.
In cases of diarrhoea of children.

Ant-acid Powder. H. of Germ.

R_x. Magnesiae calcinatae, ʒ ss;
Corticis aurantii,
Sacchari, ā ā ʒ j.
Divide in chartulas ij, capiat iij vel iv
quotidie. [See *Bismuth*. T.]

Ant-acid Mixture. Ryan.

R_x. Liquoris calcis, ʒ vi—vii;
—— potassae, ʒ iss—ij;
Magnesiae calcin. ʒ j.

Sit mistura, cujus sumat cochl. amplum
ex lactis recentis vel jusculi bovini poculo,
ter in die.

*In pyrosis, when the fluid ejected is acid, and
when the urine deposits a reddish or pink sedi-
ment, which is lithic acid.*

[A drachm of laudanum, or the sedative
solution of opium, with m v of ol. menth. is
added when flatulence, gastrodynia, or
spasm of the stomach or intestinal canal is
troublesome. I have found this combina-
tion extremely efficacious. T.]

Purgative Potion for Children. H. of Amer.

R_x. Magnesiae calcinatae, ʒ ss;
Pulveris rhei, gr. vj;
Sacchari, ʒ j;
Olei menthae piperitae, gut. vj;
Aque, ʒ jss.

Dosis cochl. min. secundâ quaque horâ.

[There is evidently too much peppermint
in this mixture—one drop would be suffi-
cient for an ounce and a half of vehicle. T.]

SUBCARBONATE OF MAGNESIA.

It possesses the same action, and is em-
ployed in the same cases as the calcined
magnesia. The preference is given to it in
cases of gravel dependent on a superabun-
dant of uric acid, &c. It is used in effe-
rescent drinks.

INTERNALLY. ʒ ss—ij, and more, sus-
pended in a potion.

PURGATIVE MINERAL WATERS.

In small quantities, tonics and excitants,
in large ones, purgatives. Externally they
are used as stimulants, in baths.

Water of Balaruc.

INTERNALLY. As a purgative.

As an excitant.

EXTERNALLY. Baths, lotions, fomenta-
tions.

Eau de Balaruc artificielle. P. Same
doses.

Water of Epsom.

INTERNALLY. From two to four glasses
daily.

Water of Sedlitz.

INTERNALLY. From one to four glasses
daily.

Strong artificial Eau de Sedlitz. P. From
one to two glasses a day.

Weak artificial Eau de Sedlitz. P. From
three to four glasses daily.

C—LAXATIVES.

CASTOR OIL.

Recently prepared, castor oil is a gentle
laxative, and very much employed, when
the effects of an irritating substance might
prove injurious to the gastro-intestinal mu-
cous membrane. It is administered in cases
of inflammation of the digestive canal. When
this oil has been kept too long it is very ir-
ritating and becomes drastic. It is employed
with much advantage as an anthelmintic. It
appears to have a special action upon intes-
tinal worms, and destroys them.

INTERNALLY. ʒ ss—ij, at several doses,
in a syrup, a cup of broth, or any other ve-
hicle.

Purgative emulsion of castor oil. P. Taken
at two doses. [It is made with yolk of egg,
as in this country. T.]

Purgative Potion. H. de la Ch.

R_x. Olei ricini,
Syrupi rhamni, ā ā ʒ ij;
Aque menthae, ʒ j.

Misce.

To be taken in two doses.

*The purgative potion of castor oil of the Hôt.
D. differs from the preceding by the syrup of
buckthorn being replaced by ʒ j of tartaric
syrup, and the mint water for ʒ ij of the
decoction of chichory.*

*The purgative potion of castor oil of the H.
St. Ant. contains ʒ ij of acacia gum, and
ʒ ij of water instead of the decoction of
chichory.*

*The potion of castor oil of the H. de la Ch.
contains ʒ ij of the syrup of chichory instead
of that of buckthorn, and ʒ ij of mint water
instead of one,*

*The purgative potion of the H. des Vén. is
composed of castor oil and the syrup of
chichory, of each ʒ i.*

Laxative Potion. Hôt. D.

R_x. Olei ricini, ʒ vj;
Oxymellis scillae, ʒ ss;
Syrupi rhamni, ʒ j.

Fiat haustus.

[Castor oil is frequently combined with
oil of turpentine and croton oil in obstinate
cases of constipation, in puerperal peritonitis,
painters' colic, tapeworm, &c. T.]

Laxative Oily Mixture. H. of Germ.

R_x. Olei ricini,
Syrupi aurantii, ā ā ʒ j;
Saponis amygdalae, ʒ iv.

Misce.

M. Dosis cochl. mag. singulâ semihorâ.
EXTERNALLY.

Enema of Castor Oil. H. of England.

R_x. Olei ricini,
Mellis, ā ā ʒ j;
Decocti hordei, ʒ x.

Fiat enema.

Employed as a vermifuge.

CASSIA.

A laxative and temperant. It is useful in the course of inflammation, to keep the bowels open. It acts very mildly; but sometimes causes colics and flatulency. It is a very commodious medicine for children and delicate females.

Subst. incomp. Alcohol.

INTERNALLY. The root peeled, \mathfrak{z} j—ij.

Decoction, \mathfrak{z} ij—iv to Oij of water, a small cupful at a dose, as a laxative and temperant.

Extract. P. \mathfrak{z} ss—j.

Confection of Cassia. P. \mathfrak{z} ij— \mathfrak{z} j.

Marmelade de Tronchin. H. de la Ch.

Rx. Pulpæ cassiæ,
Maunæ,
Olei amygdal. dulcis, \mathfrak{a} \mathfrak{a} \mathfrak{z} ij;
Aquæ florum aurantii, \mathfrak{z} ij.

Misce.

Dosis cochl. mag. singulis horis.

As a laxative.

Cassia Water. H. de la Ch.

Rx. Decocti cassiæ, Oij;
Sulphatis magnesiæ, \mathfrak{z} j;
Antimonii tartratis, gr. iij.

Misce.

To be taken during the day, in the treatment of painters' colic.

Purgative Potion. H. de Montp.

Rx. Pulpæ cassiæ,
Syrupi chichorii, \mathfrak{a} \mathfrak{a} \mathfrak{z} j;
Decocti papaveris, \mathfrak{z} viij.

Misce.

To be taken in three or four doses.

Potion Minorative de Boerhaave.

Rx. Pulpæ cassiæ, \mathfrak{z} j;
Pulveris rhei, gr. ij;
Syrupi flor. amygdal. persicæ.
q. s.

Misce.

Given to new-born infants to evacuate the meconium. A small quantity should be put on the end of the finger and introduced into the mouth.

Laxative Enema. H. de la Mat.

Rx. Cassiæ, \mathfrak{z} ij;
Aquæ, Oiv.

Decoque et cola.

TAMARINDS.

Refrigerant and slightly laxative. It is employed with advantage on account of its latter quality, in cases in which it is necessary to produce a laxative effect without irritating the intestinal mucous membrane. It is generally united with some other purgative.

Subst. incomp. The sulphates of potass, the alkaline carbonates, lime water, and the tartrate of antimony.

INTERNALLY. The pulp, \mathfrak{z} i—iv in a bolus.

Infusion, from \mathfrak{z} i—ij to Oij of water. This is an agreeable drink, and very useful in febrile diseases.

Decoction, \mathfrak{z} ij—ij to Oij of water, to be taken during the day, as a slight purgative.

Decoction of Tamarinds. P. A glassful every hour.

There is also a decoction in veal broth.

Compound Decoction of Tamarinds. Swediaur.

Rx. Pulpæ tamarindi,

Uvæ, \mathfrak{a} \mathfrak{a} \mathfrak{z} iij;

Aquæ ferventis, q. s.

Coque ad Oij. et colaturæ adde,

Antimonii tartarizati, gr. ss;

Syrupi mori, \mathfrak{z} iss.

Dosis \mathfrak{z} ij—iv omni horâ.

Tamarind Whey. H. of Italy.

Rx. Pulpæ tamarindi, \mathfrak{z} i;

Seri lactis, Oi.

Decoque et cola.

The dose is a glassful at a time as a refrigerant.

Laxative Potion. H. of Germ.

Rx. Pulpæ tamarindi, \mathfrak{z} iij;

Aquæ, \mathfrak{z} xij.

Decoque ad \mathfrak{z} x cola et adjice,

Mannæ, \mathfrak{z} ij.

To be taken at two or three doses.

MANNA.

A gentle purgative, which is very much employed in inflammatory diseases, when there would be danger in using a more energetic purgative. It is a very useful laxative for children of feeble constitutions. It is very much employed, and often combined with other purgatives.

INTERNALLY. From \mathfrak{z} j—ij, in water, or in milk.

Pectoral Electuary.

Rx. Mannæ, \mathfrak{z} j;

Aquæ florum aurantii, q. s.

Tere in mortario et adde,

Pulveris acaciæ, \mathfrak{z} ss;

Extract glycyrrhizæ, \mathfrak{z} j;

Syrupi capillariæ, q. s.

Dosis cochl. mag. sæpe ad effectum.

Electuary of Manna. H. of Germ.

Rx. Mannæ, \mathfrak{z} iij;

Olei amygdal. dulc., \mathfrak{z} j.

Tere simul et adde,

Syrupi gummi, \mathfrak{z} j.

Dose \mathfrak{z} j—iv, given to infants, as a gentle laxative.

Potion of Manna. H. de la Ch.

Rx. Mannæ, \mathfrak{z} ij;

Aquæ, \mathfrak{z} vi.

Divide in doses ij.

Compound Potion of Manna. H. de la Ch.

Rx. Mannæ, \mathfrak{z} ij;

Pulveris rhei, \mathfrak{z} ss;

Aquæ ferventis, \mathfrak{z} iv.

Macera, cola, et divide in dosis ij.

Purgative Potion. H. des Vén.

R_x. Mannæ, ʒ ij;
Sennæ, ʒ ij;
Sodæ sulphatis, ʒ ijss;
Decocti cichorii, ʒ vj.

Infuse the senna in the decoction of succory, add the manna, strain, and dissolve the sulphate of soda.

The *Purgative Poti* of the H. des Enf. differs from the preceding in containing only ʒ j of manna, to ʒ iv of water, and in the dose of senna being ʒ ij instead of ij.

Emulsive Potion. H. de Paris.

R_x. Mannæ, ʒ ij;
Amygdal. dulc., ʒ iv;
Syr. flor. amygdal. persicæ, ʒ j;
Aquæ florum aurantii, ʒ iv;
Infusi glycyrrhizæ, ʒ iv.

Sit emulsio.

The dose is a spoonful every quarter of an hour. This is a very commodious preparation for women and children.

Purgative Whey. H. of Germ.

R_x. Mannæ, ʒ j;
Potassæ supertartratis, ʒ ss;
Seri lactis, ʒ vj.

Misce.

To be taken at two doses, at two hours' interval between each dose.

Syrup of Manna. H. of Germ.

R_x. Mannæ, ʒ v;
Aquæ, ʒ xij.

Liqua et adjice,
Sacchari, lbj.

Coque. In doses of ʒ ss—j.

MERCURIALE (MERCURIALIS ANNUA).

An emollient and laxative, not much employed internally; but frequently administered in an enema.

INTERNALLY. *Compound Mercurial Honey.* P. ʒ j—ʒ j, as a laxative.

EXTERNALLY. *Mercurial Honey.* P. ʒ ij—iv, in an enema.

Laxative Enema. H. des Vén.

R_x. Decocti lini, lbj;
Mellis mercurialis annuæ, ʒ ij—iv.

Dissolve.

COMMON HONEY also acts as a slight laxative. It is used to sweeten drinks. It is employed in the composition of several officinal préparations, such as ROSE HONEY, the OXYMEL of SQUILL, &c.

The petals of the PALE ROSE enter also into the composition of several officinal preparations, such as—

The *Sirup of Pales Roses.* P., which is given in doses of ʒ ij—ʒ j, to purge children; it is also used to sweeten laxative potions.

The *Onguent Rosat.* P., used in excoriations of the mamma and the lips,

And the *Distilled Rose Water.* P., which is used as the ordinary vehicle for resolvent collyria, or which serves as an aromatic for other medicines,

VOL. VII.

PEACH FLOWERS have a feeble laxative action; from them is prepared a sirup which is used as a purgative for children.

CHAPTER XIV.

MEDICINES EMPLOYED AS REFRIGERANTS.

LEMON (JUICE).

A TEMPERANT, daily employed to quench the thirst of patients in acute diseases, especially of the abdominal organs. It is useful in certain cases of vomiting, jaundice, scurvy, &c.

Subst. incomp. Sulphuric, nitric, tartaric, and oxalic acids, lime water, &c.

INTERNALLY. *Lemonade.* The juice of one lemon to Oij of water, sweetened.

Sirup of Lemons. P. ʒ j—ij, in an aqueous vehicle.

Vegetable Lemonade. H. de Paris.

R_x. Citri medicæ, No. j;
Syrupi communis, ʒ ij;
Aquæ, Oij.

Misce.

To be taken during the day, a glassful at a dose. It is a drink very useful in acute inflammations of the stomach.

The *Limonade Citrique* of the Hôt. D., and de la Ch., do not differ from the preceding.

The *Limonade Cuite* of the H. de Paris is also similar; it is prepared with hot water, in which has been dissolved a small quantity of the bitter principle of orange peel.

Julep of Lemon Juice. H. of Eng.

R_x. Succi limonis,
Aquæ menthæ viridis, ā ā p. e.
Dosis ʒ j, bis vel ter in die in aqua hordei.

Compound Ptisan of Lemon. H. of Germ.

R_x. Lemonum pulpas, No. ij.
Corticibus seminibusque pruis remotis, dein contunde pulpas in mortario vitreo et adde gradatim,

Decocti hordei, Oij;
Panis tosti, ʒ ij;
Syrupi mori, ʒ j;
Vini rubri, ʒ vj.

Cola.

A small cupful at a dose.

Acid Mixture with Oil. H. of Germ.

R_x. Succi limonis,
Olei lini recentis, ā ā ʒ iij;
Extracti Opii, gr. iv.

Misce.

Dosis cochl. mag. singulâ semihorâ.
In cases of strangulated hernia.

EXTERNALLY.

Acidulated Collutorium. Swediaur.

R_x. Succi limonis, ʒ ss;
Sacchari, ʒ j;
Infusi lini, Oj.

Misce.

Antiscorbutic Collutorium. H. of Italy.

Rx. Succī limonis,
Sacchari, ā ā ʒj;
Vini rubri, Oj.

Misce.

CITRIC ACID.

The same action and use as lemon juice.

INTERNALLY. *Lemonade.* ʒj in Oj of water, sweetened.

Tablettes d'Acide Citrique. P. q. q.

dry Lemonade. H. de Montp.

Rx. Pulveris acidi citrici, ʒvj;
—— sacchari, lbj;
Olei limonis, q. s.

Misce.

The dose is a tea spoonful in ʒ viij of water.

TARTARIC ACID.

In large doses an irritant; in small ones, a refrigerant. It is employed with advantage in cases of gastric irritation, fevers, &c.

Subst. incomp. Lime water, the sulphates of barytes and strontian.

INTERNALLY. *Powder.* Gr. v—xv, with sugar.

Solution, ʒss—j to Oij of water, sweetened.

Sirup. P. ʒj—ij to Oij of liquid.

Tartaric Lemonade. H. de Paris.

Rx. Syrupi acidi tartarici, ʒij;
Aque, Oj.

Dissolve.

A small cupful at a dose.

The *Limonade Vegetable* of the Hôt. D. and de la Ch. contain the same quantity of tartaric syrup to Oj of water.

Dry Tartaric Lemonade. H. of Germ.

Rx. Pulveris acidi tartarici, ʒij;
Sacchari, ʒ viij;
Olei limonis, gut. viij.

Misce.

The dose is ʒj—ʒss in ʒ viij of water.

Acidulated Potion. H. Militaires.

Rx. Acidi tartarici,
Etheris nitrici, ā ā ʒss;
Syrupi communis, ʒj;
Aque, ʒvj.

Misce.

Dosis ʒss sæpe in die.

VINEGAR, OR IMPURE ACETIC ACID.

It is never employed internally in a concentrated state. Its vapour only is respired in cases of syncope, &c. Diluted with water, it is a refrigerant, which is very frequently employed. It is also used as a vehicle for other medicines. Externally, it is employed as a detergent and percussive.

INTERNALLY. ʒss—ij in Oij of water, or rather in such a quantity as to make an agreeable acid.

Simple Oxymel. P. ʒij—ʒj, and more, in an aqueous drink.

Syrup. P. ʒj—ij, to sweeten diluted drinks.

Oxyerat. H. of Paris.

Rx. Aceti, ʒij;
Aque, Oj.

A small cupful at a dose.

Refrigerant Mixture. H. of Germ.

Rx. Aceti, ʒij;
Mellis, ʒij;
Aque, Oiv.

Misce.

A small cupful at a dose.

Acidulated Gargle. H. des Vén.

Rx. Aceti albi, ʒij;
Mellis rosæ, ʒvj;
Decocti hordei, ʒvj.

Misce.

In the *Acidulated Gargle* of the H. de la Ch. the vinegar is replaced by q. s. of acetic acid.

Acetous Gargle. M. de Santé.

Rx. Aceti, ʒij;
Hydrochl. ammoniæ, ʒj;
Mellis, ʒjss;
Aque, ʒxij.

Fiat gargarisma.

Oxymel Gargle. H. St. Ant.

Rx. Oxymellis simplicis, ʒj;
Decocti hordei, Oj.

Misce.

Oxymel Enema.

Rx. Oxymellis simplicis, ʒiv;
Aque, Oj.

Misce.

Employed as a refrigerant and slight laxative.

Resolvent Fomentation. H. of Germ.

Rx. Aceti,
Alcoholis, ā ā ʒiv;
Ammoniæ, hydrochl., ʒj.

[PYROLIGNEOUS ACID is now employed with success in cutaneous diseases and superficial ulcers. T.]

BORACIC ACID.

A calmant and refrigerant, not much used except in gargles in gangrenous angina.

INTERNALLY. Gr. x—ʒss in Oij of water, as a refrigerant drink.

Calmant Potion. H. de la Mat.

Rx. Acidi boraccii, ʒj;
Syrupi simplicis, ʒjss;
Infusi althææ, ʒiv.

Misce. Dosis ʒj secundis horis.

In cerebral affections in children.

Sedative Boluses. H. of Germ.

Rx. Acidi boraccii, ʒss;
Confectionis aurantii, ʒj;
Syrupi simplicis, q. s.

Divide in bolos vi.

OXALIC ACID.

Concentrated and in large doses, it is a very energetic corrosive poison. Diluted with water, and in large doses, its deleterious action is on the nervous system. Nevertheless, it is sometimes employed, in small doses, as a temperant; but it would be much better to use citric or tartaric acid.

INTERNALLY. Gr. xij—ʒj in Oij of water sweetened.

Pastille Citrique. P. No. iij—iv.

The OXALATE ACID OF POTASS, or Salt of Sorrel, acts in the same manner as the refrigerants; it is not much used. It may be administered in doses of 3ss—j in Oij of water.

(To be continued.)

Reviews.

The Medical Quarterly Review. No. VII.
April 1835. London: Souter.

WE have much satisfaction in bearing testimony to the merits of this ably conducted journal, the present number of which excels all that have preceded it. The editor has judiciously diminished the number, and extended the limits of the reviews, several of which not only present an excellent critical analysis of the work commented upon, but involve something like an original essay on the subject.

Among the original communications is an account, by Mr. Howship, of a tumour induced by hæmorrhage from rupture of the nutritious artery within the femur.

The case is interesting from its singularity, and the resemblance of its symptoms to those of fungoid disease. We extract the account of the progress of the case, and the dissection, omitting the writer's comments, for which, though worthy of attention, we have not space.

"Sept. 17th, 1832. M. W., aged twenty-three years, about five months since, in descending a staircase, passed down two stairs, instead of one, by mistake; and, as she thought, strained her right knee, on the inner side. She described the injury as confined to a spot exactly beneath the central part of the vastus internus muscle; not at first painful or tender on pressure, but situated, as she said, within the bone. More or less occasional pain, and progressive tumour, were the consequences of the accident; the pain, swelling, and lameness still increasing, notwithstanding the means used for her relief. Her father said that for some time, latterly, she had suffered dreadfully.

"By the kind attention of Mr. Anderson, who, towards the conclusion of the case, had seen the patient, I was not only enabled to be present at the examination, but also, with the father's consent, to remove the bone, for more minute subsequent investigation.

"The tumour was situated just above the knee, on the inner front of the thigh, the size of a moderately large melon; diminishing as it extended upwards, terminating just above the middle of the femur, and yielding

an obscure fluctuation. The leg and foot were loaded with œdema. The integuments (which were healthy), when laid aside, exposed the tense fascia, within which a fluctuation was now more distinctly perceived. The fascia, and thin substance of the expanded muscles beneath, being divided, the cyst was laid open, from which a quantity of bloody serum flowed out. The opening being freely enlarged, the contents of the tumour appeared to be traversed by fine membranous septa, whose interstices were filled with grumous blood, masses of fibrine, and serum. In several parts, large coagula of blood were found, confined by a thin film of expanded cellular membrane. The membranous expansions in some parts were rather more firm than in others: at one point was observed, to a trifling extent, a fine lamina of a cartilaginous substance.

"The femur, for the extent of the tumour, was exposed: it felt rough, and at the lower part was extensively laid open, by the active operation of progressive absorption, by which the inner condyle was nearly destroyed. Upon the linea aspera, a light and delicate osseous fabric had for some extent been deposited. Several portions of the detached periosteum were recognized in the tumour, involved in the fibrinous blood; the medullary cavity of the bone being filled with coagula. The lower part of the femur was brought away, and laid in water, to macerate.

"Nov. 15, 1832. I called upon the father and sister; from whose account I set down the following particulars.

"About ten days after the accident, she first felt a little pain, which was compared to rheumatism; at that time she walked as well as ever, and till a month afterwards, when she first began to walk occasionally lame.

"About a month after the injury, walking with her sister, she suddenly stopped, and said 'Oh dear me; what a pain I have got in the knee! I do not think I can go any further.' In a short time this pain went off, and she reached home very well. The part now began to swell a little, and was somewhat tender above the knee, if pressed.

"Seven weeks after the accident, she left the family with whom she had lived, and came home; and, in walking to her own house (a distance of nearly two miles), said she felt a throbbing pain; but it was trifling. For the following three weeks she could bear, and walk, upon the limb, as firmly as ever. She repeatedly had leeches, blisters, and poultices applied.

"On the 18th of June, she went into St. George's Hospital, where she staid about a month, using the means just mentioned, and also applying, as it appeared, an ointment containing tartarized antimony. Urged to submit to amputation, she left the hospital and returned home.

"About six weeks before she died, a day

tinguished surgeon kindly visited her, at her own house, and assured her that 'if she were the queen of England, and worth the Indies in gold, no medical man could do her any good;' and humanely cautioned her, therefore, not to go to any expense with this view.

"At that time the tumour, very large, was always in pain: if, at any time, she dropped off to sleep for a few minutes, she would jump up suddenly, as if a dart had shot through her thigh. She moaned much in her sleep, and, if awake, was often convulsed, as if in a fit; when her father, perhaps, inquiring 'Mary, are you in pain?' she would reply, 'Yes, father: I am quite sensible.'

"She frequently felt severe pains, like pins and needles, passing rapidly upwards, from the toes to the hip, and through to the back; the limb, towards the close of her sufferings, becoming swelled, and oppressed with œdema.

"For the last nine or ten weeks, she was not able to stand at all; yet was said to have been but little feverish, to the last; although latterly, she took large and frequent doses of laudanum, with scarcely any effect, her sufferings frequently inducing her to pray earnestly for death.

"The femur, cleared from the soft parts, presented the following appearances. The cylinder of the bone was not enlarged, but had lost much of its substance, by progressive or interstitial absorption, which had entirely removed the anterior and internal portions of the inner condyle, exposing the cancellated structure, also extensively destroyed by the same agency; so that, of the internal condyle, the thin articular surface, covered by its cartilage, was nearly all that remained. Neither had the fine vascular membranes lining the longitudinal canals, within the compact substance of the shaft of the bone, been less active; for these canals, extensively and considerably enlarged, had at certain points become united laterally with each other, inducing a loss of strength to the solid bone, with numerous openings upon its external surface.

"Upon the *linea aspera*, new bone had to some extent been deposited; but on no other part of the femur.

"An attentive examination of this preparation demonstrates, that absorption had commenced within the medullary cavity; the internal parts having suffered most materially, the substance of the cylinder less, and the outer surface least; proving that the cause of the disturbance and destruction of the osseous fabric must have been seated within the cancellated cavity. Even in those parts where the cancellous structure yet remains, in the seat of the disease, its condition is entirely changed; for, if observed with a good magnifying glass, it will be perceived that, instead of a reticulated texture of rounded fibres, the whole is re-

duced, apparently from pressure, to so many exquisitely fine, thin, flattened plates, here and there entirely disappearing, in consequence of absorption having completed their removal.

"From the above recent and ultimate appearances of this disease, illustrated as they are by the previous symptoms, there seems no reason to doubt that the whole was the progressive effect of continued pressure and excitement, disturbing the healthy functions, first within the medullary cavity, and subsequently among the soft parts beneath the fascia of the thigh, consequent to the rupture of some branch of the nutritive artery of the bone; and that the case may therefore be regarded as an instance of progressive internal hæmorrhage."

There are several other communications of considerable interest, from which we regret that we cannot make any excerpts.

—o—

The American Cyclopædia of Practical Medicine and Surgery; a Digest of Medical Literature. Edited by Isaac Hays, M.D., Surgeon to Wills' Hospital, Physician to the Philadelphia Orphan Asylum, &c., &c. Part VI. Philadelphia, January, 1835. 8vo. pp. 120. Carey, Lea, and Blanchard.

THE editor of this valuable work has long and ably conducted one of the best, most comprehensive and useful of medical periodicals—our respected contemporary, the *American Journal of the Medical Sciences*. He is also the translator of Broussais' works, and an original author of great reputation. He is assisted in the execution of the work before us, by several of the most eminent professors in America. This Cyclopædia differs widely and materially from every medical dictionary in our language, and from most of those in the French and German. It not only comprises medicine and surgery, but obstetrics, descriptive, surgical, and pathological anatomy, physiology, toxicology, legal medicine, and therapeutics. It may justly be designated "Library of the Medical Sciences."

Before we offer our opinion on the execution of this national work, we shall insert the terms of its publication. It is published in parts averaging 112 pages each, and illustrated with numerous wood-cuts. It is expected to be completed in forty parts, which will make eight volumes of 560 pages each. The parts will be published at as short intervals as possible. The price of each part is

about two shillings and three pence, or five dollars for ten parts.

On a careful perusal of the present number, which contains no less than fifty articles, we cannot but observe, that almost all are treated far too superficially. The exceptions are Angustura Bark, Ankle, which occupies fifteen closely-printed pages, Anthrax occupying seven, Antimony thirty-five, and Anus (unfinished) thirty-three.

The greater number of the articles have been written by the editor; and we feel convinced, that the very summary way in which he treats most of them is to be ascribed to the narrow limits which he has prescribed to the work. This alone can explain the unsatisfactory manner in which the articles Animalcule, Animalization, and Animism, are executed. We offer this stricture more in regret than for the purpose of finding fault, as we really think that twice the space allotted to the size of this work would not be adequate for its proper execution. If instead of 4480 pages, the proprietors allowed double the number, then and only then could the work give even a condensed view of the present state of the many sciences which it embraces. Suppose it extended to eight volumes, the size of Cooper's Surgical Dictionary, it would not exceed the amount allotted by the French cyclopedists to medicine and surgery exclusively.

In making this statement we beg to be understood that nothing is farther from our intention than the slightest idea or wish to depreciate this production. It is in fact infinitely superior and more useful than any other in our language, as it embraces much more matter than any work of the kind with which we are acquainted. As a dictionary of terms of medicine, surgery, obstetrics, and therapeutics, it is unequalled by British works. It is of course less comprehensive on medicine than Dr. Copland's Dictionary, or the Cyclopædia of Practical Medicine, works exclusively devoted to this subject; but to those about to commence the practice of the healing art, who have lately left the schools, and will base their therapeutical views on anatomy, physiology, and pathology, the American Cyclopædia presents to their minds these sciences in a concise yet comprehensive form, with all that is valuable in remedial means.

If this work were illustrated by plates on the different subjects of which it treats, it would have a most extensive circulation both in this and every civilized country in which medicine is cultivated. We entertain the expectation that this object will be effected at no distant period in London.

We are not disposed to be querulous; but in a work similar to the American Cyclopædia of Medicine, on which there are at least fifty eminent writers and professors engaged, we can scarcely excuse sins of omission.

We inform our transatlantic contemporaries, that at this side of the ocean all is not gold that glitters; and we remind them of this adage, as we observe they have passed over the works of Dr. O'Beirne and Mr. Salmon, while they have quoted others pirated from them.

Upon the whole, there is great labour, research, and experience evinced in this production, and we most cordially wish it success.

Foreign Medicine.

Outline of M. Rostan's Lecture on the Diseases of the Nervous Centres.

IN his present course of lectures on this subject, M. Rostan first called the attention of his hearers to the chief foundations of organic medicine, namely, that nothing is found in man but organs in exercise: that when these organs are sound, the functions—that is, the movements of the organs—are also sound; that if the organs are altered, their movements are irregular, the functions are in a morbid condition, &c., &c. Applying these axioms to the diseases of the nervous centres, M. Rostan proposed to elucidate the particular pathological disturbances to which this organ is liable; previous to which, however, it is necessary to establish the brain as a compound organ, presiding over different acts. M. R. himself holds it as a truth, that each function of the encephalo-spinal axis is produced by a specific organ, acting as it were in an isolated manner. Thus, maniacs retain all their power of movement, though their intelligence is disturbed. On this subject the lecturer quoted the experiments of Foville, Delaye, Pinel, Grandchamp, and others. The first order of pathological conditions of the nervous centres comprehends

Alterations of Movement.

These may be general or partial, permanent or transitory, varied in a thousand ways. In studying them, the following considerations should previously be weighed and influence our reasoning.

Movement may be altered both by a lesion of the organ which executes it, and of the organ which commands it, or of the organ which transmits the command. Though the action of the muscles is frequently augmented in the diseases of the nervous centres, this does not hold in the majority of the disorders to which man is subject, as we see in the premonitory symptoms of the most acute febrile affections, typhus fever, small pox, &c. Tremor of the limbs may be produced by various causes, as the abuse of spirits or mercury, the action of cold; and is a character of old age. In all these instances, are we to consider it as independent of all organic lesion? Bichât and his followers beheld in it only a perversion of contractility, but M. Rostan recognises it as the effect of a more or less appreciable modification of the nervous centres—a modification which, for instance, cannot be denied in the case of senile trembling.

He then remarked upon the density of the brain of old persons, its tendency to become of a brownish colour, the shrinking it seems to undergo, the retreat it makes before the thickening of the diploe, and the invasion of it by the internal table of the skull bones &c. He recalled the other organic changes, which it is easy to detect in the principal nervous cords, and confidently deduced from the whole, that the functional disorders mentioned (tremors) are in every case referable to an appreciable organic modification.

The stiffness and contracted state of the limbs, which have been advanced by some authors as pathognomic signs of softening of the nervous centres, is also attendant on cerebral hemorrhage.

Convulsions have been divided into tonic and clonic; in the former the muscular contraction is permanent, and causes a complete immobility; in the latter the contraction alternates with relaxation, and the convulsed parts are troubled by incessant shocks.

Tetanus belongs to the class of tonic convulsions. Here there is organic change; for the functional disorder is of continuance. For a long time this was denied. "There are some observers," said M. Rostan, "who seek only a negative result from a post mortem examination. They cannot or they will not ascertain the existence of numerous lesions, which would attract on the very onset, the attention of the most common-place observer." M. Rostan is of opinion that the organic modification concomitant with tetanic phenomena, has its seat in the membranes of the spinal marrow. This modification is the result of an inflammatory process, so that no very well defined difference between tetanus and myelitis can be drawn.

In catalepsy and chorea, the alterations which the nervous centres undergo, though transitory and difficult to fix upon, are nevertheless real in existence.

Picking of the bed clothes (carphology)

occurs chiefly in meningitis, meningo-encephalitis, and typhoid fever. In this too there is alteration of the nervous substance, which if we are at times unable to appreciate, the imperfections of our means of anatomical investigation, rather than the principles laid down, are to be accused.

It has been said, and is daily repeated, that in persons who sink under epilepsy, the organic modifications bear no relation to the symptomatic disorders. But the very fact of epileptic attacks being periodical, demonstrates that the organic modification is not permanent, and is therefore not likely to be easily if at all detected after death; the objection therefore strengthens the organic doctrine. The alterations attendant on epilepsy have not been hitherto discovered. M. M. Baubet and Cazauviel, in their monograph on this subject, have mistaken one of the effects of the disease for its cause: they have not considered that the congestion about the meninges and the brain during the fit is induced by the same cause as that which makes the face and limbs suffused and turgid. Neither can the cartilaginous state of the medullary enveloping membranes account for the symptoms of epilepsy; for the organic change, like the symptoms it begets, must necessarily be fugacious.

Passing to the subject of paralysis, M. Rostan remarked, that by a proper appreciation of that condition, the diagnosis of cerebral affections may be satisfactorily established, though more than one modern pathologist have slighted the deductions that may be drawn from this most interesting of functional perversions. For a long time paralysis was supposed to be a disease altogether sui generis, and in some way independent of any organic lesion of the nervous centres. This was the error of Pinel, Landré-Beauvois, and others, an error fraught with the grossest therapeutical mistakes. In 1785 the Académie des Sciences commissioned Mauduyt and Halle to experiment on the effects of electricity in paralysis; and it is plain from the words of the commission, that the Academy regarded it as a specific complaint, no mention at all being made of its organic origin.

According to M. Rostan, paralysis is as sure a guide in cerebral diseases, as are the râles and other auscultic signs in thoracic disease. It is only since the year 1815 that this proposition has been appreciated, and that the reverse one of the essentiality of paralysis has been at all subverted.

When paralysis is general, when it affects indiscriminately all the agents of motion, it does not form so positive a sign as when it is partial; for then the whole encephalon is involved, unless indeed it be only the mesocephalon (tuber annulare). Palsy is also general in congestions, in meningitis terminating in a copious serous effusion; in syncope, asphyxia, narcotism, intoxication, hysteria, — General palsy may

depend on congestion of the brain and immoderate hemorrhagic effusion, both acting by compressing the pulpy substance of the encephalon.

In cerebral congestion, the palsy supervenes suddenly; but in a few hours, or at most in a few days, the patient recovers his motor faculty. Such, however, is not the case in the palsy arising from a considerable sanguineous effusion.

A knowledge of the circumstances preceding the general palsy, is sufficient to distinguish meningitis as a cause.

In syncope, the paleness of the surface, the absence of the pulse, the slow and scarcely perceptible respiration, diagnosticate with sufficient accuracy.

In asphyxia, as also in narcotism, a knowledge of the influence that has been applied, and some special signs that will be hereafter mentioned, aid the physician in the appreciation of the organic modifications that determine the palsy.

The smell of spirits from the mouth, and the vomiting of characteristic matters, render the paralysis from intoxication perfectly recognisable.

Hysteria and epilepsy always present a series of convulsive symptoms, that precede the resolution of the powers, and the paralytic attack.

In cerebral hemorrhage there are no precursory symptoms: the palsy is permanent. If we desire to inquire into the exact seat of the sanguineous effusion, we must first determine whether the palsy was in the first instance local or general. In the former case, the probabilities lean to the conclusion that a considerable hemorrhage has taken place into the ventricular cavities, and produced compression. In the latter case, we have every reason to suspect hemorrhage in the central portions of the brain.

As yet, there are but few cases of general softening of the nervous centres; but in all those of which we have any knowledge, the paralysis has had precursory signs, that announce an evident morbid process.

With regard to local palsy, it is opposed to encephalic alteration. This fact, though contested by some minds with retrograde tendencies, has been well known from the time of Herophilus downwards. It has been said that when hemorrhage occurs in the posterior lobes of the brain, it causes paralysis of the side corresponding to the lobule affected. But M. Rostan remarks with reason, that nothing is more easy than to err on this subject; for he has again and again seen the best informed clinical observers fall into mistakes concerning it. He is therefore inclined to place but small confidence in the facts opposed to the general law, so long recognised, that the lesion of a cerebral hemisphere induces functional perversions in the side opposed to the diseased hemisphere.

Not unfrequently paralysis is confined to

one arm or one leg. An attempt to explain this phenomenon has been made by Foville, Pinel, and Grandchamp, who say that the striated bodies preside over the movements of the lower extremities, and the thalami optici over the thoracic extremities. Though M. Rostan believes in the existence of particular portions, destined to rule over certain limbs, he considers those assertions to be as yet premature.

Paraplegia may be complete or incomplete, and affect the lower extremities in succession or simultaneously. It most commonly depends on an alteration of the spinal marrow. Though primarily only partial, it eventually becomes general, owing to the minor degree of isolation of the nervous fasciculi of the spinal cord.

Crucial paralysis depends on alterations in various points of the cerebral hemispheres.

The palsy of the organs of the senses is with difficulty referred to any organic lesion that is always identical in its seat. In palsy of the tongue, it is necessary to form a distinction that may reconcile certain facts in appearance contradictory. Palsy of the tongue is frequently suspected, when in fact there is only annihilation of the memory of words: or the inverse may be the case, and the movements of the tongue be only perverted, without the memory having suffered in any particular. Now, it is this distinction that may reconcile the opinion advanced by M. Bouilland, who has placed the memory of words in the anterior lobes of the brain—and the facts stated by M. Foville, who has ascertained the existence of an alteration in cornu ammonis in individuals that stammer.

Oesophageal paralysis is somewhat rare, and the seat of nervous alteration on which it depends, has not been yet well determined.

It has been stated that the close study of the progress of the phenomena of paralysis, is a powerful aid in the diagnosis of affections of the nervous centres. Thus, in cerebral hemorrhage, the paralytic attack is sudden; in softening it is progressive, and is always preceded by particular signs to be hereafter detailed. The increasing progress of paralysis, shews the existence of softening or profound organic alteration of the brain; while its gradual decrease announces a cerebral congestion or a hemorrhage that has reached a certain point.

Sometimes paralysis is permanent after sanguineous effusions into the nervous centres, in which case, there has been a forcible laceration of the encephaloid mass, to some extent.

All the preceding facts and propositions have been contested: palsies with alteration of the nervous masses, and alterations of those masses without palsy, have been quoted. These facts, at best insufficient and incomplete, may at most lead the logical physician to conclude, that in the nervous centres, as in other organs of the body, there exist, in some

exceptional cases, certain latent affections, and that the means of anatomical investigation yet remain to be perfected. In the palsies produced by electricity, lead, mercury, &c., the nervous pulp appears to have undergone no change; but M. Rostan maintains that it is impossible for the physiologist and physician in these cases to do otherwise than credit the existence of an organic change in that substance—a change that very possibly will be made clear to us by better directed researches.

EDICTS OF MEDICAL CORPORATIONS —THEIR INJUSTICE AND ABSURDITY.

EACH new *curriculum* is a source of misery to somebody—to teachers whose audiences it diminishes, to students whose anxieties it protracts, or to parents whose purses it drains; and all this is, and will be, without any commensurate improvement in the qualification of practitioners. As long as the *certificate system* endures, lecturers will be exasperated, pupils tormented, and parents incommoded, to no good effect. When will the thick-witted potentates who rule the medical world be brought to comprehend that paper is not knowledge? When will they be convinced that a candidate might come before a board of examination clothed with certificates instead of a coat and small-clothes, and depart as great a lout as he came?

Under the present system there is no encouragement for talent among teachers, none for diligence among pupils. The lecturer may deliver the best or the worst discourses that ever proceeded from the mouth of man—it is quite immaterial which, so that they be delivered at the right time and place, and under the right auspices: the student, on the other hand, has only to provide himself with plenty of *stationery*—few quires of paper with the right

stamp upon it; as for the examination, it is a mere morning's amusement for a young gentleman endowed with a moderate share of *non-chalance*, who has been about the schools for several seasons, and learned his catechism from a grinder. It is true that this formidable process does occasionally frighten a nervous youth out of his senses; but does it ever demonstrate that the candidate understands his profession? Never. It sometimes sufficiently evinces that he does not; and herein lies its sole utility.

A *viva voce* examination before a board never can be a satisfactory test of practical knowledge; a man may know Cullen's Nosology by heart, or be able to repeat Mason Good's Practice of Physic verbatim from one end to the other, and yet be utterly incompetent to form the diagnosis, or conduct the treatment, of the simplest case at the bed-side of the patient.

Let the framers of regulations be assured that the public will not be deluded much longer with such a system of humbug.

It will occur to some of the more sagacious laics, that a student with strong sense in his head, books at his hand, experienced friends to advise him, dissecting rooms open to him, and a world of disease around him, may be illuminated with a few broad gleams of medical knowledge, though dwelling far from any *recognized* school; they will demand in his behalf a fair examination, and, if he can pass it, they will not be disposed to confide at all less in this outlaw of medical science than in the favoured disciple of a recognized school, however well supplied with certificates, which testify that he has sat out a certain number of prelections, but which by no means testify that the discourses were worth the hearing, or that the *alumnus* was not asleep while they were delivered.

In short, the said sagacious laics, in other words, "the intelligent portion of

the public," will declare peremptorily, that if a man possess a sufficient knowledge of his profession, they do not care one straw how or where he got it, and that he has an unquestionable right to exercise his abilities for the good of the community; all which, being mere matter of common sense and plain justice, must inevitably come at last to be generally admitted and acted upon, though all the corporations on earth should oppose it to the death. The fact is, every subject relating to the business of the world, admits of being reduced to the principles of common sense; and the great tendency of social improvement is to elicit these principles from the obscurity in which prejudice, false reasoning, and self-interest have involved them. The common sense of mankind will, some day or other, begin to bear advantageously on medical politics, and several complex questions will then be reduced to very simple conditions.

In reiterating what we have often said before, that a full, fair, and *practical* examination on every branch of medicine ought to be the sole test of qualification, we shall be met by the old cant about the difficulty of passing such an examination, and the consequent paucity of legally qualified practitioners. Now, what does the first part of this objection amount to but a full recognition of the defects of the present system. We are told that to make the candidate dissect and demonstrate, instead of answering a few silly questions, would try him too severely; yet this candidate is the individual to whose practical knowledge of anatomy the safety of hundreds is to be entrusted! We are told that to take him to an hospital, and see whether he knows one disease from another, and how to prescribe for patients, would be an impassable ordeal; yet this is the man on whose judgment the question of life or death is daily to depend! With regard to the insufficient supply of practitioners, shall we call the the objection ridiculous merely, or abso-

lutely insane, when it is notorious that the supply of practitioners is at present so superabundant that the doctors bid fair to fulfil literally the destiny of man—"to replenish the earth and subdue it;" for, in a short time they are like to have an overwhelming majority over all the rest of mankind!

—o—

ODD MEDICAL QUESTIONS.

THE following are a few of the questions proposed at the commencement of the 16th century by the Parisian faculty, to the candidates of the different concours. They afford a ludicrous insight into the objects of medical inquiry in those days.

An semel in mense inebriari salutare? An paralyticis vinum et themæ? An verminosis affectibus amara potius quam dulcia? An vesicæ calculo laborantes secare liceat? An ex coitu cum menstruata fœtus nascatur elephantiacus? An in pleuritide, ut insolens est, vini appetitus, sic illius usus concedendus? An philtis amor conciliari posse? *Conclusio posse!* An vita humana physicis remediis ad millesimum annum possit prorogari?

Among other questions proposed in 1617, to the celebrated Riverius was the gallant one:—An mulieres rationi animi et corporis sint viris perfectiores?—the simple one, An et quomodo cucurbitia trahant? and the modest one, An cum claudicante, quam non claudicante muliere, major sit voluptas? To which Riverius—whether from subtle reasonings or from facts, the deponent saith not—answered "Major est viro voluptas."

These that follow are more rational and practical, e. g.—An lues venerea ab immoderato inter sanos amplexa suscitari possit? An eodem sit materia sudoris et urinæ? An hectius lac et balneum? An ophthalmiæ vinum? An phthisicis lignum sanctum? An scorbutus ellerboro? An pregnantibus et pecantibus absurda sint concedenda?

The physio-chemical question:—An metalla semen habeant et inter se possint invicem transmutari? was actually answered by Deidier in the affirmative.—(From a Memoir on the Origin of Medicine in the last number of the *Revue Medicale*, in which the author labours hard to establish, and concludes by asserting, the truisim "that medicine originated from God").

—o—

Spontaneous Obliteration of the Aorta.

M. LOUIS lately exhibited to the Académie de Médecine a preparation of a complete obliteration of the aorta a little above its bifurcation; as also of both primitive iliacs. These changes had occurred in a woman 45 years of age.

MEDICAL QUACKERY.

"Such *laws* we have, and yet, tho' strange,
'tis true,
We have as base, abandon'd *doctors* too."

To the Editor of the London Medical and Surgical Journal.

SIR—As you have ever proved yourself an enemy to quackery, whether in or out of the profession, whether its practiser has nothing but his ignorance and impudence to rely on, or whether he can add half a dozen important letters at the end of his name—letters which only shew the greater degradation of the man, "fallen from so high a state"—may I presume on your pages, by offering a few remarks on medical quackery in general. Unfortunately for the profession, the laws which regulate it are formed so flimsily, and are administered so inefficiently, that almost any one may break through them with impunity; men totally uneducated, or worse, with just enough knowledge to do mischief, establish themselves beneath the quibbles of the Apothecaries' Act, and practise medicine and surgery, to the great injury of the educated medical practitioner; he may have spent his life in the acquirement of knowledge, at much pecuniary expense, and much self-denial; he may have taken the diplomas of the different corporate bodies, and taken them with honour; and yet, a man who has saved himself all this trouble and expense may have the same privileges, the same chance of success; then what do the diplomas of the corporate bodies benefit their possessor? Truly it is said they are necessary; but who shall deny the existence of unlicensed practitioners, who laugh to scorn the powerless threats of the *qualified* and injured? Shall I be told the diplomas give their possessor respectability in the eyes of the community, and that they enable him by that means to be more successful in life?—shall I be told this, when facts stare me in the face to contradict it? Do I not see advertisements in the journals of every passing day of the week, that gives this assertion the lie? Do I not see men flourishing in practice, patronized by the aristocracy, and publishing popular works upon the most important branches of the profession, without the possession of a single diploma, or even a knowledge of the anatomical structure of the part they profess to treat when diseased—as has been proved, and in your journal, within the twelvemonth? and yet will these worthies store their books of 400 quarto pages with histories of cases, wonderful cases, and no less wonderful cures!—cures that the credulous public take for gospel truth. That public should remember the words of the great Lord Grizzle, in Tom Thumb:—

"Cases! why, Public, 'tis all flummery;
They made the cases first, and then they
cured them."

The apparently cynical expression of the great Dr. Johnson, with regard to the success of quackery, has more truth in it than at first sight would appear. Does not the success of such mountebanks as I have been describing prove its correctness? Does not the immense sale of quack medicines—medicines bearing his Majesty's licence, and made patent, prove that the remark was just? Surely it does. It proves two things more—the little regard the government of the country has for science, and its shameless sacrifice of that science on the altar of mammon! Is this an overdrawn picture of the unjust laws that regulate our profession? But let us inquire how the diplomas of the corporate bodies benefit their possessor; it is known to even the merest tyro in the science of medicine, that there are numbers of the most talented, the most industrious practitioners, with a dreary prospect before them; their talent cannot save them from poverty, and their industry scarcely finds them wherewithal to subsist on; and yet these men were told that the possession of the diploma would lead them to respectability and emolument; they struggled, they studied, spent their youth in the attainment of knowledge; and for what? to see some ignorant, self-sufficient, unlicensed individual bearing away in triumph the emolument they had struggled for, the same for which they had panted, and which, were our laws better constituted, would have been theirs. Such, Sir, are some of the few evils of the present state of medical jurisprudence. Let me look now at another evil in the ethics of the profession. Are there no laws of etiquette existing, by which a regularly installed practitioner should be excluded from the profession when he becomes a disgrace to it? Shall the voice of censure be raised against the ignorant unlicensed, whilst we pass over in silence the quackery of the *legally qualified*? Shall we see the purity of our profession violated, and by those who should be its guardians and ornaments, and not condemn them? And yet, how shamelessly do the *great* amongst us, as well as the small, forget that "high moral character" which they tell us is necessary to be possessed by every practitioner in physic! Do not such know, that however much they may mislead the public by their catch-penny books, that they cannot deceive the profession? Do they think there are no eyes on them that pierce through the flimsy veil of hypocrisy with which they foolishly endeavour to disguise their intentions? They are about as wise as the ostrich, when she buries her head in the sand and thinks herself safe from her pursuers.

There are men, Sir, in the world, who would sacrifice "reputation" and every honourable feeling upon the shrine of ava-

rise; in our profession, unfortunately, as well as in others, such men are to be found. There ought, Sir, to be something in a profession of such respectability as the medical—a something that soared above mere gain; there ought to be a feeling of shame at an unworthy action—there ought to be a love of the profession for its sake alone; and a respect for themselves would lead them to respect their fellows, and to feel that any degradation of the honour of the profession would also degrade them as members of it. But let me ask if men can have any regard for it, who profess to cure diseases that are known to be incurable—who puff themselves off in newspapers in paid-for paragraphs—who publish books of cases and cures which never occurred, and who would endeavour to mislead the public on the strength of their names being registered in the books of a learned profession?

There can be but one answer, and that must condemn them. In the law, if an attorney has committed himself, he can be struck off the rolls: in the church, if a clergyman is convicted of a misdemeanour that is likely to bring the Church into contempt, he can be deprived of his living—why is there no law in force with regard to such things in our profession? Verily, it shews little wisdom in our legislators: and yet, Sir, there are men hardy enough to throw down the gauntlet in defence of such a system as now exists; they will condemn, in unmeasured terms, the practice of quackery by men holding no diploma; they will pour the vials of their wrath on the heads of those who are “fighting the good fight”—who have denounced the system of favouritism, money influence, and family patronage, in raising men of mean talents to important situations. What wonderful consistency do these anti-reformers shew—how profound their thinking! they condemn some of the effects, and yet will they uphold the cause of bad legislation. Let them look nearer to themselves—let them look to members of the Colleges of Medicine and Surgery in Great Britain generally—and then let me ask them, in the words of a great medical reformer, “What is the reason that great names do not always accompany great talents, or why great talents do not always accompany great names?” I will leave them to answer this, and will shortly send you a few remarks on the hospitals of the metropolis. Yours, very truly,

—o—

J. F. C.

A FEW REMARKS ON PURGATIVE MEDICINES.

“Nemo solus sapit,
Feliciter is sapit, qui periculo alieno sapit.”

To the Editor of the London Medical and Surgical Journal.

Sir—There are no medicines in the *Materia Medica* which demand so much attention

from the practitioner—none of so much benefit in disease—none in which such power is possessed over the human body, as purgatives. The subject is one which engaged the attention of the older physicians, and even later writers; but it is only within the last thirty years that it has been taken up, thoroughly investigated, and proved to be one of the most valuable additions to modern medicine, both as regards its simplicity and effective action. That proper attention was not given to the subject by the older writers, may be seen from their works; and modern writers may equally be charged with the same culpable neglect of such simple and effective remedies. This may be accounted for by that natural love of former opinions, and confiding too implicitly in them. Another circumstance is, that practitioners are so apt to be led away by subtle and dangerous theories broached by men, that seem so pleasing to the imagination, so simple in their details, but which are founded on false and delusive principles. If we wish to advance the science of medicine, we must look to nature, observe the laws which regulate its action, and then, by comparison of the healthy and diseased state, we shall by experience know how to regulate our treatment of disease. It is thus by comparison, and the accumulation of facts, that we can arrive at conclusions, as praiseworthy of our industry as they are of importance to the profession. Medicine is a science of facts, orderly and well arranged; no theory is necessary to assist us in any practical point. We must leave theory to the elegant and inductive reasoner—leave him to range in that speculative field of medical philosophy which has employed the powerful intellects of the most cultivated men for ages; and it still remains as open and as free for the mind of man to range as formerly.

Dr. Paris remarks, in his able work, that purgative medicines may act in three ways on the alimentary canal.

1st. By stimulating the muscular fibres of the intestines, whence their peristaltic motion is augmented, and the contents of the bowels more quickly and completely discharged.

2nd. By stimulating the exhalant vessels terminating in the inner coat of the intestines, and the mouths of the excretory ducts of the mucous glands; by which an increased flow of serous fluids takes place from the former, and a more copious discharge of mucus from the latter, the effect of which is to render the faecal matter thinner and more abundant.

3rd. By stimulating the neighbouring viscera, as the liver and pancreas, so as to produce a more copious flow of their secretions into the intestines.

These divisions appear in practice to be extremely judicious, and gives the practitioner a practical and scientific view of his subject. The first division, which increases the peristaltic action of the intestines, is of

the greatest importance in many forms of fever; for here the peristaltic action is diminished, and the necessity for their exhibition will be apparent. For the investigation of this interesting fact to its utmost extent, we are indebted to Dr. Hamilton of Edinburgh. It was known and generally adopted before this, but not in the free and extended manner of Dr. Hamilton. In typhus fever purgatives must be confessed to be of the greatest importance by those who have seen the disease, tried the remedy, and witnessed the good effects. Dr. Hamilton mentions many cases of this kind, and his favourable account has tended much to increase the practice. I have seen several cases in which continued purging was kept up for a length of time, with complete success. Jalop and calomel, with senna, manna, &c., were the purgatives employed. There are several cases related in the *Lancet* of last week, which are additional testimony in favour of their exhibition in typhus fever.

The second division presents us with a class of medicines which produce a discharge of serous fluids from the exhalents. They are extremely useful in inflammatory fever, dropsy, and other diseases of this kind; saline purgatives, and many vegetable substances, come under this head,—as elaterium.

The third mode of operation is to increase the biliary and pancreatic secretion. This can be done by mercurial purgatives. The importance of this is seen in chronic disease of the liver, and of the mucous coat of the intestines.

But it is not in one or two diseases that purgatives are useful; there are some of course in which a more favourable impression is exerted. In *CHOREA SANCTI VITI*, we see, after all other medicines have been exhausted in vain to quell the force of the disease, or even to relieve the dreadful spasms and nervousness of the patient, purgatives, after a long continuance, reduce the disease, improve and strengthen the constitution of the patient. This was remarkably seen in a case at the Charing Cross Hospital; tonics and other medicines only relieved the disease, but a long and persevering continuance of purgatives, to the satisfaction of many, removed the disease; this was an extremely violent case—you could not speak or approach the patient without the symptoms being violently increased. In many forms of dyspepsia, where the biliary and pancreatic secretions are deficient, we have only to exhibit our mercurial purgatives, followed up by other adjuncts, unnecessary to mention, and we shall in the majority of cases find the disease decline by their exhibition.

There are several other diseases in which purgatives seem to be of the greatest consequence, not only from their powerful and beneficial action, but from the nature of the malady. Mania, a name so painful to the feelings of all, where reason is perverted by

its overpowering influence, and the faculties of man are laid dormant; it must be obvious to all that it deserves our paramount attention and consideration. There is no disease which has baffled the science and skill of the physician so much as mania; none in which so many devices, so many plans of practice, have been proposed, but without avail; therefore I say no disease demands so much the skill, the judgment, and experience of the practitioner as this. To recover man from a state resembling more the brute creation, to his own reason and judgment, must be the noblest of all human endeavours, and the greatest of all human desires. That mania depends upon different exciting causes must be apparent; as from disease, disordered functions, excitement of the moral feelings, &c. But it is not my intention to enter into details, but merely mention particular cases in which purgatives are of essential benefit. We often see cases of mania occur without any apparent cause, without any of those premonitory signs which are seen in others. To what can this be attributed? what conjecture can we offer? That some irritation of the secretory system is the prominent cause that presents itself; and this will be found not without foundation; for if inquiry is made, the secretions will be found unnatural. Even in some confirmed cases this is generally the case; and it is to this only that we should direct our attention. I do not here speak of those confirmed cases in which disease of the brain or its membranes are supposed to be connected with the disease, but from the sudden and unaccountable occurrence of mania, in persons of supposed health, strength, and sound intellect. I well remember the case of a young lady, whose bowels were naturally costive, being suddenly seized with mania; that some severe irritation of the secretory system was the exciting cause, became afterwards apparent. Her menstrual courses suddenly ceased, her bowels were confined; bleeding was practised, calomel was given, and several other medicines, but without in the slightest degree relieving the bowels, and in fact every expedient was tried to open them; and it was not until croton oil was exhibited (it was about this time, 1830, brought a good deal into notice), two drops in a dose, that the bowels were opened; and another dose having been given, free purging moved, which was kept up for about three days, when the patient's faculties returned to their natural state. It has been found by a course of purgatives in mania, and in many of its forms, as melancholy mania, partial mania, &c., that the greatest benefit is derivable from their use. There appears to be so great a sympathy existing between the alimentary canal and the head, that we cannot wonder at the many cases of temporary mania which occur, and which, by the continued judicious employment of purgatives, will generally prove of essential benefit to the patient.

The subject of the sympathetic connexion which exists between the alimentary canal and head would be an extremely interesting investigation, and would much forward our views with regard to the treatment of insanity.

In all chronic diseases purgatives may be used with considerable success—but they must be continued in many cases for a long period, and require the greatest attention from the practitioner..

—o—

PARISH JOBBING.

To the Editor of the London Medical and Surgical Journal.

SIR—I was somewhat surprised on perusing a letter in your journal of last week, signed Londinensis, respecting the persecuting treatment to which I was subjected last September, at the election of surgeon to one of the districts of the large and opulent parish of Saint Pancras. I had entirely banished such contemptible proceedings from my memory, and thought every one else had buried them in the waters of oblivion; for if I had wished to have drawn public attention to such conduct, I should have availed myself of the public press at that time. However, your correspondent, evidently under the idea of rendering justice to myself, has done so; in consequence of which I feel myself called upon to verify as far as I can with propriety, the statement he has put forth.

The part which concerns my late friend and master, Mr. E. W. Wright, is correct in every particular; and I trust you will permit me to pay a just tribute to his memory. He had a few pupils, who with myself agree that he was ever ready to impart what medical and surgical knowledge he possessed (and sound and practical it was) to us, his treatment being more as a father to his sons than teacher to his pupils; not one of us would regret passing through another apprenticeship with such a man; but enough—he died regretted by his friends, beloved by the poor, and respected by all.

It is equally true that he met with unwarrantable opposition more than once, by a man who at that time ought not to have been allowed to enter into competition with him, not being qualified at the time.

It is also true respecting the treatment to myself, after his decease, and that, owing to party feeling, I lost the election; that I never in any shape or way received the least expression of thanks for my services all the time; but what could I expect from a mixed set of men, the majority of whom had no pretensions to respectability, composed of eating-house keepers, oil-shop men, green-grocers, butchers, coal-shed keepers, retail beer-shop keepers, bankrupts, and insolvents, and a few gentlemen, the latter of

whom voted in my favour, and for which I respectfully thank them.

I was likewise the medical officer attached to the parochial Cholera Hospital, and twice nearly fell a sacrifice to its arduous and constant duties—having sometimes as many as sixteen patients in the collapsed state to attend to at once; to report their cases hourly, night and day, and the treatment adopted; to dispense all the requisite medicines; to keep a diary of all cases admitted; and frequently I have not seen the inside of a bed for a week successively, and no assistance except the advice of my kind friend Dr. Roots, to whom I am chiefly indebted for my knowledge of disease, and for whose instruction and advice I feel grateful, and am proud to acknowledge it. For what did I do so? to be turned out of an appointment that I justly merited.

Mr. Editor, I fear I have overstepped the bounds of prudence, in talking too much of self; but, as Mr. G. Burnett justly observes, although “the last person a man should suffer to speak of him, is himself; for whether his words be few or many, it is likely he will be blamed for having said both too little and too much, still there are occasions, and the present appears to be one, in which such a risk should be encountered.”

There is one point to which I wish to draw your attention. The directors made it a sine qua non that the successful candidate must reside in the district. Now, a period of seven months has elapsed since the election, and Mr. Delisser has not come to reside in the parish, although he had his name painted on the door of No. 63, Judd Street; and there your correspondent is in error in stating that he had a surgery in the parish; for, would you credit it?—I went to ascertain the correctness of each item, when I found Mr. Delisser's name had vanished, the door fresh painted, and Mr. Murphy's mother residing there. Save the mark! Murphy! “Something rotten in the state of Denmark.” So Mr. Delisser, the parish surgeon, has neither house or surgery in the parish—is not a parishioner. Can any reasonable man credit it, or honest men allow such barefaced conduct to pass unnoticed; to even throw the gauntlet in their teeth, and have his own address printed on the parish orders, condemning himself, and not one out of one hundred and twenty dare enter the lists against him! Oh ye vestrymen of Saint Pancras, I am ashamed of you.

Your correspondent has been kind enough to pass an encomium on my humble professional abilities, for which I leave those of my own acquaintance who know most of me, to decide whether I deserve or not. Perhaps I may be allowed to say, if I cannot uphold the respectability of the profession to which I have the honour to belong, I will endeavour not to disgrace it; for as we daily see the profession endeavouring to bring themselves into public contempt,

must it not necessarily follow that the community at large will take advantage thereof?

Yours very truly,

HENRY BIRD.

15, Southampton Terrace, Kentish Town.

May 11th, 1835.

Hospital Reports.

WESTMINSTER HOSPITAL.

Lupus.

SOPHIA BORNHOYD, aged 21, was admitted, March 18th, into Percy Ward, under the care of Mr. W. B. Lynn; having disease of the lips and face, of two years' duration. She has of late lived at home with her parents, her father being coachman to a private gentleman. She is of a pale, delicate, leucophlegmatic habit, and possesses many of the marks of the strumous diathesis, which, however, does not appear to have ever developed itself in any of its ordinary forms of actual disease; she says that she never has had any inflamed or enlarged glands, nor do any cicatrices appear, to contradict the statement. Neither does it appear that she has ever laboured under any constitutional disease, as syphilis; and her general health appears to have been tolerably good. She is, however, the subject of amenorrhœa emansionis, the catamenia only having been noticed five or six times. There is also leucorrhœa generally present.

She states that six years ago, a hard roundish tumour, about as big as a pea, appeared in the inner angle of each eye, for which she was an out-patient at the St. George's Infirmary, Grosvenor-square, where they were extirpated by Mr. Heaviside. The cicatrices are still very distinct. She has a very troublesome degree of deafness, under which she has laboured about two years. It is about the same period of time that the disease for which she has been now admitted into the hospital first appeared, in the shape of fissures of the epithelium covering the prolabium of both lips, but especially the under one. This has gone on progressively increasing, until it has formed a hardish tumour involving both lips at their left commissure, extending inwards upon the mucous membrane, and outwards upon the skin. The surface of this tumour is ulcerated, and secretes an ichorous discharge, frequently also bleeding, and that especially when irritated. It is attended with slight pain, which is aggravated by being touched; around the margins of the sore, thin crusts occasionally form. There is likewise a tubercular eruption on the face, consisting of partially distributed largish flat papular-shaped tubercles of a reddish livid hue. A rather large spot has within a few weeks appeared on the columna nasi, which appears disposed to spread and ulcerate. During the course of the progress of this

affection, she has been several times a patient of Dr. Roe's at the old hospital, and on one occasion was admitted into the house, without, however, the progress of the disease being checked. Since her admission on the present occasion, Mr. Lynn has only directed a few aperient remedies, which he hoped might have been sufficient.

25th. Since last report she has been transferred to the care of Dr. Roe, and removed to Tillard Ward; and Dr. Barham, the gentleman who now fills, with credit to himself and advantage to the institution, the office of clinical assistant, and under whose more immediate care the patient falls, it appears has at once recognised the case as a distinct specimen of lupus. She is at present suffering under a slight diarrhœa, for which she is taking a chalk mixture, with aromatic confection.

28th. The diarrhœa has been relieved, and the following lotion has been directed to be applied to the ulcerated surface.

Rx. Iodini ℥ij;
Potassæ hydriodatis, 3 ij;
Aquæ 3 j.

M. Ft. lotio.

31st. The iodine lotion has been discontinued, as it causes considerable pain. The affected part of the lip is much the same, but if any thing rather more tumid.

April 2nd. Much the same; the following have been prescribed:

Rx. Argenti nitratis, gr. xvj;
Aquæ destillatæ, 3 viij.

M. Ft. lotio.

Rx. Iodini gr. x, in balneum inficiatur, et postea ægra estimmergenda.

April 8th. The pain, tumefaction, and ulceration of the lips are all more extensive at present than they were at the last report, and there appears to be a more irritable condition of the parts affected. The spot on the columna nasi has also extended. Persistat.

14th. Remains much the same; she has been directed to omit the lotion and bath last prescribed, and merely to employ the oxide of zinc as a dry application.

18th. The disease appears to be somewhat increased, and there is more bleeding and glairy secretion from the ulcerated surface. She has had a little nausea, and has been ordered for it as follows.

Rx. Ext. colcynt com. gr. x.
Ft. pil ij, h. s. s.;
Rx. Acid hydrocyanic gtt. xvj;
Aquæ, 3 viij.

M. Ft. Mist.

Capt. cochl. ij o. 4ta hora.

22nd. Much as before; she has been ordered as follows.

Rx. Decocti sarsaparillæ, Oj;
quotidie sumend.

25th. Some amendment is perceptible since she has been taking the sarsaparilla, which she continues; there is an evident diminution of both the tumefaction and pain.

30th. The swelling daily becomes less, and the surface less irritable, as indicated by its gradually putting on a more healthy character, and by the cessation of the bleeding. She leaves the hospital on Tuesday next, (the taking-in-day) as change of air is thought likely to be of service to her. She continues the use of the sarsaparilla.

Retention of Urine from extraordinary Chronic Enlargement of the Prostate, with extensive Disease of the Entire Urinary System.

MATTHEW INIS, aged 70, was admitted April 18th into Northumberland Ward, under the care of Mr. W. B. Lynn, suffering under retention of urine. On the day of his admission Mr. Lynn passed a catheter, after some trouble, which afforded him great relief by evacuating the bladder; but the next morning the accumulation of urine was so great as to give him great distress, and Mr. Lynn, after many trials, could not succeed in passing the catheter. After having recourse to various expedients, Mr. Lynn regarded the puncture of the bladder as the only resource; and proceeded to do it from the rectum. He did not persevere in this, however, from the immense size of the prostatic tumour, which would have rendered such an operation worse than useless. Recourse was now again had to the catheter, various modifications of which were tried; but from the existence of false passages in the urethra, and the great barrier at the neck of the bladder, these were for a long while ineffectual. Mr. White, who arrived at this juncture, was requested to assist, but for a long time his endeavours were no more successful. At last, however, in a happy moment, and by a dexterous manœuvre, he succeeded in introducing the instrument, and in this way a large quantity of turbid offensive urine was evacuated from the bladder. The instrument subsequently required to be introduced twice daily, and the same description of urine was always obtained, mixed occasionally with ropy mucus.

The progress of the case, we are sorry to say, we cannot record minutely; but the system became gradually affected by the local disturbance; his tongue became furred and dry; his countenance anxious; appetite bad; pulse feeble; and he fell into a low semi-comatose state, from which he was only with difficulty roused, so as to enable any answers to be obtained from him. In this way, gradually sinking, he died on the 29th. He was bled soon after his admission, which gave rise to a rather severe attack of erysipelas of the arm, which threatened to extend to the trunk, but its progress was checked effectually by the plan of treatment which Mr. Snowdon, the house-surgeon, adopted. The inflammation was relieved by the poppy fomentation, and its further extension prevented by the application of nitrate of silver around the limb, at

the shoulder and wrist, so as to completely encircle the limb in both situations.

Inspection of the Body 30 hours after Death:

The head was not examined.

In the thorax there were found slight pleuritic adhesions, which being readily torn through, were evidently of recent formation.

There was very extensive concentric hypertrophy of the left ventricle of the heart, as shewn by making a transverse division of the organ, which exhibited a scarcely apparent cavity, surrounded by its firm fleshy parietes, of at least an inch and a half in thickness. The right side of the heart was quite unimplicated in the hypertrophy, and its ventricular cavity was seen extended, in the shape of a narrow interstice, over the hypertrophied substance of the left. In the right ventricle, and extending into the sinus of the aorta, was found a large coagulum, which almost filled its cavity, but had no adhesions to its lining membrane. It possessed considerable firmness, had a smooth polished surface, and was of a semi-transparent yellowish colour. On cutting into it a sero-albuminous fluid of the same colour escaped. None of the valvular apparatus of the organ was affected.

The cavity of the aorta, more particularly in the situation of its transverse arch, was considerably dilated, and its lining membrane had undergone the osseous transformation on its attached surface.

The patches and granules of bone were of various sizes and shapes, occupying almost the entire surface; the lining membrane in some places appeared to have been absorbed, thus allowing their margins to project into the cavity, and giving to the touch a feeling resembling that of a rasp.

Abdomen.—The liver was somewhat congested, but in other respects healthy.

With one exception, the intestinal canal, which, however, was not minutely examined, presented nothing abnormal. There existed a small inguinal hernial sac on the right side, which most probably had contained a portion of the sigmoid flexure of the colon, which was found lying loose in the pelvic cavity. This intestine, at least, had evidently been strangulated either in this or some other way, for the extent of two or three inches; it was of a deep livid mahogany hue. Below this, the seat of stricture, it was in a highly contracted state, but above, was very much dilated, from an accumulation of flatus, so that its parietes were semi-transparent.

The mucous membrane of the rectum was found highly congested, and presented one or two spots of ecchymosis.

Urinary Organs.—The kidneys were extensively diseased: we will describe the appearances presented by the right. It was surrounded by a peculiar grey, soft adipose tissue, and adhered very slightly to its investing capsule. It was of a somewhat larger

size than natural, a great portion of its anterior surface was in a state of complete ramolissement, with intermediate points of indurated structure. In several parts the tissue had become absorbed from the ulcerative process; in others there was excessive hyperæmia; in others, again, ecchymosed spots of a livid hue, or slight fungous granulations. Although, doubtless, the changes which the organ had undergone are all referable to chronic inflammation, yet at first sight it might have suggested the idea of medullary disease. There were also one or two serous cysts, about as large as a pea. The same appearances presented themselves at the summit of the organ, but much more partially on its posterior surface. On making a section of the kidney, the disease, so apparent on its surface, was found to have involved very generally the secreting portion of its structure, and to a less extent the tubular. The calyces, infundibular, and pelvic cavities, were found considerably dilated inwards, and contained a quantity of grey diffuent matter, of a highly urinous, and, perhaps, ammoniacal smell, consisting, doubtless, of a mixture of urine and mucus, and perhaps of some pus. The mucous membrane lining the general cavity of the kidney was somewhat thickened, and exhibited blood-vessels in its texture, in an extremely congested state, especially the veins, which might be almost esteemed varicose. It was not, however, ulcerated, unless a few linear fissures, which appeared in the pelvis, could be ascribed to that source. The left kidney was similarly diseased, but not to the same extent. In the substance of the tubular portion were found several opaque, whitish spots, which the dissector, Dr. Barham, regarded as consisting of tubercular matter.

The ureters were considerably dilated, from an accumulation of the same fluid as that found in the renal cavity; they likewise exhibited similar appearances of congestion, &c. as those described to have been met with in the tissue of the pelvis. Whilst in both the ureters, the most dilated portions were situate at their upper and lower extremities, they each presented a very remarkable constriction just above the point where they descend into the pelvis, so that they each represented a double cone, having their apices united at this point.

The bladder, being opened, was found to have undergone extreme hypertrophy of its muscular coat; its mucous coat was likewise highly thickened, and of a reddish yellow colour; it was also softer than natural. It was projected by the hypertrophied muscular fibres into the cavity of the viscus, in the shape of large thick rugous elevations. The coat of the bladder varied from a quarter to half an inch or even more in thickness. The openings of the ureters were of the usual size. Projecting into the cavity of the organ, and occupying all its lower por-

tion, was found the third lobe of the prostate gland, which had acquired an immense size, being about twice the ordinary size of the entire adult prostate, when not affected by disease. It had two openings into its substance, evidently of recent formation, and doubtless produced by the efforts to pass the catheter. The lateral portions of the organ were enlarged in proportion; the tissue composing them was of a yellowish white colour, and of a consistence somewhat firmer than that of the hard medullary parts of the base of the brain. The verumontarium was also enlarged. The bladder contained a portion of a similar fluid to that met with in the ureters, but the greater part of the vesical tumour was produced by the enlarged prostate gland and hypertrophied coats of the viscus. The urethra, in its membranous and bulbous portions, was considerably inflamed, and contained three false passages, two of which were of recent date, whilst the other appeared to be of long standing, and communicated with the cavity of an abscess situate in the perineum, which contained about an ounce of pus.

—o—

MEDICAL REFORM ASSOCIATION.

To the Editor of the London Medical and Surgical Journal.

SIR—You will oblige the Medical Reform Association by the insertion of the following notice.

At a meeting of the Association, it was resolved—That the decision in regard to the prizes shall be postponed till the essays have been examined by a member of the British Parliament, who kindly promised to read them.

I have the honour to remain,

Sir,

Your obedient Servant,

JOHN EPPS, M.D.

Honorary Secretary to the Medical Reform Association.

89, Great Russell-street.

May 8th.

—o—

Re-appearance of Malignant Cholera in London.

We have been informed by Dr. Kenny, of the Strand, that he attended a fatal case of blue cholera this week, in his immediate neighbourhood. The man had rice-coloured evacuations, violent cramps, low whispering voice, cold breath and tongue, with blueness of the extremities. He expired on the third day of his illness.

—o—

CORRESPONDENTS.

Dr. Fletcher's Lectures.—We daily expect the receipt of Dr. Fletcher's valuable lectures; and we beg to assure our readers that their non-appearance is no fault of ours.

Erratum—Dr. Hooper's age was 63—not 56, as stated in our last.

THE

London Medical and Surgical Journal.

No. 173.

SATURDAY, MAY 23, 1835.

VOL. VII.

SELECT LECTURES,

FROM

M. BROUSSAIS'

Course of General Pathology and Therapeutics,
translated and revised

By JAMES MANBY GULLY, M.D.

LECTURE I.

IN a few months from this time, twenty years will have elapsed since Broussais published the first volume of his *Examen des Doctrines Medicales*. It was a forcible and ingenious method of at once shewing the weakness of preceding doctrines, and of making clear, by comparison with them, the strong position of his own, the broad physiological base on which it was founded. I say broad, for though the common cant of many who pretend to know his doctrines, is to decry them as narrow and exclusive in relation to the organs and functions of the body, I trust that those who will read the following lectures will find, as I have done, ample reason for rejecting an assertion so contrary to all that Broussais himself ever taught. And here, indeed, is one very influential motive with me in the translation and publication of the present course; myself convinced, from some considerable attention to the subject, of the strong vein of truth that runs through the doctrines in question; convinced also, that were they more intimately known to British readers, much error with regard to them would be dispelled, and much admiration of them elicited—I have not considered a system of pathology of twenty years' standing too old for an introduction to our language. To hear numbers who have never read a line uttered or penned by Broussais; who have never practised or seen put into practice his methods of cure; to hear such sneering at "the Broussain Theory," is sufficient to excite a degree of pity that would carry one through the philanthropic labour of transcribing huge tomes, did they even contain less interesting matter than these—of elucidating complex positions, did they even

VOL. VII.

boast of less precision and clearness than those taken up by the learned pathologist.

One great peculiarity in the doctrines of Broussais, or as they are collectively called, the physiological doctrine is, that they contain no single material from the systems of antecedent writers. No one can accuse him of sending forth a *rifacimento* of what had gone before him. Search them through; neither the *animus* of Stahl, the *irritability* of Haller, the *error loci* of Boerhaave, the *spasm* of Hoffman and Cullen, the *sthenia* nor *asthenia* of Brown, can be traced. He thought for himself, he thought, careless of past names and reputations, he saw that all had been in the wrong track, and gathering wisdom from their wanderings, he struck out into the high road of physiological truth, and found that it was the direct path to pathological precision. It is because he revolutionized medicine, because he undertook a demonstration of it in a way so totally different from preceding authors, and yet so harmonious in all the parts of itself, and with all that is observed at the sick bed, that his physiological doctrine quickly took root, and speedily sprang up in France. And, perhaps the very same reason may account for the tardiness and even dislike with which it is received in this country, where Cullen's *First Lines* is still a text book both with corporate examiners and students.

However caused, it is certain that a profound ignorance of the *real* propositions maintained by the followers of the physiological medicine, still exists among us. Possibly the tangible and easy form of lectures may induce many to make themselves acquainted with the facts and reasonings on which it is based. To render this more probable, I shall refrain from giving the entire course on the pathology of all the diseases comprised in the seven categories at the conclusion of the first lecture, and confine myself to those parts of it which exhibit the prominent features of the author's peculiar medical tenets. I shall also refrain from commenting on the original (as I had at first intended to do) in order that no

L L

cloud, in the shape of notes, should obstruct the light that pervades the professor's enunciation of his reasonings.

J. M. GULLY.

11, Gerrard-street, Soho, May 18, 1835.

Irritation.

The living body is irritable and contractile in all its parts in various degrees—in the nerves, the muscles, the vessels, and the cellular tissue, which is the common bond of all the organs. This irritability is manifested either by a painful or an agreeable perception, or by a movement; but first of all by a movement, for no perception can take place without certain conditions of the nervous system—conditions that are not always present. Of this question I have fully treated in my *Physiologie appliquée à la Pathologie*.

Stimulated to a certain extent by fit agents, the body acts in a normal manner, is composed and decomposed, and lives equally and harmoniously. This is the most generalized idea of stimulation, which, however, differs from irritation. Should the body be stimulated beyond this extent, or by unfit agents, its functions are deranged and become anormal, the phenomena of composition and decomposition change and deviate—it becomes morbid. If it be denied that it is in consequence of having been too much, too little, or improperly stimulated, that the body becomes diseased, I will not dispute the point; I would merely remark, that, if a morbid condition of the body is present I am only aware of it by the presence of some irritation, of some stimulation different from that which obtains in the healthy state, and to which I give the name of *irritation*; or by some diminution of the normal and usual degree of stimulation. It will be asked, why are you unable to recognise it in any but this light? Because it is the movement alone that impinges on my senses. I care not by what route the morbid cause has arrived; the disease is an incontestable fact to my understanding, only by the augmentation, the diminution, or the anomaly of the stimulation. The augmentation is an irritation, the diminution a sub-excitation, the anomaly—but this we shall see further on. Thus irritation plus, irritation minus, or anormal irritation, furnish us with the diagnosis of disease, and guide us in its treatment. This irritation will inform us, in irritative disorders, what organ is primarily affected, what secondarily, and of the action of our remedies. Those who have seen or have treated such diseases, may remember that if the remedy has been beneficial, the patient has been less irritated—if hurtful, the contrary.

In what part does irritation appear? what are the tissues in which it is exhibited?

In the first place, we see it in mobile parts—parts not env
sub-
stances. The more

vessels a part contains, the more prominent is it there, particularly if the part be situated externally. But if it be out of sight—if the primum mobile of the phenomenon we observe be invisible, as is the case in internal disorders, how are we to recognise irritation? Certainly by the phenomena it usually produces when visible, and which are, as it were, its shadow. We shall therefore begin by examining irritation as it occurs externally, in order to our familiarization with its phenomena.

But before doing this, you will perhaps desire that I should say something of the fluids. I shall be glad to do so, the more because in these days they can by no means be passed over. No modification in the solids can take place without the fluids participating in it; and while the latter are continually being transformed into solids, it is on the connexions between the two that all the secretions, normal and anormal, and all the changes of the animal materiel are dependant; besides which, when the body is in a morbid condition the fluids also are altered. But let us inquire whether these alterations, whose existence is indubitable, furnish us with the means of ascertaining the nature of disease.

The fluids may be the vehicles of morbid causes. Virusses, at least those whose existence is beyond question, and which we know by plain deduction, as the small pox and vaccine virus, enter the body by the fluids. So long, however, as they are confined to the fluids, you have no signs of disease, and their mere presence in the fluids does not constitute a disease. They enter quite as freely into the body of one who suffers in no degree from them, as into that of another whose health is thereby deranged. Will any one be rash enough to assert that they have altered the fluids of an individual before the alteration of sensation and movement have given notice of such an effect? Are there not persons whom it is impossible to infect with small pox and cow-pox?

In examining other virusses, those for instance of typhoid affections produced by putrid miasms, can it be affirmed that the blood of those, who as yet feel no disorder from it, but who nevertheless are absorbing it by every inlet, is altered, when it differs, in no respect, from reputedly healthy blood? You every day see persons who absorb the most fetid gases, who exhale such by respiration, by eructations, by flatus downwards, and by the skin, to a degree that disgusts every one near to them; and who, notwithstanding, are not diseased. That they may become so, some disorder in the action of the solids is requisite, and of this irritation is the index; then, and then only can a disease be said to exist. The same applies to all infections.

Even in plethora, a state that has been more especially advanced for the purpose of renovating the doctrines of the humoral pa-

thology, the solids alone present themselves to our senses. In fact, how would you proceed to judge of a plethoric condition, by the complexion? There are persons with a higher complexion without plethora, than others with plethora; there are persons, from being highly coloured in a former plethora, are less so, or not at all, in a subsequent one, and vice versa. Draw blood from their vessels, still you see nothing that can certify to you; for there are individuals that have an exceedingly fibrinous blood without being plethoric; and there are others again, the inhabitants of hot climates for instance, whose blood is less fibrinous, at the same time that they are decidedly plethoric. Hence it is impossible to ascertain the existence of plethora by the fluids alone.

In short, I defy you to shew me a disease that can be attested by the alterations of the fluids. This alteration cannot be affirmed to exist until the solids point it out, notwithstanding that these very fluids are capable of conveying the causes of the disease. It is, however, argued that the fluids are so far the seat of disease, that a multitude of destructive causes by their means enter the body and produce no effect until after they have been absorbed; and experiments are quoted, particularly those of the cupping-glass and ligature, which prevent the effects of poison by obviating its absorption. But in the first place it is not always the case that poisons enter by absorption. Some extremely active substances, as certain gases, act in a manner which we are unable to explain, but so suddenly as to be incompatible with the tardy pace of absorption, and the transmission of which is referred to the route of the nerves alone. There are others that derange the health by a stimulation directed immediately to some surface of relation; others again that produce an afflux, a vesication, a rubefaction, a corrosion, a burn, for instance, without the introduction of any thing into the fluids. But granting that all these poisonous substances are introduced by means of the fluids, what we have advanced is in no way thereby shaken; a movement must still indicate their action, for there is no disease nor any species of death exempt from some cry of pain, some convulsion, partial it may be, of the solids; and the movement caused by the agent, whatever it be, is not manifested until that agent has commenced its action on the nervous system.

Again, I am told "you are afraid to administer bark in intermittent fever, lest it should irritate the stomach; but it does not cure the fever by acting on the stomach but by being absorbed." But what is the gist of this? if bark will irritate the stomach, of a man having gastritis with intermittent fever, after its absorption, am I on that account to be less careful not to administer it? This very forced necessity is a fact that

proves how essential it is to look to the state of the solids in the first place. We may be assured that medicine may be both studied and practised without reference to the fluids; for, if we only succeed in re-establishing the normal modus of stimulation, the fluids return of themselves to health; whereas, if we attempt to act on the fluids alone, we shall find it impossible, for, to affect them, the remedies must first impinge on the solids; and, should they do so too vehemently, instead of regulating, they only disorder the movements of them.

To resume; without denying the alteration of the fluids in disease, and assenting to the fact that the body was in the first instance fluid; without asserting that irritation is the *only* cause of disease—a thing that I have never uttered, nor any true physiologist advanced; without denying that a morbid cause may reside in the fluids without being in any way manifested; I maintain that irritation ought to be our guide in pathology; and that we shall find incessant occasion for it as a means of diagnosis, as the rule of therapeutics, and as the index of the changes that are continually taking place in diseases; it is the torch by whose light the physician ought to proceed. This is my profession of faith on the subject of irritation.

Let us now reduce to precision our ideas on this great phenomenon, whose utility to the physician I have pointed out. Two tissues introduce irritation to us; we *must* thus attach it; for, in itself, it is only an abstraction like the hypersthenia or asthenia of Brown. Some have said that our doctrine resembled his; but this is utterly erroneous. We proceed upon the facts discovered by Haller—facts that observation has rendered fruitful, but which Brown had his own peculiar way of viewing and estimating. He made an abstract idea of irritation, and confounded it with an excess of the powers, even of the general powers of the subject; he referred to excitement without caring for either fluids or solids, just as the partizans of the humoral doctrine referred to the fluids, without bestowing a thought on the solids, through the intermedium of which their medicines were to act on the fluids.

With us, therefore, irritation is not an abstract idea.

The tissues with which the idea of irritation is connected are, first, the nervous tissues, which are divided into three sections, the central nervous tissues (brain and spinal cord); the sensitive and motor nerves; the ganglionic nerves, or the nervous apparatus of the great sympathetic; secondly, the vascular tissues, also divided into several sections; the sanguineous vascular tissues, of which the heart is the centre; the lymphatic vascular tissues, again divisible into absorbent and ganglionic tissues; the secretory and excretory tissues; the areolar or serous tissues, or those for isolating the organs.

There are also erectile tissues, whose elements are the vascular, nervous, lymphatic, and sometimes the secretory.

In each of these tissues irritation may establish itself, and in an astonishing manner disappear and emerge, change locality, and give rise to a series of phenomena, with a more detailed idea of which I shall endeavour to present you. Thus, in the nerves, irritation gives rise to pain, convulsions, exaltation of the intellectual faculties, and by progression, to their abolition or anomaly. In the sanguineous apparatus, it produces congestion of blood, increased heat of the part, alterations of the fluids and solids. In the non-sanguineous as in the sanguineous tissues, it induces congestion, but not congestion of coloured blood; there is also increase of temperature, and a morbid condition in a smaller degree than in the purely sanguineous capillaries.

It must not be hence inferred that I consider every congestion to be necessarily produced by an irritation, or that an irritation necessarily produces a congestion. Congestion may be caused by any obstacle to the movement of the fluids; and whatever the cause be that retains them in a part, these fluids almost invariably irritate in a major or minor degree. Congestion may be the consequence of a defect of contractility, in which case the consequent irritation is less. It may come on in consequence of the predominance of physical over vital laws, as is observed at the close of diseases; as the patient sinks and the power of life diminishes, that of physics and chymistry rises superior, and the decomposition of the body commences with the active fulfilment of the laws of attraction and of the affinities. This congestion by gravity is also observed in dead bodies, where it is important to distinguish it from that arising from other causes.

Now that you have a summary idea of irritation, considered locally, you must learn that it is transmitted—that, commencing at one point, it passes to others. But if you do not like this mode of expressing the fact, you may say that on the access of an irritation in one point, another irritation comes on in some other. This is a primary fact which no one can contest. Let us look for a few more. The blood put in motion by irritation, particularly by that of the heart, may accumulate in different organs; and should these be inclined to retain it, secondary congestions are formed there. The fluids that have been altered by irritation may proceed to different organs and induce an irritation in them. This happens when the venous or lymphatic radicles absorb pus or any other irritating matter from a focus of decomposition, and convey it into the system; in this case the individual, instead of being infected by others, infects himself—an occurrence observed in various

instances. When there is an irritation, certain fluids are retained in the vessels, others are effused and remain in the areolar spaces: in these, tissues become organized, are decomposed, and sometimes cause disorganization of the solids, in consequence of the aberration of the vital influence thereon. Therein also a simultaneous alteration of the fluids and solids occurs, and formidable changes follow.

Thus you may remark that irritation is the *primum mobile* of numerous phenomena.

Let us now endeavour to bring these phenomena into some precise order, and more particularly approximate them to tissues; we will take those in which irritation should be most prominent. *I do not wish to confine it to any particular tissue*, for nature bears no part in exclusive assignments. But if it cannot be said to be confined exclusively to this or that tissue, we may very frequently affirm that it predominates in the sanguineous apparatus, in the centre of that apparatus, in the coats of the vessels, in the sanguineous capillaries, in those parts, in short, where there is an excess of red fluids. This, as you may conceive, is liable to produce inflammation.

Irritation may predominate in the areolar systems, which are not sanguiferous in the healthy state, but which then become so. A phlegmon is then the consequence.

It may predominate in the tissues that have another office than that of circulation, as in the various secretory organs. It is then necessary to determine whether sanguineous irritation is uppermost, or whether that of the secretory vessels themselves predominates. In these you will have other shades of irritation, to which a specific name may be given; long ago I proposed that of sub-inflammation. By some it has been adopted, by others rejected; even the majority of the physiological doctrinists have thought proper to apply the word inflammation to the irritations that exist without predominance of sanguineous capillaries. I am by no means convinced by what has been said on this point. In order to the classification of inflammatory diseases, and especially to their treatment, it is essential to be aware that there are irritations beneath the standard of true inflammation, inasmuch as the history of inflammation, properly so called, does not include that of the sub-inflammations; and if we look only for inflammation in these disorders, we shall assuredly commit errors. It therefore becomes necessary to admit a vascular irritation that is slightly or not at all sanguineous, that in ordinary circumstances is more fixed, more tenacious of its existence than inflammation itself, and that disorganizes a part in a manner peculiar to itself. It may be also moveable. A more intimate examination of the symp-

tomatology, the anatomical characters, and the treatment of these sub-inflammations, will suffice to shew the exact subdivisions that should be made in them—divisions that I have hitherto hinted at, only in a general way.

It is evident that irritation may predominate in the nervous apparatus, as a phenomenon of inflammation, and also in another manner; for you shall see cases of insanity, after which no inflammation can be found, but instead of it, an increased density and whiteness of the cerebral substance. Thus, irritation prominent in the nervous tissues may be exhibited, either in an inflammatory or sub-inflammatory form. The same obtains in extremely complex apparatus, in such as have functions that require the concurrence of a great number of organs. In them irritation is diversified, and in time and place it may be surprised in its different shades; and the degree of activity or stimulus that would render it sanguineous or of another kind, may be ascertained. A similar remark may be made of the nervous cords.

In the nervous extremities or the nervous twigs reduced to a capillary state, there are purely nervous irritations, which cannot be referred to inflammation, which have not the same progress, and do not require the same treatment. It is in consequence of an imperfect recognition of these facts that antiphlogistics have been improperly applied; and this again has caused animadversions to be passed on the physiological doctrine, that it does not deserve.

I shall finish this lecture with a classification of diseases or a kind of nosological distribution, which I do not present to you as definitive, but which may give you an idea of the plan of this course of general pathology and therapeutics. I have endeavoured to arrange so that the principal phenomena shall be placed in the front, and those dependant on them subsequently. In this manner we shall have to study—

1. Acute and chronic inflammations. These will first be considered in the different apparatus, for there they are more easily recognised; then in the organs forming these apparatus: and lastly, in the tissues forming the organs, in which it is not always easy to distinguish them. They will then be arranged according to a degree of descending evidence, commencing with those the deduction of which is easy, and closing with those in which it is less so. The causes of these inflammations will be divided into those common to the majority, and treated of according to the five orders of hygienic materials, and into specific causes.

2. Sub-inflammations. Here the same order will be observed.

3. Neuroses. We shall have those of the nervous centres, of the nervous cords, and of the nervous capillaries. We shall divide them into neuroses consequent on inflam-

mations, and sub-inflammations, and into primitive neuroses as they arise from common or specific causes, just as in the inflammations and sub-inflammations. This distinction among the causes appears to be important, because it has been attempted to establish a class of specific affections, apart from irritations. There are, however, irritations sometimes inflammatory, sometimes sub-inflammatory, sometimes nervous, all exhibiting the same phenomena as the common, though differing in their progress.

4. Organic alterations, which sometimes become the predominating disease. These will be dwelt upon in the different apparatus, organs, and tissues, considering them in the descending order of evidence, as the effects of preceding affections (external violence included), and as primitive, or arising from unknown causes. (Vicious conformations are in this category).

5. Alterations of the fluids which are stagnant, diffuent, or disordered; stagnant in the vessels, out of the vessels, in cavities: diffuent from the vessels, secretory organs, or cavities: disorderd in the vessels, in the cavities, or the interstitial spaces. All these will be considered either as caused by the preceding affections, or by known or unknown causes independent of them.

6. Debilities; to be considered in the organic apparatus, in the organs, in the tissues, and in the entire organism, according to the degree of descending evidence, as effects of preceding affections or as primitive. In the latter character they recognise known or unknown causes, the former being similar to or dissimilar from those of the preceding affections, while the unknown remain to be discovered by analogy or otherwise.

7. Anomalies of the vital phenomena hitherto inexplicable; this is a provisional section.

As regards therapeutics or the action of the modifying, curative means, applicable to disease, this will be placed after each series of analogous affections. In this manner I think no disease will pass without investigation.

LECTURES
ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS,
FROM BIRTH TO PUBERTY.

By DR. RYAN,

*Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XXXVI.

Petechiæ—Cyanosis—Lentigo—Ephelis—Chloasma—Aurigo or Icteritia—Kironosis.

GENTLEMEN—Petechiæ are small spots of a livid red colour, formed by a drop of blood deposited in the tissue of the skin.

They are often observed in typhus, small-pox, measles, and other contagious diseases. The history of this disease is graphically given under the title Hemacelinosis, by M. Rayer, in his work on diseases of the skin, and will be noticed on a future occasion. This disease is frequently observed in adults, but rarely in infants. It affects feeble, delicate, or ill-nourished infants. The skin is dotted with a number of small round violet red spots, which are sometimes of a black colour. They arise from a diseased state of the blood, according to some; and of the capillary vessels, according to others. Petechiæ may occur with or without fever in adults and children. In the latter there is seldom any fever, but in severe cases there may be hæmorrhage from the gums, stomach, intestines, or bladder; or there may be inflammation of these organs. I have seen three remarkable examples of petechiæ in children between two and three years old, and a cure was effected by carbonate of soda saturated with lemon juice, and proper doses of quinine, with mercurial pill, as recommended by Dr. Harty, of Dublin. One of these children was declared incurable at the Middlesex Hospital, and another at the Infirmary for Children, Golden-square. I have not seen the disease congenital; but it has been observed at the Foundling Hospital in Paris, by M. Billard. He states that he had seen the disease in two new born infants, who presented a most remarkable state of debility and prostration of strength; one of these was eight days old, in whom the disease gradually disappeared, after assuming a dark, livid, and yellow colour; the other, who was younger and more feeble, died almost immediately. It was aged three days, and was admitted into the Foundling Hospital, March 27th, 1826. It was of the full size, its skin slightly jaundiced, and its lower extremities œdematous. The face, the trunk, the legs and arms, were covered with violaceous petechiæ of different sizes. Their diameter varied from a very small size to that of a lentil seed. The unequal manner in which they were disseminated, and the yellowish spaces which presented between them, gave the skin the appearance of that of a tiger. The infant remained in this state of inanition for two days, drinking some drops of milk, crying much, and respiring with difficulty. It died on the night of the 29th of March, and the body was examined next morning.

Digestive Apparatus.—The stomach was filled with a very large quantity of viscid black blood, the internal surface, as also that of the jejunum was covered with petechiæ similar to those on the external surface of the body. There were effusions of blood in different parts of the intestinal canal, and the mucous membrane corresponding to these effusions, presented petechial ecchymoses, like those of the stomach; the end of the ileum contained a blacker and more fluid blood; the large intestine

was the seat of a follicular eruption; it contained, near its extremity, a considerable quantity of blood; its parietes were thickened and firm. The spleen was extremely large, and gorged with black blood; it presented, near the insertion of the short vessels, an oblong and superficial rupture, on the surface of which adhered a clot of blood, which was solid. A large tea-cupful of blood was found in the abdominal cavity, which resulted most probably from the rupture in the spleen. The heart was very voluminous, and gorged with blood; a yellowish fluid was in the pericardium; the surface of the heart was covered with petechiæ, so were the pleuræ. The foetal apertures were free; the lungs were engorged; the kidneys and bladder presented numerous ecchymoses. The brain was the seat of great congestion.

The cellular tissue of the extremities and abdominal integuments presented large ecchymoses, and the blood which formed them was infiltrated and coagulated in the meshes of this tissue.

The state of this infant was similar to what has been often observed in the adult. The different sanguineous exhalations resulted from plethora and congestion in the respiratory and circulatory apparatus. The coincidence of the sanguineous exhalation on the internal and external surface is worthy of remark. I remember the case of a male child aged three years, who was a patient at St. John's Hospital, under my care, in whom the symptoms and morbid appearances were precisely similar to the preceding; but in this case there was effusion of blood on the base of the brain.

The treatment consists in the use of vegetable acids, on the principle of its being nearly allied to scurvy and purpura; and according to Dr. Stevens (*Treatise on the Blood*), of saline remedies. He advises muriate of soda, nitrate of potass, tartarized soda, and the carbonate of soda, saturated with lemon juice. The following formula was recommended by Dr. Stevens during the malignant cholera of 1832, which some declared to be efficacious and others useless.

Muriate of Soda, 1 drachm; carbonate of soda, 1 scruple; oxymuriate of potass, 7 grains—to be given in a wine glassful of water every quarter of an hour.

Mr. Cameron declares, in his work on diet, that Dr. S. plagiarised from his report sent to the Navy Board in London, in which he gave many cases of scurvy cured by nitrate of potass; and he further added that the patients became of a florid complexion by the use of this remedy. It has been given in barley-water, whey, &c., in fevers, from time immemorial, and its antiseptic power in preserving animal food is too well known to require further notice.

M. Billard advises to leave hemacelinose or petechiæ to nature; but when there is well marked sanguineous congestion, then leeches should be applied over the affected part.

Cyanosis—Lentigo—Ephelis—Chloasma.—There are other alterations in the colour of the skin, which may be congenital. Cyanosis or blueness of the skin is sometimes observed, and is caused by the want of obliteration of the foramen ovale, or foetal opening between the auricles of the heart. This defective organization of the heart allows the intermixture of the venous and arterial blood, and causes a dark, dusky, indigo, leaden, or blue colour of the skin. The coloration may be general, or very slight when the aperture is small, and life may be continued to an indefinite period; but the general health will be delicate, with a peculiar coldness of body. This coloration may continue for life, or gradually diminish and disappear by the complete closure of the foramen ovale. There are various other spots, such as the different varieties of lentigo (freckles), ephelis (tan or sunburn), chloasma or hepatic spots (*maculae hepaticae*), which may be congenital, though they usually appear at later periods of life.

Aurigo—Icteria—Congenital Jaundice.—M. Baume relates a case of an infant (*Mémoire couronné par l'ancienne faculté de Médecine de Montpellier, Obs. 10*) whose mother was affected with jaundice; it likewise was affected with the disease, and which augmented after birth. This infant died at the end of four weeks, and at the autopsic examination the choledic duct was found obstructed by a viscous and yellow matter; the liver had contracted some adhesions at its left lobe; the right lobe was almost obstructed and hard.

M. Desormeaux describes a female infant, born at the full time, who was extremely thin and feeble. Its skin was of a yellowish green colour, like that of the surface of a hardened yolk of egg. The amniotic fluid was also of this colour, and tinged the linen cloths on which it was effused, of a yellow colour. This infant, after some time, became of a natural colour, and acquired good health. (*Loc. Cit. p. 400*). Kerkringius cites the case of a woman affected with jaundice, who was delivered, at the eighth month, of a dead infant, so yellow that it appeared like wax. On dissection, all the tissues, and even the bones, were tinged with the same colour. (*Spicileg. Anatom. Obs. 57, p. 199*).

Kirronosis.—M. Lobstein describes a disease of the embryo and foetus, which he termed *kirronose*, in which the serous and transparent membranes, as well as the nervous pulp, are stained of a fine golden yellow colour, which cannot be removed by boiling, or maceration in water or alcohol. It is only the action of light that renders it pale, and causes it gradually to disappear. The cause of this coloration is unknown. (*Mémoire sur la Kirronose Report. d' Anatomie, t. i, p. 28*). M. Billard describes four cases in which the brain and spinal marrow were of an intense yellow colour; two in

which this colour was in isolated spots, and three in which the spinal marrow was yellow and uniform. In these last there was general jaundice of the integuments. (*Traité des Malad. des Enfants, 1834*). He also remarks that Lobstein observed the yellowness of the spinal marrow before the possibility of the secretion of bile.

This Professor has met with another kind of jaundice, consisting of an infiltration of a yellow fluid in the cellular tissue of the skin, muscles, and organs, the effect of a complete disorganization of the cerebellum in a full grown foetus, which died and was examined a few hours after birth. It is worthy of observation that it manifested marked signs of muscular irritability and contractility seven hours after death.

The foetus was born after a natural parturition of six hours. It was small for an infant at the full period; very yellow over the whole of the body; it had excoriations on the face, and the epidermis of the feet and hands was elevated. The intestinal tube was moderately filled with a yellow albuminous fluid, and there was no meconium. The liver was of the ordinary size; the gall bladder contained a green thin matter. The spleen was very voluminous, three inches in length, and one and a half in breadth. The urinary bladder was half filled with a yellow albuminous fluid resembling that contained in the intestines, and had its membrane spotted with purple red patches, resembling petechiae. The umbilical arteries and veins were contracted, and their walls thicker than in the ordinary state. The lymphatic vessels of the chest were very apparent: some of them appeared distended with a yellow fluid; the conglomerate glands were equally yellow and semi-transparent. The tunics of the arteria innominata and the right carotid artery were strewed with the same purple spots as the vein. They were not effaced either by ablation or by scraping the vessel. An incision of the teguments of the head being made, there was found the remains of a tumefaction of the scalp. Under the cranium were observed, 1st, a yellow lymph effused between the pia mater and the cortical substance, which extended upon the surface of both hemispheres; 2nd, a collection of blood in two points of the brain, one behind the right frontal protuberance, the other under the left parietal protuberance; 3rd, there was little blood in the vessels of the brain, or in the sinuses of the dura mater, and there was no water in the ventricles; 4th, the external layer of the cerebellum was of a deep red colour, about a line in thickness, which, being incised, presented a total disorganization of the substance of the cerebellum, which was changed into an albuminous matter, thick, of a yellow colour, and like the yolk of an egg, which had been beaten up. The medulla oblongata, the nerves which belonged to it, as well as the spinal

marrow, did not present any extraordinary appearance; nevertheless, between the dura mater and the laminae of the vertebræ was found a yellow lymph resembling that which was effused upon the hemispheres of the brain. The muscles, in general, were pale, inclining towards a yellow colour; they presented, as well as the right cavities of the heart, marks of a very intense irritability. The interstices of the muscles, the subcutaneous cellular tissue, and especially that of the arteries, were soaked in the same yellow fluid of which I have spoken above.

This case merits attention on several accounts, and especially upon that of the alteration of the medullary substance of the cerebellum, of which there is no similar analogy in the brain of the adult; for, according to M. Lobstein, it does not resemble either encephaloid disease, or medullary sarcoma; which proves, as the learned Professor observes, that greater stress than ever ought to be laid on the study of the change of organization in the tenderest age, and that the comparative study of the diseases of the foetus and adult, would be more fecund in new and interesting results.

Some lecturers in this country deny that jaundice may be congenital. This only proves their superficial acquaintance with the records of medicine, as well as their limited observation. The disease is certainly rare, and may not have been observed by an individual practitioner; but this is no satisfactory proof that it may not or does not exist. I have seen it, and shewn the infant so affected to my pupils at St. John's Hospital, in 1834; and others may now see it in health.

M. Billard dissected eighty new born infants affected with jaundice. In four cases the brain and spinal marrow were of a deep yellow colour; the tissue of the heart, the pericardium, the pleura, the peritoneum, the conjunctiva, the mucous and peritoneal coats of the intestinal canal, the inner coat of the bladder and abdominal parietes were jaundiced. He never saw the lungs icterous, though often infiltrated with a yellow serum. The liver was generally yellow. The muscles were yellow in some cases, while the cellular and adipose tissue were perfectly white. In other examples the adipose tissue was jaundiced, without the integuments, muscles, or different organs having been affected. He states that jaundice may attack different parts in succession. In the eighty cases, there were fifty in which the liver and abdominal vessels were gorged with blood; though forty were without jaundice. In two instances only was the bile more abundant and copious than usual. This careful observer remarked, that when the skin was intensely red, and left a yellowish mark after pressure with the finger, instead of a white one, jaundice generally supervened from the third to the eighth day. He concludes, first, that jaun-

dice may be local; second, that the states of the liver and the bile vary most considerably; and the exact morbid condition of the former, which causes jaundice, is perhaps unknown; third, that the congested state of the liver or integuments does not invariably induce the disease; the cause of which is unknown. He objects to the opinion of Armstrong, Underwood, and Dewees, who make a distinction between jaundice of infants and adults, on the grounds, that in the latter, the alvine evacuations are white, the tears and different secretions are yellow, which he considers as the result of a more intense degree of the same disease.

Lastly, he advises that all cases should be left to nature; and that medicines are unnecessary, unless the cerebral, thoracic, or abdominal organs are affected. This is a general opinion with our best national, and many foreign authors; but though it is correct in most instances, it is liable to exceptions. I have repeatedly observed cases of jaundice in new-born infants, "yellow gum," which did not yield to any plan of treatment, but proved fatal; and I should not rest satisfied unless I employed mercurial purgatives in these cases. It is true that the disease generally disappears in a few days, though it may continue for weeks, notwithstanding the most active treatment. It is astonishing what large doses of aperient medicines are necessary in this disease; I have known so much as four grains of calomel and three tea-spoonful of castor oil exhibited to an infant of two days old, before the bowels were acted upon; and even much larger doses have been exhibited.

Professor Hamilton of Edinburgh has repeatedly ordered the syrup of buckthorn, which he discovered was compound tincture of aloes, in the dose of an ounce before it acted as aperient in some cases. The forty-eighth part of this quantity would act briskly on most young infants. A gentleman connected with the Royal Infirmary for Children in the Waterloo-road, informs me that he has known calomel urged to the extent of an ounce in some diseases of children, without bad effect, but with advantage.

I have recently directed your attention to a case of congenital jaundice at the hospital, which most of you have seen. The mother had laboured under the disease during the two last months of uterine gestation, or pregnancy. Her infant was born feeble and delicate, and as yellow as an adult affected with jaundice. It was drowsy and evinced a want of appetite. Its jaundice continued for six weeks. It gradually got well by the use of calomel, castor-oil, and manna; and is now as healthful an infant as any of its age.

The icterus neophytorum, or "yellow gum" of nurses is generally a slight affection, and usually yields to calomel and castor-oil; but it may prove fatal. There is no less reason why an infant should la-

bour under hereditary jaundice than under syphilis, small-pox, &c. The disease often supervenes after birth, and this owing to the improper food which is almost invariably given to new born infants, which deranges the stomach and digestive organs, including the bowels and liver, &c. It is also worthy of recollection that the skin may be of a bronze colour at birth, similar to that produced by the long use of lunar caustic or nitrate of silver in adults. It may also be preternaturally white in congenital anasarca and other dropsies.

Congenital Inflammation of the Skin.—A great diversity of opinion has long existed among physicians on the subject of congenital inflammations of the skin; some relating cases in proof of their existence, and others denying the authority of such observations. The majority of obstetricians, however, entertain the affirmative, and some able writers the negative. It has long been admitted that infants may have been labouring under syphilitic eruptions, generally of a dark or copper colour, and these are most common about the generative organs. For my own part, I am decidedly of this opinion, though others have disputed it. Among these is M. Andry, whose valuable monograph on congenital diseases I have already quoted. He argues as follows: Of all the eruptive affections, small-pox is the one which appears to have been observed most frequently on the foetus. Many authors pretend they have seen the infant born with true variolous pustules, or with cicatrizations having the greatest resemblance to those which follow this disease; others have seen infants born at the natural period or prematurely, presenting the different degrees of the variolous eruption: some of these infants died a short time after their birth, others have lived, and after their cure have presented the natural cicatrizations of small-pox. Some of these facts had been observed in foetuses whose mothers had been affected with small-pox, or exposed to the contagion of the disease during pregnancy, so that a great many authors contend that small-pox, as well as all other contagious diseases, such as measles, syphilis, &c., were transmitted directly from the mother to the foetus. Some observations appear to militate in favour of this opinion; but other facts prove that the foetus may be spontaneously affected with small-pox without the mother having experienced any symptoms of the disease during pregnancy, or having been exposed to the variolous infection; besides, many most respectable authors having denied all direct transmission of contagious diseases from the mother to the foetus, while contained in the womb; it is therefore possible to doubt of the certainty of the first opinion. It has been the same with vaccination; and here transmission has not only taken place, but in certain cases, it is said that the vaccine tubercles have been seen developed in the

same part of the foetus as the inoculation had been performed in the mother. A case proving what we are now speaking of, is related in the *Journal de Progres des Sciences et Institutions Medicales*, t. xv, p. 246. The mother had been vaccinated nine days before parturition, and the infant, of which she was confined, had upon the arm regular vaccine tubercles, in the same number and on the same points that the mother had. This would certainly be one of the strongest proofs in favour of the transmission of contagions from the mother to the foetus; but this equality of number, this same position of pustules, the information obtained from the parents and other persons dwelling in the same habitation, all strangers to medical science, desirous of the marvellous, &c., all make us doubt the veracity of this observation; moreover, if such was really the case, similar facts would take place more frequently, and it would be sufficient to vaccinate the mother to preserve the infants they carry in their wombs from contracting the small-pox, not only during intra-uterine life, but even after birth. Unfortunately it is not so; and the two very interesting cases related by the celebrated Dr. Jenner, in which two females, being vaccinated during gestation, were confined with two infants, having variolous pustules perfectly developed, prove that the foetus may be affected with variola spontaneously, and without the mother transmitting the disease to it (p). Dr. Joerg of Leipsic, in his excellent *Manual of the Diseases of Children* (*Handbuch Zum Erkennen und Heilen der Kinder Krankheiten*, 1826), has produced some very strong proofs against the direct transmission of any contagious disease whatever from the mother to the foetus (l). After having established that contagious affections can only be transmitted in three different ways, namely, by miasms, contact, and inoculation, he successively examines, if the foetus be found in a situation capable of receiving the contagion in any of these three ways. The blood, which is the only direct communication between the mother and foetus, is not capable in any disease of transmitting contagion from the individual to whom it belongs to another person; thus to communicate hydrophobia, the plague, syphilis, small-pox, vaccination, &c., it would be useless to endeavour to convey these diseases by the blood of any of the individuals affected with any of them; it must be by the saliva or pus of buboes, venereal chancres, variolous, or vaccine pustules, to which recourse should be had! (This opinion is contrary to the fact, as small-pox, syphilis, and other contagious diseases are transmitted to the foetus through the blood, or in some way at the time of procreation). Moreover, the membranes which envelope the foetus are living organs, almost similar to plants, and consequently slightly or not at all capable of isolating the foetus, but prevent

it from contracting contagion; they are even an insurmountable barrier to all kinds of miasma. It is the same with respect to the liquor amnii, in which the foetus floats, and which, in continually moistening the nasal fossæ, the mouth and apertures of the other cavities, is opposed to the entrance of every contagion or miasm into these passages. It is only when these membranes are torn, that the liquor amnii has been discharged, when the foetus is in immediate contact with the walls of the womb or vagina, that the possibility of contagion from the mother to the infant can be reasonably admitted; and in this case the mother infected with syphilis, small-pox, and other similar diseases, may transmit these diseases to her infant, but in these cases the phenomena of disease are only manifest some time after birth.

It is well known that many individuals, from causes unknown, are not susceptible of contracting the most contagious diseases, even in the most favourable circumstances for contracting them; if we consider the principle acts of the life of the foetus, and especially the respiration, the slight activity of the skin, the nullity of the brain and nerves, the absolute defect of the action of the organs of sense, &c., it will be seen that the foetus possesses in a slight degree, the faculty of receiving, by transmission, the contagious diseases of the adult age, as it does of transmitting them itself. Moreover if it can be affected by contagion in the womb of the mother, why do not the embryos and new born infants present traces of, or even the diseases with which the mother was affected? We may remark here, that infants in the first months of their existence are little apt to contract every species of contagion; and it is a received precept of the present day, that vaccination ought not to be performed until six weeks or two months after birth. Innumerable observations have shown that the skin of an infant, at this age, is little susceptible of receiving vaccine contagion.

In always not admitting any species of direct contagion from the mother to the foetus, at the same time it is impossible to deny, that if the pregnant woman be affected with serious contagious diseases, these would have a marked influence on the health and development of the foetus, from the inevitable injury which would be the consequence; it is thus that Duettel (*De morbis foetuum*, dissert. præses F. Hoffman, Italæ, in 4to, 1602, p. 26) relates a case in which a woman, a short time before her confinement, was seized with confluent variola: she produced a healthful infant to all appearance, and presenting no traces of variolic pustules, which nevertheless died of convulsions on the sixth day after its birth, and in which the intestines were found gangrenous in several points of their extent. It is my opinion that small-pox, as well as all other

diseases, may develop itself spontaneously in the foetus, the same as we see it take place in infants and adults, without having been exposed to contagion; that it may go through its different periods, during the abode of the foetus in the uterus, leave on its skin the natural cicatrizations, and in fine, that it may affect it at its birth, or cause the death of the embryo at an epoch more or less distant from its intra-uterine life. Mauriceau himself, according to the account of his parents, came into the world with the seeds of small-pox.

Some persons pretend that the foetus may be affected with measles; but without denying the possibility of this assertion, we think it would be very difficult to establish it. In other respects, the reflections we have made concerning small-pox may equally refer to the measles, as also to scarlatina, which at present has not been observed in the foetus. (*Mémoire Sur les Maladies du Fœtus et de ses Annexes. Par V. Andry, D.M.P. Journ. de Progress des Sciences et Institutions Médicales, 1830, t. 1, p. 142, &c.*)

The opinions maintained in the foregoing quotations are very easily refuted. In the first place, I shall prove, by numerous citations, that the infant in the womb may be born with the eruption of small-pox, measles, and syphilis; in the second place we have only the author's assertion that the infant may be born with small-pox, though the mother has not had the disease—an assertion in open contradiction to his doctrine, that contagious diseases are not transmissible from the mother to the infant in her womb; thirdly, he cannot reasonably deny a positive fact, that the infant, whose mother was vaccinated a few days before delivery, laboured under vaccination; fourthly, he draws an objectionable conclusion from the two cases related by the illustrious Jenner—that infants whose mothers had been vaccinated a short time before parturition were born with small-pox! because recent experiments have proved beyond all doubt that vaccination is only a modification of small-pox; fifthly, the hypothesis of Dr. Joerg is opposed to facts, as every one engaged in the practice of obstetrics is aware that the foetus in utero may be contaminated, at the moment of conception, with syphilis, though neither parent has the disease in a primary form; and several successive premature births will take place between the seventh and eighth months of pregnancy—the infants being born dead and putrid, as attested by Dr. Beatty of Dublin, Dr. Hamilton of Edinburgh, &c. (See my *Manual of Obstetrics*.) And it is also well known to observant practitioners, that infants may be born alive with copper-coloured eruptions, which will only yield to mercury, taken by the parent or the little sufferer—when a cure will be speedily effected, and the infant rapidly acquire strength and vigour, as I attest by many observations made in hos-

pital and dispensary practice. It will be admitted that the contamination of syphilis will vary in different constitutions. Some affected will have healthful infants; others will produce feeble delicate offspring, with eruptions or ulcerations on the genital organs, and when the parents are deeply infected, their infants will be born prematurely, between the 7th and 8th months of pregnancy, the body being deprived of life for some time, and putrefaction apparent. In this last case the parents cannot be cured, unless they undergo a course of mercury before the woman is again pregnant; for otherwise repeated courses may be tried in vain, as the infants will continue to be born dead, and putrid. Infants are born with ulcerations, independently of syphilis, as noticed by Hippocrates. I knew a lady who was salivated four times during different pregnancies, but she still had premature labours, and the infants were born dead, and putrid. On the last occasion she began the use of mercury, after having missed one menstrual period. I told her it was extremely likely that she was pregnant, as women affected as she was have a great aptitude for conception, and that if she was in this state, the infant would be born dead as before. My opinion was correct. I advised a conjugal separation for some weeks after her delivery, during which the husband and wife took mercury and sarsaparilla. The latter soon conceived, bore a living infant, and has now a large family. My idea was that the offspring was infected at the moment of conception; and before this, that the parents should be cured, to exempt it. I shall now adduce ample evidence that the infant in the womb may labour under small-pox or measles, and consequently under contagious diseases. Sober reflection on the following facts must convince every candid hearer of the truth of this position.

NEW REGULATIONS, APOTHECARIES'
HALL, &c.

“Quod si contemplationem legis naturæ satis comprehendissent, etiam illud scissent.”

To the Editor of the London Medical and Surgical Journal.

SIR—The regulations which you have inserted in the last number of your journal, as emanating from the collected wisdom of “Rhubarb Hall,” fully justifies the application of the censure conveyed in the motto which I have chosen for the heading above. No doubt these worthies are acquainted with Erasistratus—at least by name—and consequently I need not point out to their notice the author from whom I have quoted; but I shall merely observe that the present application is neither an overstrained or forced perversion.

It appears to me, that all the regulations

as to study, lectures, &c., have been framed by the worthy “or Worshipful” Society, as if for the mutual advantage of themselves and the Royal College of Physicians. Thus: “no lectures on the practice of physic would be received, unless—if delivered in London, or within seven miles thereof—delivered by a fellow licenciate, &c., of the College of Physicians.” The new regulations include “Materia Medica,” under the same regulation; “and both the former and the latter delivered without the bills must be by a fellow, &c., or by a graduated doctor of a British University of four years’ standing.” Now, sir, the first inquiry is, have the Apothecaries’ Company any such powers? I maintain not. In the first place, the association with the College of Physicians confers no abstract or independent right to teach medicine in any of its branches. The privileges, &c., of the College extend to the *practice* only of physic within the bills, and they have nothing whatever to do with the teaching.

The degree of doctor from a University confers the right—I mean the legal right—to teach in that faculty in which the degree has been taken; and if by *British University* be meant those of Oxford or Cambridge, although the law does not recognise the abstract right of any other to practise physic, yet I doubt if it excludes the graduates of other universities from *teaching* medicine. Now I understand the Worshipful Company have a solicitor, and lawyers of various kinds attached to their establishment; and surely it would be as well that they submitted their crude and unconcocted regulations to such salutary revision, before they exposed themselves by assuming powers infinitely greater and more arbitrary than those so unhappily granted to them by law. I will remind them of a short clause in their own act—that is, the act constituting them a corporate body: “Provided, however, that nothing herein shall be taken or construed as in any manner affecting the *rights and privileges* of the Royal College of Physicians, or of our other *Universities of Oxford and Cambridge*.” Now I ask, are not the regulations a direct and positive encroachment upon the rights and privileges of the two, and indeed of all other universities? The regulations are based upon the principle of compelling graduated physicians to associate with the Royal College, and empty their pockets into the coffers of the College. I have no hesitation in asserting, that the Court of King’s Bench would compel the Court of Examiners to admit a candidate presenting certificates from a graduate in medicine in a British University, to examination, in despite of their regulations; and I have good reason to believe, that if the Society last sufficiently long, and refuse to examine a candidate under the above circumstances, the right will be tried in the Court of King’s Bench, by moving for a mandamus. Let then this Worshipful Company consult their legal advisers before they get into a hobble;

for should matters come to issue, they will reap nothing but defeat and disgrace. I remain, &c.,
ALPHA.

London: May 14, 1835.

A NEW PRACTICAL FORMULARY

OF HOSPITALS, OR A

Collection of Formulæ of the Civil and Military Hospitals of France, Germany, Italy, Great Britain and Ireland, &c., containing the Indication of the Doses in which simple Substances, magistral and officinal Preparations of the Codex are administered, the use of New Medicines, and general precepts on the art of prescribing. By M. EDWARDS, M. D., and P. VAVASSEUR, M. D., of the Hospitals of Paris—1834. Translated and augmented by M. RYAN, M. D. &c. &c.

(Continued from p. 499.)

FORREL.

A refrigerant and antiscorbutic very much employed. [It is scarcely ever used as a remedy in this country. T.]

INTERNALLY. *Decoction.* Manip. i—ij in Oij of water.

Refrigerant and Diuretic Juices. P. ʒj—iv in the morning.

HERB BROTH.

Rx. Acetosellæ,
Pyri,
Chærophylly,
Lactucæ com., ā ā manip. j;
Butyri,
Sodæ muriatis, ā ā q. s.
Aquæ, Oij.

Coque et cola.

A small cupful at a time, to facilitate the action of purgatives.

[Common barley-water or oatmeal-tea would perhaps be as efficacious. T.]

ORANGE JUICE very much resembles that of Lemon, and, like it, is used to prepare a Sirop, P., which is employed as a refrigerant.

WHITE and RED GOOSEBERRIES, MULBERRIES, CHERRIES, RASPBERRIES, the POMEGRANATE, &c., are also employed to prepare refrigerant drinks. Syrups, which are in constant use, are likewise prepared from them.

CHAPTER XV.

MEDICINES EMPLOYED AS EMOLLIENTS.

GUM ACACIA.

AN emollient which is very much used in cases of gastritis, phlegmasia of the air passages, &c., and which enters into the composition of a great number of officinal preparations.

INTERNALLY. *Powder.* ʒss—ʒj, in a potion.

Solution, ʒss—j to Oij of water.

The *Eau de Gomme* of the H. de Paris contains ʒss of gum to the same quantity of water.

Mucilage of Acacia Gum. P. ʒss—j, frequently during the day. This preparation is generally used as a vehicle for other medicines.

Gummy Alkaline Powder, or Vegetable Soap. P. ʒ of acacia, ʒj of carb. potass. Gr. xij—ʒj, and more.

Pâte de Gomme Arabique. P.

Sirop. P. ʒj, and more, to sweeten emollient drinks.

Ptisaniferous Powder. H. of Montp.

Rx. Gum. acaciæ,
Extracti glycyrrhizæ, ā ā ʒij;
Potassæ nitratis, ʒij.

A tea-spoonful in a glass of water.

Gumous Potion. H. de la Ch.

Rx. Gummi acaciæ, ʒj;
Aquæ, ʒij;
Syrupi simplicis, ʒj.

Misce.

Gumous Emulsion. H. of Germ.

Rx. Gum. acaciæ, ʒss;
Emulsionis, simplicis, ʒxij;
Aquæ, q. s.

Misce.

ʒij—iv to be taken frequently during the day.

Calmant Potion. H. of Italy.

Rx. Gum. acaciæ, ʒj;
Aquæ destillatæ, ʒss;
Syrupi althææ, ʒjss;
Decocti hordei, Ojss.

Misce.

The dose is half a glassful. Used in nephritic colic.

Mucilaginous Mixture. H. of Eng.

Rx. Mucilaginis acaciæ, ʒvij;
Misturæ gum. acaciæ, ʒij;
Aquæ destillatæ menthæ, ʒv;
Syrupi simplicis, ʒj.

Dosis ʒij ter in die.

Simple Looch. H. des Ven.

Rx. Acaciæ gum.,
Sacchari, ā ā ʒij;
Aquæ, ʒv.

Misce.

Employed as an emollient and excipient for other medicines.

GUM TRAGACANTH.

It possesses the same properties as gum acaciæ, and is employed in the same cases. It is also used to give a consistence to certain preparations, and to suspend certain insoluble substances in water.

INTERNALLY. *Powder.* Gr. x—xv, in a potion of ʒiv.

Mucilage. P. ʒj—ij.

Compound Powder Gum Tragacanth. H. of England.

Rx. Gum. tragacanthæ,
— acaciæ,
Amyli, ā ā ʒjss;
Sacchari, ʒij.

Misce.

ʒss—ij in an aqueous vehicle.

MARSH-MALLOWS.

An emollient very much employed, both internally and externally, in the treatment of phlegmasia. [Seldom used in this country. T.]

INTERNALLY. *Decoction or Infusion*, \mathfrak{z} j to Oj of water.

The *Infusions of Marsh-mallow* of the Hôt. D. and de la Ch. do not differ from the above preparation.

Sirop. P. \mathfrak{z} j—ij, to sweeten emollient drinks.

Tablettes de Guimauve. P.

Mucilage of the Root of Marsh-mallow. P.

Infusion of Marsh-mallow. H. Militaires.

Rx. Althææ, \mathfrak{z} ij;

Glycyrrhizæ, \mathfrak{z} j;

Aquæ, Oijss.

Decoque ad Oijss et cola.

A small cupful taken at a dose.

EXTERNALLY. *Decoction*. In lotions, fomentations, local baths, &c.

Emollient Collyrium. H. des Enf.

Rx. Radicis althææ, \mathfrak{z} j;

Aquæ, Oss.

Decoque et cola.

Employed in acute ophthalmia.

Calmant Gargle. Hôt. D.

Rx. Decocti althææ, \mathfrak{z} vj;

Syrupi mellis, \mathfrak{z} ij.

Misce.

Employed in inflammatory angina.

The *Gargarisme de Guimauve* of the H. de la Ch. does not differ from the preceding.

Calmant Fomentation. H. of Germ.

Rx. Foliorum althææ, manip. iv;

—— papaveris, manip. j;

—— hyoscyami, pug. ij;

Aquæ, Oj.

Decoque et cola.

Emollient Enema. H. de la Ch.

Rx. Radicis althææ, \mathfrak{z} j;

Aquæ, Oj.

Decoque et cola.

MALLOW (LEAVES AND FLOWERS).

They possess the same properties, and are used in the same manner, and in the same cases as the marsh-mallow.

INTERNALLY. Flowers. *Infusion or Decoction*. Pinc j—ij to Oij of water.

Pectoral Ptisan. F. A small cupful at a dose.

Infusion of Marsh-mallow. Hôt. D. and H. de la Ch.

Rx. Florum malvæ, \mathfrak{z} ij;

Aquæ ferventis, Oij.

Decoque et cola.

A small cupful at a dose.

EXTERNALLY.

Fomentation of Mallow. H. de la Ch.

Rx. Fol. malvæ, \mathfrak{z} j;

Aquæ, Oj.

An emollient.

Calmant Gargle. H. de la Mat.

Rx. Infusi florum malvæ, \mathfrak{z} iv;
Lactis recentis, \mathfrak{z} i.

M.

BORRAGE (LEAVES AND FLOWERS).

Borraga is an emollient, diuretic, and sordific, much employed in a number of inflammatory affections.

INTERNALLY. *Decoction and Infusion*. Manip. j—ij to Oij of water.

The *Decoction of Borraga* of the Hôt. D. and de la Ch. contains \mathfrak{z} ij of the flowers of borraga to the same quantity of water.

Expressed Juice. P. \mathfrak{z} ij—iv.

Distilled Water. P. \mathfrak{z} ij—iv, as a vehicle for diuretic potions.

Extract. P. \mathfrak{z} j— \mathfrak{z} j.

Infusion of Borraga. P. (\mathfrak{z} j—Oj, honey \mathfrak{z} j.) A cupful at a dose, taken hot.

COMFREY.

An emollient not much employed at the present day. Formerly very much used in hæmorrhagies from the lungs, intestines, &c.

INTERNALLY. *Decoction*. \mathfrak{z} ss—j in Oij of water.

The *Decoction of Comfrey* of the Hôt. D. contains the latter quantity.

Sirop. P. \mathfrak{z} j—ij, in a potion, or to sweeten calmant drinks.

LIQUORICE.

Liquorice is a pleasant demulcent, principally employed to sweeten ptisans in the hospitals. The powder is used as an excipient for other medicines, and to envelope boluses and pills.

INTERNALLY. *Powder*. Gr. xvij— \mathfrak{z} j. Not much employed.

Infusion. \mathfrak{z} ij—iij in Oij of cold water.

Extract. P. \mathfrak{z} iv— \mathfrak{z} i.

Pâte. P. q. s. A popular remedy for colds.

Pâte de réglisse anisée. P. q. s.

COCOA.

A nutritive emollient; constantly used as an analeptic aliment. The oil concremented is employed as a calmant, in phlegmasia of the pulmonary and urinary organs. Externally it is applied to hæmorrhoidal tumours, chaps of the nipples, &c.

INTERNALLY. *Simple Chocolat*. P. As an aliment and an excipient for other medicine.

Chocolat à la Vanille. P. The same usages.

Oil or Butter of Cocoa. P. \mathfrak{z} j—ij, in an emulsion, or in pills.

Pectoral Cream de Tronchin.

Rx. Butyri cacao, \mathfrak{z} ij;

Syrupi tolutani,

—— capillaris,

Sacchari, ā ā \mathfrak{z} i.

Dosis cochl. mag. subinde.

EXTERNALLY.

Emollient Suppositorium.

Rx. Butyri cacao,
Cerati simplicis, ā ā p. e.

Cerat Employed in Chaps of the Lips.

Rx. Butyri cacao,
Cere albæ, ā ā partem unam;
Olei amygdalæ, partes duas.

Misce.

LINSEED.

An emollient very much employed. It is administered internally in phlegmasia of the urinary organs; also in inflammatory affections of the lungs, &c. It is the most common of emollient cataplasms.

INTERNALLY. *Decoction*, 3 ss—j in Oij of water.

Mucilage. P. 3 j—3 ij.

Infusion of Linseed. Hot. D. and H. de la Ch.

Rx. Lini semin. contusorum, 3 ij;
Glycyrrhizæ radicis, 3 j;
Aquæ, Oij.

Decoque et cola.

A cupful at a dose, taken hot, in inflammatory affections of the urinary system and air passages.

Compound Decoction of Linseed.

Rx. Infusi semin. lini, Oij;
Potassæ nitratis, 3 j;
Mannæ, 3 j.

A cupful to be taken at intervals.

EXTERNALLY. *Decoction*. In lotions, fomentations, &c.

Emollient Catapasm. P. q. s.

Calmant Enema. Hot. D.

Rx. Lini seminum, 3 ij;
Aquæ, Oij.

Decoque cola et adde,

Olei olivæ, 3 ij.

The *Emollient Enema* of the H. de Paris consists of ʒij of linseed.

The *Enema of Linseed* of the H. des Enf. contains 3 ss of linseed to Oj of water.

Emollient Fomentation. H. de la Mat.

Rx. Lini seminum, 3 j;
Florum malvæ, 3 j;
Aquæ, Oj.

Decoque et cola.

Employed in cases of abdominal inflammation, and in inflammatory œdema, which frequently takes place after parturition.

Emollient Catapasm. H. de Paris.

Rx. Farinæ lini,
—— hordei, ā ā p. e.
Aquæ, q. s.

Boil to a proper consistence. It is applied to inflammatory tumours, and upon the uninflamed skin, in cases of phlegmasia of the surrounding parts. It is likewise applied to keep up a flow of blood after the application of leeches.

LINSEED OIL.

Linseed oil is an emollient, and slightly laxative. It is not much administered in-

ternally, on account of its disagreeable flavour. It is used externally in enema, embrocations, &c.

INTERNALLY. 3 ss—j, in broth.

EXTERNALLY. In ointments, embrocations, and as an excipient for divers liniments. q. q.

[The lin. calcis (equal parts) of linseed oil and lime-water is a favourite remedy for burns and scalds in this country. T.]

Emollient Enema. H. of Germ.

Rx. Specierum emoll. 3 j;
Aquæ, Oj.

Coque, cola et adde,

Olei lini, 3 ij.

M.

SWEET ALMONDS.

Sweet almonds are frequently employed in the form of an emulsion, to combat internal inflammation.

INTERNALLY. *Milk of Almonds*. P. 3 ss—j frequently during the day.

Looch Blanc. P. A spoonful at a dose.

Sirop d'orgeat. P. 3 ss—j, to sweeten emollient and diuretic drinks.

Emulsion of Sweet Almonds. H. of Paris.

Rx. Amygdal. dul. 3 ss;
Aquæ, Oj;
Syrupi simplicis, 3 j.

Misce.

A small cupful to be taken at a dose.

Emulsive Ptisan.

Rx. Amygdal. dul. 3 j;
Avenæ sativæ, 3 iij.

Tere simul et adde,

Decocti hordei, Oij;

Syrupi violæ, 3 ij;

Aquæ cinnamomi, 3 iv.

M. *A small cupful at a dose.*

White Looch. H. St. Ant.

Rx. Amygdal. dule. No. xv;
Tragacanthæ pulv. gr. xx;
Syrupi simplicis, 3 ij;
Olei amygdalarum,
Aquæ flor. aurantii, ā ā 3 ij;
—— fontanæ, 3 iv.

Misce.

A spoonful at a dose.

Emulsive Looch. H. des Enf.

Rx. Emulsionis amygdalæ, 3 iv;
Syrupi simplicis, 3 j;
Tragacanthæ, gr. vi.

Dosis cochl. mag. sæpe in die.

OIL OF SWEET ALMONDS.

In large doses almond oil is a laxative; in small quantities an emollient. It is employed in pulmonary inflammation. This oil is used as a laxative to purge children and persons of a delicate constitution.

INTERNALLY. 3 ss—j, mixed with a syrup, or with the yolk of an egg.

Looch sans émulsion. P. A spoonful at a dose.

Lo

The same doses.

Oleagenous Potion. H. de la Ch.

Rx. Olei amygdalæ, ʒ ss;
Gum. tragacanthæ, gr. x;
Syrupi simplicis, ʒ i;
Aquæ, ʒ ij.

Dosis cochl. mag. urgenti tussi.

The *Looch Blanc* of the H. des Enf. differs only from the preceding potion in the tragacanth being replaced by ʒ ij of acacia gum, and the quantity of water being ʒ iv.

The *Looch Simple* of the same hospital contains ʒ ij of almond oil, and the same quantity of simple syrup and of water.

Oleagenous Potum. Hôt. D.

Rx. Infusi bechic.,
Olei amygdal. dul., ā ā ʒ ij;
Syrupi simplicis, ʒ j.

Misce.

Employed in inflammations of the chest, to calm the cough.

The *Oleagenous Potion* of the H. des Enf. contains only ʒ ss of oil to ʒ iv of a gum-mous vehicle.

EXTERNALLY. In embrocations, and as a vehicle for divers liniments.

Simple Cerat. P. q. s.

Cerat of Galen. P. q. s.

Emollient Enema. H. of Germ.

Rx. Olei amygdalarum,
Sacchari, ā ā ʒ j;
Decocti hordei, Oss.

Misce.

Emollient Cataplasma.

Rx. Olei amygdalarum, ʒ ss;
Lactis ferventis, Oj;
Micæ panis, q. s.

Fiat cataplasma.

Sometimes ʒ ij of camphor is added to this cataplasma.

OIL OF OLIVES.

An emollient and laxative, employed in the same cases as the oil of almonds; very much used in cases of poisoning by certain acrid substances. This oil acts also as an anthelmintic, and enters into the composition of a great number of plasters and liniments.

INTERNALLY. ʒ ij—ʒ j, mixed with water by the aid of a mucilage.

Oleagenous Potion. H. des Vén.

Rx. Olei olivæ, ʒ ij;
Mucilaginis acaciæ, ʒ v;
Syrupi capillaris, ʒ ij.

Misce.

Dosis cochl. mag. urgente tussi.

Oleagenous Emulsion. H. of Germ.

Rx. Olei olivæ, ʒ j;
Vitelli ovi, No. j.

Tere et adjice,

Aquæ, ʒ vij.

Dosis cochl. mag.

EXTERNALLY. As a vehicle for divers liniments and enemata.

Oleagenous Enema. H. of Italy.

Rx. Olei olivæ, ʒ iij;
Decocti althææ, ʒ ix;
Mellis, ʒ j.

Misce.

Emollient Enema. H. de la Mat.

Rx. Foliorum malvæ,
—— pyri, ā ā ʒ ij;
Aquæ, Oij.

Decoque, cola et adde,
Olei olivæ, ʒ iij.

Misce.

The WHITE and NUT Oil possess the same properties, and are employed in the same diseases.

HOUSTOOTH.

An emollient and diuretic, daily employed in inflammatory diseases, especially of the urinary organs.

INTERNALLY. Decoction. ʒ ss—j to Oij of water.

Ptisan of Dog's-grass. P. A glassful at a dose. Same proportions, sweetened with liquorice.

Expressed Juice. P. ʒ ss—j.

Decoction of Houndstooth, or Common Ptisan.
H. de Paris.

Rx. Graminis canini, ʒ j;
Glycyrrhizæ, ʒ j;
Aquæ, Oij.

Decoque et cola.

A cupful at a time.

PEARL BARLEY.

An emollient in constant use in a number of acute diseases.

INTERNALLY. Decoction. ʒ ss—j to Oij of water.

Ptisan of Pearl Barley. P. A cupful at a dose.

Compound Decoction of Barley. British Hospitals.

Rx. Decocti hordei, Oij;
Caricæ fructus concisi,
Uvarum passerum, demptis acinis, ʒ ij;
Glycyrrhizæ rad. concisæ et contusæ, ʒ ss;
Aquæ, Oj.

Decoque ad Oij, et cola.

A cupful at a dose.

Decoction of Barley with Gum. H. of Germ.

Rx. Hordei, ʒ vi;
Gum. acaciæ, ʒ j;
Aquæ, Oij.

Coque, cola et adde,
Sacchari, q. s.

Misce.

A cupful at a dose.

Acidulated Decoction of Barley. H. of Germ.

Rx. Decocti hordei, Oij;
Limon. incis., No. ij.

Coque ad Oj et adde,
Sacchari, ʒ ij.

A small cupful at a dose.

EXTERNALLY. Decoction. In lotions, fomentations, injections, gargles, &c.

Farine. In cataplasms.

Resolvent Cataplasma. H. des Enf.

Rx. Farinæ hordei, \bar{z} viij;
Saponis amygdal., \bar{z} iv;
Aque, q. s.

Misce.

RICE.

An emollient and slight nutritive, much employed in inflammations of the digestive tube. [According to Dr. Tytler, deteriorated rice caused cholera in India and Europe, from the first appearance of the disease in 1817, to the last in Europe in 1833. T.]

INTERNALLY. Decoction. \bar{z} ij—iv in Oij of water.

The *Decoction of Rice* of the Hôl. D. and de la Ch. do not differ from the above in their proportions. This decoction is frequently diluted with the decoction of catechu, and sweetened with quinces. It is then employed in cases of diarrhœa, &c.

Acidulated Decoction of Rice.

Rx. Pulveris oryzæ, \bar{z} j;
Aque, Oiv.

Decoque, cola et adjice,
Syrupi hordei, \bar{z} ss;
Succi citri, \bar{z} j.

Misce.

A cupful at a dose.

OATMEAL.

It possesses the same properties as the preceding substances. Much employed in diseases of the chest.

INTERNALLY. Decoction. \bar{z} ij—iv to Oij of water. This decoction, which is commonly called *Eau de Gruau*, is often diluted with milk, and sweetened with the syrup of gum. An infusion (oatmeal tea) is drank to facilitate the operation of purgatives.

STARCH.

The same properties and usages as the above. More employed externally in enemata than internally.

EXTERNALLY. Decoction. \bar{z} ij—iv to Oij of water, in an enema.

Mucilage of Starch. H. of England.

Rx. Amyli, \bar{z} iij;
Aque, Oj.

Rub the starch, gradually adding the water to it; then boil till a mucilage is produced. In clysters. In some cases laudanum is added.

Starch Enema. M. de Santé.

Rx. Decocti amyli, \bar{z} v;
Olei lini, \bar{z} j.

M.

Starch Enema. H. des Enf.

Rx. Amyli, \bar{z} j.
Aque, Oj.

Boil.

DRIED RAISINS, FIGS, DATES, and JUJUBES, are known under the name of *Pecti-*

ral Fruits, and are frequently employed as emollients in diseases of the chest.

INTERNALLY. The pulp of the Date. P. q. q.

Pâte de Dattes. P.

PRUNES possess the same qualities, and are likewise laxative. A decoction of them is employed to purge children.

The seeds of GOURD, MELLON, and CUCUMBER are known under the appellation of *Semences froides majeures*. They are employed to prepare emulsions, which have the same properties as the milk of almonds.

HEMP SEED is employed in the same manner.

Cow's and ASSES' MILK are employed as emollients and slight nutritives in diseases of the chest, either pure or diluted with barley water. (*Hydrogula* of the H. de la Ch.)

WHEY is a refrigerant and emollient. It is employed in inflammatory diseases. It is generally used as a vehicle for other medicines.

GELATIN is used to prepare emollient and strengthening baths. It is the basis of the *Gelée de corne de cerf*, P., and is used in many other preparations.

VEAL, FOWL, TURTLE, FROGS, VIPERS, and LOBSTERS, are used to prepare emollient broths, which are employed in cases of acute disease.

Bouillon de Veau. P. A cupful at a dose.

Bouillon, or Eau de Poulet. P.

Bouillon de Colimacons. P.

Bouillon d'écrevisses. P.

Bouillon de Vipères. P.

Sirop de mou de Veau. P. \bar{z} j—ij, in pectoral drinks.

The *Espèces Emollientes*, P., are equal weights of the following ingredients:—

Dried leaves of Mallow,
————— Marsh-mallow,
————— Mullein,
————— Groundsel,
————— Pellitory.

The *Espèces Béchique*, P., are composed of equal parts of the flowers of the following:

Dried flowers of Mallow,
————— Amaranth,
————— Coltsfoot,
————— Red poppies.

The *Espèces Béchique*, composed of fruits, are equal parts of the following:—

Dates,
Jujubes,
Figs,
Raisins.

The *Espèces Pectorales*, P., are composed of equal parts of

Dried leaves of Maidenhair,
————— Veronica,
————— Hyssop,
————— Ground-ivy.

These preparations are administered in form of decoction, \bar{z} j to Oij

CHAPTER XVI.

MEDICINES EMPLOYED AS CAUSTICS, RUBEFACIENTS, AND EPISPASTICS.

CAUSTIC POTASS.

A VERY energetic caustic, leaving a soft, greyish eschar, which is easily detached. It is employed to establish setons, to open cold abscesses, or, accompanied with induration of the neighbouring parts, to cauterize envenomed wounds, &c. It acts internally as a corrosive poison; nevertheless, it is administered, very much diluted, in gravel, nephretic colics, and other affections dependent on a superabundance of uric acid. It is likewise recommended in the treatment of scrofula and some diseases of the skin, such as leprosy, &c.; but this solution, although much diluted, speedily oppresses the stomach, and causes anorexia; which prevents its use for any length of time.

INTERNALLY. *Solution of Potassa.* P. Gut. v—xx, in a potion.

Alcoholized Solution of Potassa. H. of Germ.

Rx. Potassæ causticæ, 3j;
Alcoholis, 3 viij.

Liqua.

The dose is gut. xx—xl, in a mucilaginous potion, as a diaphoretic, &c.

EXTERNALLY. As a caustic. The manner of applying it is by placing a very small portion in an aperture cut in adhesive plaster, just sufficiently large to cover the part only that is intended to be cauterized. The whole should be covered with another piece of sticking plaster.

Collyrium de Gimberant. H. of Germ.

Rx. Potassæ causticæ, gr. j;
Aque destillatæ, 3j.

Misce.

Stimulating Lotion of Saviard. H. of Germ.

Rx. Potassæ causticæ, 3ij;
Camphoræ, ʒij;
Sacchari, 3ij;
Aque, Oij.

Dissolve.

Employed in the treatment of atonic and fungous ulcers.

CAUSTIC SODA.

The same properties as the caustic potassa. Not much employed.

EXTERNALLY.

Pommade employed in Tinea. H. St. L.

Rx. Sodæ causticæ,
Sulphatis potassæ, ā ā 3ij;
Adipis, 3ij.

Reduce the soda and the sulphate, and incorporate them with the lard.

Employed in frictions on the diseased head, after the scabs have been removed by means of

VOL. VII.

cataplasms, and the hair cut short; the head should then be covered with blotting paper.

PROTONITRATE OF MERCURY.

A very energetic caustic; employed in tetters, cancerous ulcerations of the skin, and even those of the neck and of the breast.

Solution of the Protonitrate of Mercury. H. St. L.

Rx. Hydrarg. proto-nitratis, 3j;
Acidi nitrici, 3 viij.

Dissolve.

It is applied by means of a small brush, and the part cauterized covered with lint which has been also imbibed with the caustic.

CHLORIDE OF ANTIMONY (BUTTER OF ANTIMONY).

A caustic, whose action is prompt and energetic. It is often employed to cauterize narrow and sinuous wounds, such as the bites of enraged animals.

It is applied by means of a camel's hair pencil, or by lint. Care should be taken to absorb the blood before it is applied, as that liquid rapidly decomposes it.

THE IMPURE ACETATE OF COPPER—VERDIGRIS.

A caustic, employed to suppress fungous flesh, and to destroy syphilitic excrescences, &c.

EXTERNALLY. The surface of the wound should be sprinkled with a small quantity of this substance.

Onguent égyptiac. P. To dress fungous ulcers.

The NITRATE OF SILVER, the WHITE OXIDE OF ARSENIC, the SULPHATE OF COPPER, the RED OXIDE OF MERCURY, SOLUTION OF AMMONIA, and the MINERAL ACIDS, act as violent caustics. We have already mentioned, in the foregoing chapters, other effects on the economy.

The same may be said of the rubefacient and epispastic substances, of which the most common in use are—CANTHARIDES, BLACK MUSTARD-SEEDS, TATRATE OF ANTIMONY, CROTON OIL, &c. &c.

CHAPTER XVII.

MEDICINES GENERALLY EMPLOYED AS ANTHELMINTICS.

POMEGRANATE (BARK OF THE ROOT).

Astringent and anthelmintic. Very much employed in tænia, and with much success.

INTERNALLY.

Anthelmintic Decoction.

Rx. Cort. rad. puniceæ granati, 3ij;
Aque, Oij.

Macera per horas xxiv, coque ad Oj, cola et adde,

Syrupi menthæ, 3j.

M M

To be taken at three doses, half an hour's interval between each dose.

This decoction is employed with much success in tænia. A purgative potion should be administered the evening before taking it. The first or second dose sometimes occasions vomiting; but this circumstance should not prevent administering the third, which will not produce this effect. If the tænia is not entirely expelled, a similar preparation should be given the following day.

Some practitioners prefer giving for two or three mornings two glasses of a weaker decoction, composed of twelve drachms of the bark boiled for half an hour in three pints of water. In this case it is necessary to administer a purgative immediately after.

Tincture of Filix Mas. Peschier.

Rx. Folior, filicis maris, ʒ ij;

Etheris sulphurici, q. s.

Macerate per aliquot tempus, dein cola.

Dose, mʒij—xxx in pills, with an extract.

EXTERNALLY. *Eacha.* ʒ ij in Oj of water.

This decoction is used at la Charité.

MOUSSE DE CORSE (HELMINTHOCORTON).

A mixture of animal and vegetable substances, fuci, ulvæ, conservæ, corallinæ, &c.

INTERNALLY. Gr. x—ʒ ij. *Infusion*, ʒ ij—Oj of water.

CORALLINE.

This substance appears to act as a vermifuge, on account of the sea weed with which it is mixed, and the saline matter with which it is impregnated. Nevertheless, it is often employed with success in cases of lumbrici.

INTERNALLY. *Powder*, ʒj—ʒ j.

Infusion. ʒ j—ʒ j in Oj of water.

Anthelmintic Powder.

Rx. Corallinæ (de corse),

Artemesie contræ, ā ā ʒ iij;

Hydrar. submur., ʒj.

Divide in chartulas octo quotidie sumendas.

Decoction of Coralline. Hôt. D. H. de la Ch.

Rx. Corallinæ, ʒ j;

Aquæ, Oij.

Decoque et cola.

A glassful at a dose.

Vermifuge Potion. H. de la Mat.

Rx. Corallinæ, ʒ iv;

Aquæ ferventis, ʒ vj.

Macerate, cola et adjice,

Syrupi mellis, ʒ j.

M. For a dose.

TIN.

An anthelmintic, not much employed at the present day.

INTERNALLY. *Powder*, or *Filings*. P. ʒ ss—j, incorporated in honey or syrup.

Vermifuge Powder. H. of Germ.

Rx. Stanni, ʒ ij;

Sulphatis ferri, gr. v.

Misce et divide in chartulas six, quarum capiat unam secundâ quâque horâ.

Vermifuge Electuary. H. de la Ch.

Rx. Stanni pulv., ʒ j;

Ext. artemesie vulg.,

Pulveris jalapæ, ā ā ʒ j;

Syrupi cichorii, q. s.

Divide in bolos xij vel xv, quorum capiat unum singulâ semihoræ.

SEMEN CONTRA-TARTARIAN SOUTHERN-WOOD.

Rather an energetic anthelmintic, principally employed to destroy lumbricoides and ascarides.

INTERNALLY. *Powder.* Gr. xx—ʒ ij, incorporated with honey.

Infusion. ʒ ij—iij in water, wine, or milk.

Vermifuge Powder. H. of Germ.

Rx. Artemesie santonicæ, ʒ ss;

Potassæ tartratis, ʒ iij;

Sacchari, ʒ ij.

Divide in chartulas xvi, quarum capiat unam tertiâ vel quartâ quâque horâ.

Vermifuge Boluses. H. de Paris.

Rx. Artemesie santonicæ, ʒj;

Submuriatis hydrargyri, gr. vj;

Camphoræ, gr. xvij;

Syrupi simplicis, q. s.

Divide in bolos iij, quorum sumat unum vel duos quotidie.

Anthelmintic Boluses. H. Militaires.

Rx. Artemesie santonicæ, gr. x;

Hydrargyri submur., gr. ij;

Mellis, q. s.

Fiat bolus.

Decoction of Tartarian Southernwood. Hôt. D.

Rx. Artemesie santonicæ, ʒ ss;

Aquæ ferventis, Oij.

Decoque et cola.

A cupful at a dose.

Anthelmintic Fotion. H. of Italy.

Rx. Artemesie santonicæ, ʒ j;

Pulveris rhei, ʒ ij;

Aquæ ferventis, ʒ viij.

Coque ad ʒ vj, cola et adde,

Syrupi cichorii, ʒ j.

Divide in doses duas.

The *Especies Anthelmintiques* are composed of—

Dried flowers of tansey,

———— abisinth,

———— chamomile.

The infusion is prepared from ʒ j to Oij of boiling water.

Reviews.

Encyclographie des Sciences Medicales, Repertoire Generale de ces Sciences au 19eme Siecle: Bruxelles. Encyclography of the Medical Sciences, and General Repertory of those Sciences in the 19th Century. Vol. I.—ABA—ADU. Brussels.

If the present rage for dictionaries, encyclopedias, encyclographies, and other compact masses of information goes on, the bibliopoliſts will assuredly be under the necessity of shutting shop. Instead of the formal, parliamentary (in pomp we mean), post octavo, with hugely-ledged lines, and margin as broad as the Humber, we have now the close typed, closely lined, double-columned page, with scarcely margin enough on which to scratch the literal errata, or mark an extract by a pencil line. Then, as to price, if it be pleasure to find ourselves sailing rapidly through three whole volumes of the former race of books, and to deceive ourselves thereby into the belief of extensive reading, yet, as in the case of most pleasures, we pay dearly for it; for, are not three volumes post octavo sold for 11. 11s. 6d.? And can we not have a fasciculus of some cyclopedia for much less, though it contain much more? True, it behoves us to mount our spectacles on nose to con the small letter-press; true, the close writing begets close reading, and compels us to endue the garment of attention, which to many is like the shirt of Nessus to Hercules—consumedly troublesome: true, so glorious a shew of books does not

“Cram the creaking shelves;”

but what of that and more than that? It is not what cometh in but what goeth out that defileth the softness and purity of a man's temper; and shall not our minds be infinitely more placid in withdrawing, with a sigh, seven or nine shillings from the pocket, than in voiding, with a groan four times that amount? “Alas!” exclaim the booksellers, “medical men have ceased to read; none of them buy books now.” Right, messieurs les libraires, but we read a book, and a book that contains a score of such books as you desire to publish: though you sell only one book, we read twenty; though you lose per centum we gain per caput. Therefore, long live the encyclopedists, the

encyclographists, the lexicographers, and the whole race of beneficent genii, who spare our pockets and furnish our attics at a small cost!

But “to turn to something of more serious mood,” we have to tell our readers that the present work is one of real merit. It professes to be a reprint of the *Dictionnaire de Medecine et de Chirurgie Pratiques*, and the second edition of the *Dictionnaire de Medecine* of the Parisian press, in the compilation of which, the first names of French medical literature are included. The object of the editors, in making this double choice, would appear to be to conciliate readers of both the doctrines that have been contending for the supremacy in France; for, though in the prospectus we are told that, “in reprinting the *Dictionnaire de Medecine et de Chirurgie Pratiques*, they appear to hoist the banner of the physiological doctrine, whilst in giving a preference to the *Dictionnaire de Medecine*, they proclaim the superiority of eclectism, and that such is not their aim,” yet it is afterwards stated, “that it has been left to the physician himself to judge between and appreciate the opinions advanced on both sides”—hence the choice of the two works in question.

Those, therefore, of our readers who have had the opportunity of ascertaining the merits of the French works, will also be *au même* of passing judgment on this junction of the two. It is not merely a reprint, however; the remarks of the Belgian editors are interspersed, and moreover, the articles on the same subject from the two French works are ingeniously bound together, so as to form a whole from which facts and opinions of various shades may be drawn. There must be also some condensation, otherwise the articles comprised in the alphabetical range which heads this notice, could scarcely have been included in 316 pages of letter-press, close and double-columned though it be.

An important feature also is the list of authorities that terminates each subject treated of. In the preface great credit is taken for this, and more especially for the introduction of modern authors into the list: we give the editors the same credit, but must also remark, that had a greater number of

names of the olden time been cited, we should have been better satisfied. Neither French nor Belgian are, however, *au fait* of the ancient authors: the English are somewhat more so; but the Germans put all the three to the blush, when pitted on that score. The bibliographical references are in this work remarkably well managed; thus, instead of under the head "Abdomen," collecting all the authorities on the anatomy, physiology, and pathology of that region at the end of the article, those on the normal anatomy are placed after the description of that part of the study of the cavity in question; those on the morbid anatomy in their place; on the pathology of the various parts included in the region, under those parts, and so on; rendering a reference at once easy and clear.

It can scarcely be expected that we should extract from this voluminous publication; nor is condensation a very easy operation. If our readers will take our word for it, however, without requiring a specimen of the manner of treating the subjects, we can conscientiously recommend that manner to them. We also venture to prophesy that this publication as it proceeds will obtain a prominent place among the collections of medical writings now in progress in the various European countries. The articles in the present volume, to which attention is more particularly worthy, are Abscess, Abdomen, Absorption, and Accouchement.

We shall notice the succeeding volumes as they proceed from the press.

—o—

The Epidemics of the Middle Ages. From the German of J. F. C. Hecker, M.D., Professor at Frederick William's University at Berlin. Translated by G. B. Babington, M.D. F.R.S. London: 1835. 12mo. pp. 206.

ALTHOUGH it be admitted that the attention of the practitioner ought to be chiefly directed to the diagnosis and treatment of disease as presented to him in his own experience, still we should be taking a very imperfect view of the scope and bearing of medical science if we were to regard as useless the retrospect of its past history. The records of epidemics which have infested former generations, afford useful data to the medical philosopher; and even the details of opinions now acknow-

ledged to be erroneous, and of practice which has become obsolete, throw important light on the progress of human intelligence, and the steps by which the art we profess advances towards perfection.

Many of our readers have no doubt perused with interest the first part of the work whose concluding portion is now before us. The epidemics here described are of a less fearful character than the gloomy pestilence which swept away so large a proportion of the human race; they include the various morbid saltations which have at different times afflicted the sons of men.

In the first chapter is an account of St. John's or St. Vitus's dance. The earliest visitation of this kind mentioned by our author occurred in the year 1027, near the convent Church of Kolbig, in the neighbourhood of Bernburg.

"According to an oft repeated tradition, eighteen peasants, some of whose names are still preserved, are said to have disturbed divine service on Christmas eve, by dancing and brawling in the churchyard, whereupon the priest, Ruprecht, inflicted a curse upon them, that they should dance and scream for a whole year without ceasing. This curse is stated to have been completely fulfilled, so that the unfortunate sufferers at length sunk knee deep into the earth, and remained the whole time without nourishment, until they were finally released by the intercession of two pious bishops. It is said, that upon this, they fell into a deep sleep, which lasted three days, and that four of them died; the rest continuing to suffer all their lives from a trembling of their limbs."

In the year 1237, a hundred children were seized with a dancing malady; and in 1278 two hundred fanatics took to capering upon a bridge at Utrecht, and ceased not their orgies till a priest passed with the host, on the appearance of which the bridge gave way, and the unhappy votaries of Terpsichore were all drowned.

But the grand eruption of the dancing plague took place in 1374.

"The effects of the *Black Death* had not yet subsided, and the graves of millions of its victims were scarcely closed, when a strange delusion occurred in Germany, which took possession of the minds of men, and, in spite of the divinity of our nature, hurried away body and soul into the magic circle of hellish superstition. It was a convulsion which in the most extraordinary manner infuriated the human frame, and excited the astonishment of contemporaries for more than

two centuries, since which time it has never reappeared. It was called the dance of St. John or of St. Vitus, on account of the Bacchantic leaps by which it was characterised, and which gave to those affected, whilst performing their wild dance, and screaming and foaming with fury, all the appearance of persons possessed. It did not remain confined to particular localities, but was propagated by the sight of the sufferers, like a demoniacal epidemic, over the whole of Germany, and the neighbouring countries to the north-west, which were already prepared for its reception by the prevailing opinions of the times.

“So early as the year 1374, assemblages of men and women were seen at Aix la Chapelle who had come out of Germany, and who, united by one common delusion, exhibited to the public both in the streets and in the churches the following strange spectacle. They formed circles hand in hand, and appearing to have lost all control over their senses, continued dancing, regardless of the bystanders, for hours together in wild delirium, until at length they fell to the ground in a state of exhaustion. They then complained of extreme oppression, and groaned as if in the agonies of death, until they were swathed in cloths bound tightly round their waists, on which they again recovered, and remained free from complaint until the next attack. This practice of swathing was resorted to on account of the tympany which followed these spasmodic ravings, but patients were frequently relieved in a less artificial manner, by thumping and trampling upon the parts affected. While dancing they neither saw nor heard, being insensible to external impressions through the senses, but were haunted by visions, their fancies conjuring up spirits whose names they shrieked out; and some of them afterwards asserted that they felt as if they had been immersed in a stream of blood, which obliged them to leap so high. Others, during the paroxysm saw the heavens open and the Saviour enthroned with the Virgin Mary, as indeed the religious notions of the age were strangely and variously reflected in their imaginations.

“Many who were seized at the sight of those affected, excited attention at first by their confused and absurd behaviour, and then by their constantly following the swarms of dancers. These were seen day and night passing through the streets, accompanied by musicians playing on bagpipes, and by innumerable spectators attracted by curiosity, to which were added anxious parents and relations, who came to look after those among the misguided multitude who belonged to their respective families. Imposture and profligacy played their part in this city also, but the morbid delusion itself seems to have predominated. On this account religion could only bring provisional aid, and therefore the town-council benevolently took an interest in

the afflicted. They divided them into separate parties, to each of which they appointed responsible superintendents to protect them from harm, and perhaps also to restrain their turbulence. They were thus conducted on foot and in carriages to the chapels of St. Vitus, near Zabern and Rotstein, where priests were in attendance to work upon their misguided minds by masses and other religious ceremonies. After divine worship was completed, they were led in solemn procession to the altar, where they made some small offering of alms, and where it is probable that many were, through the influence of devotion and the sanctity of the place, cured of this lamentable aberration. It is worthy of observation, at all events, that the dancing mania did not recommence at the altars of the saint, and that from him alone assistance was implored, and through his miraculous interposition a cure was expected, which was beyond the reach of human skill.”

This uproarious epidemy seems gradually to have become less frequent, and finally extinct, unless the disease now called *chorea* is to be regarded as a degenerate offspring which follows its parent *non passibus equis*.

Dr. Hecker takes an ingenious view of the probable moral and physical causes of this strange distemper, and observes, in reference to its pathology, that “the bowels, which in many were debilitated by hunger and bad food, were precisely the parts which in most cases were affected with excruciating pain; the tympanitic state of the intestines points out to the intelligent physician an origin of the disorder, which is well worth consideration.”

The second chapter treats of *tarantism*—the dancing disease of Italy, supposed to arise from the bite of the tarantula.

“Those who were bitten, generally fell into a state of melancholy, and appeared to be stupified, and scarcely in possession of their senses. This condition was, in many cases, united with so great a sensibility to music, that, at the very first tones of their favourite melodies, they sprang up, shouting for joy, and danced on without intermission, until they sank to the ground exhausted and almost lifeless. In others, the disease did not take this cheerful turn. They wept constantly, and as if pining away with some unsatisfied desire, spent their days in the greatest misery and anxiety. Others, again, in morbid fits of love, cast their longing looks on women, and instances of death are recorded which are said to have occurred under a paroxysm of either laughing or weeping.”

This disease began in Apulia, where *tarantula* is common: towards the clos

the fifteenth century it had extended into other parts of Italy, and an universal *arachniphobia* prevailed.

"Nothing short of death itself was expected from the wound which these insects inflicted, and if those who were bitten escaped with their lives, they were said to be seen pining away in a desponding state of lassitude. Many became weak-sighted or hard of hearing, some lost the power of speech, and all were insensible to ordinary causes of excitement. Nothing but the flute or the cithern afforded them relief. At their sounds they awoke as it were by enchantment, opened their eyes, and moving slowly at first, according to the measure of the music, were, as the time quickened, gradually hurried on to the most passionate dance. It was generally observable that country people, who were rude, and ignorant of music, evinced on these occasions an unusual degree of grace, as if they had been well practised in elegant movements of the body; for it is a peculiarity in nervous disorders of this kind, that the organs of motion are in an altered condition, and are completely under the control of the overstrained spirits. Cities and villages alike resounded throughout the summer season with the notes of flutes, clarinets, and Turkish drums; and patients were every where to be met with who looked to dancing as their only remedy. Alexander ab Alexandro, who gives this account, saw a young man in a remote village who was seized with a violent attack of tarantism. He listened with eagerness and a fixed stare to the sound of a drum, and his graceful movements gradually became more and more violent, until his dancing was converted into a succession of frantic leaps, which required the utmost exertion of his whole strength. In the midst of this overstrained exertion of mind and body the music suddenly ceased, and he immediately fell powerless to the ground, where he lay senseless and motionless until its magical effect again aroused him to a renewal of his impassioned performances.

"At the period of which we are treating there was a general conviction, that by music and dancing the poison of the tarantula was distributed over the whole body, and expelled through the skin, but that if there remained the slightest vestige of it in the vessels, this became a permanent germ of the disorder, so that the dancing fits might again and again be excited *ad infinitum* by music. This belief, which resembled the delusion of those insane persons, who, being by artful management freed from the imagined causes of their sufferings, are but for a short time released from their false notions, was not entertained without the most injurious effects: for in consequence of it, those affected necessarily became by degrees convinced of the incurable nature of their disorder. They expected relief indeed, but not a cure, from music;

and when the heat of summer awakened a recollection of the dances of the preceding year, they, like the St. Vitus's dancers of the same period before St. Vitus's day, again grew dejected and misanthropic, until, by music and dancing, they dispelled the melancholy which had become with them a kind of sensual enjoyment."

The third chapter is on the *tigretier*, or dancing mania of Abyssinia, and in the fourth are some interesting remarks on the effects of sympathy and imitation in the production of nervous diseases. There is an appendix containing some curious excerpts from old German works, and eight specimens of the music to which the *tarantati* were wont to dance.

On the whole, this little volume is a very interesting contribution to medical literature, and the profession here are much indebted to Dr. Babington for presenting it to them in an English dress.

Foreign Medicine.

Chemical Composition of Articular Concretions.

GUYTON and FOURCROY, in 1782, asserted that the composition of gouty concretions was principally phosphate of lime. Subsequently, in 1797, Dr. WOLLASTON shewed that urate of soda was the chief component of these concretions, and such has been the general belief since his time. Very lately, however, M. LASSAIGNE has been induced to deny this exclusive analysis, from having examined two stones that were extracted from the knee of a man of 70 years of age. These he found to contain

Animal matter soluble in boiling water	37,2
Sub-phosphate of lime	49,9
Carbonate of lime	12,9
	100,0

Journal de Pharmacie.

Total absence of the Genitals—Exit of the Urine by the Umbilicus—Displacement of the Anus.

Pierre Louis VALLEE, aged ten years, exhibited the following appearances:—

Ordinary size of body, fresh complexion, slight squint, total want of the genital organs, perforation of the abdomen for the exit of the urine. Instead of being in the centre of the abdomen, the umbilicus is in the lower portion of it, from 1 to 4 lines above the pubis, the space between the pubis and sternum being 8 inches 9 lines. The umbilicus is a triangular depression, 1 inch 6 lines large: in this depression two tumours, or rather fleshy excrescences exist; one nearly the size of a hazel nut is irregularly round and covered with a reddish skin, the other smaller and divided into three

parts by fissures. These three divisions appear to be rather recent fleshy growths than integuments long exposed to the air: such, however, is not the case. From each side of the latter tumour there is a cleft, out of which the urine is continually dribbling. On the mons veneris the skin is rough and uneven. The arch of the pubis is scarcely distinguishable, either on account of its non-existence or because the patient prevents a full examination, for he complains greatly of being touched in those parts. The iliac foramen is filled with a large tumour, formed by an intestinal hernia: if it be pressed the urine flows more freely; on the opposite side there is also a tumour which appears to be formed by fatty tissue.

Between the summit of the umbilical triangle alluded to and the anus, there is only a space of 2 inches 6 lines. The anus is exceedingly narrow, and appears to have a slightly developed sphincter. From it there is a cleft which separates the buttocks; from the coccyx to the anus the space is 3 inches 4 lines, and the cleft along it is very deep.

The parents of this child are of a sallow complexion, and remarkably thin; their other children are of scrofulous constitution: the youngest has an umbilical hernia.

As this child increased in age he slept less, his appetite meantime augmenting in an extraordinary manner. At present he eats nearly three pounds and a half of bread in the day; his stomach is always craving, though after each meal he suffers pain in it.

In consequence of the extreme sensibility of the edges of the clefts that give issue to the urine, it has been impossible to ascertain the depth and extent of the organ containing it. The fæces are very frequently voided, and are seldom felt on such occasions. The recumbent posture being painful to the child, he generally remains seated in bed, and as his head nods backwards and forwards, he frequently knocks it against the posts, which he says relieves the colicky pains he so often has at night. He walks with difficulty, and cannot run at all; the power of the right arm and leg is almost lost. His intellect is exceedingly precocious, and his sensitiveness of mind often obliges him to desire death.

In the above case there has evidently been an arrestation of development, the anterior parietes of the bladder being wanting, constituting what is called exstropion of the bladder. The child most probably belongs to the female sex, but whether there is a womb within or not, is of course uncertain. The hernia of the left side would appear to be formed by the rectum, which instead of descending into the pelvis, seems to pass immediately below the urinary organ, and turning at a right angle, to end just below the pelvis.—*Gazette Medicale*, May 2.

Acute Myelitis confined to the posterior half of the Spinal Marrow: general Opisthotonos.
By Dr. Marco Paoloni.

The following case, extracted from the *Bulletino delle Scienze Mediche della Societa Medica-chirurgica di Bologna*, for June, 1834, shews that general opisthotonos sometimes depends on inflammation of the posterior or cerebellic cords of the spinal marrow, the brain remaining unchanged.

A strong man in the flower of his age entered the hospital of St. Ursula, for a double hydrocele of the tunica vaginalis, consequent on a gonorrhœal orchitis. On the right side a palliative treatment was put in practice, and on the left, where the tumour was of older date and larger, the radical cure was attempted. In doing this, besides an extensive incision of the tunica vaginalis, it was necessary to excise a portion of the membrane. No fever ensued for the two following days. On the third, however, an intense one sprung up, with lancinating pains of the wound, delirium, and distressing sensation along the vertebral column. The contro-stimulant method immediately employed subdued in some degree the fever, and the lancinating pains diminished. This amelioration was accompanied with the sloughing of an extensive angrenous eschar that had invaded the cellular tissue around the testicle, the tunica vaginalis, and internal surface of the scrotum.

On the seventh day after the operation, when the wound was kindly granulating, and the general inflammatory phenomena were almost entirely subdued, the patient became sensible of some difficulty in moving the jaw, and a slight stiffness of the posterior muscles of the throat, described by himself as if a cord was drawing him backwards. The trismus became complete; the rigidity extended to the muscles of the trunk, which bent the body backwards, and as it proceeded to the legs, they also became in a state of forced extension, and even somewhat bent backwards. Deglutition was impossible, the respiration difficult, the belly was meteorized, the bowels bound, the skin hot and covered with a copious viscid sweat; the pulse vibrating and feverish. Bleedings, which shewed a buffy coat, repeated applications of leeches along the sides of the vertebral column, purgative clysters, and hot fomentations, all failed in warding off his death, which took place at the end of three days.

Dissection, Twenty-four Hours after Death.
—Except a slight venous injection, the meninges of the brain were sound. The brain, cerebellum, and medulla oblongata were also sound in all points. The whole posterior surface of the vertebral dura mater was of a dark red colour, particularly at the cervical and lumbar regions; this colour was altogether absent from the anterior surface. The arachnoid was strongly injected: a great quantity of serosity floated between the

two membranes, especially at the points above mentioned. After withdrawing the pia mater, the whole posterior surface of the spinal cord was seen to be palpably softened: in the cervical and lumbar regions it was almost diffuent. This softening was circumscribed in a very remarkable manner at the posterior part of the cord, while the whole of the anterior surface retained its consistence, colour, and other characters in a normal condition. A distinct line of demarcation existed between the diseased and healthy portions. The posterior roots of the spinal cord participated in the morbid changes.

In the genital organs all the constituents of the spermatic cord were found strongly adhering together, and the spermatic vessels were gorged with blood. Great difficulty was experienced in separating the vas deferens from two nervous branches, which being of a deep red colour, that could not be removed by repeated washings, may be considered to have been inflamed. The strong adhesions of the spermatic cord about the inguinal ring prevented the possibility of tracing these two nerves into the abdomen. Neither of the testicles were altered in texture.

The thoracic and abdominal viscera were normal; only the lungs were slightly congested.

This case proves that an affection of the posterior cords of the spinal marrow produces forced extension of the whole body. The following case will prove that inflammation of the cerebral hemispheres, on the contrary, produces forced flexion of the body; and both cases tend to demonstrate the justness of Bellingieri's views on the "nervous antagonism."

Meningitis of the Cerebral Hemispheres, with Emprosthotonos. By Dr. Francis Morotti.

Joseph Bianca, aged 12 years, and enjoying habitually good health, fell asleep, after hard labour, with his head bare and exposed to the heat of the noon-day sun. On awaking he felt himself unwell, and as he got daily worse, he entered, three days afterwards, the hospital of Vercelli. The symptoms then were—almost total blindness and deafness; continued coma, only interrupted by low feeble groans; countenance sunk; squinting; spasmodic closing of the eyelids of the right eye; the trunk of the body strongly bent forwards; the limbs bent, and when any attempt was made to extend them he disclosed the pain he experienced by groans; the pulse hard and small.

Notwithstanding copious bleedings and alvine evacuations the symptoms persisted all the following day and then became worse. In the evening he died in the midst of excruciating tortures.

Dissection, Twenty-four Hours after Death.—Considerable injection of the cranial, dura, and pia mater; the sinuses gorged with blood containing a quantity of sero-purulent

fluid, which was also abundant in the sufractuositities of the cortical and the base of the cerebral lobes. On cutting the white substance the blood vessels were seen in a gorged state. Neither the cerebellum nor spinal cord were changed. The inflammation extended over the whole exterior surface of the cerebral lobes, but was more marked on the right side: it was this side that had been exposed to the sun while the boy was sleeping.

THE HUNTERIAN MUSEUM.

WE have so often committed violent assaults upon the *twenty-two* of Lincoln's Inn, that when we express a wish to hold amicable converse with them touching a matter of great interest to science, we suppose they will not give us credit for sincerity. We do assure them, however, that our present intentions are entirely pacific; that the observations we are about to make, have no tendency to swamp the council with general practitioners—none to subvert the much-loved certificate system—none to contaminate the purity of mechanical surgery with the slightest tincture of medical knowledge. We have a favour to ask, the concession of which cannot possibly do them any harm, and will confer an infinite benefit on the rest of the profession: it is something which, as members of the College, we have an unquestionable right to demand—something which we have vehemently demanded before, and which, when the fit of politeness that has seized us at present has passed off, we shall again demand with an uncompromising sturdiness.

"Not fierce Othello in a louder strain,
Roar'd for the handkerchief that caused his pain."

Our request is, that the Hunterian Museum may be made available for the purposes of study.

The importance of comparative ana-

tomy and physiology, always recognised by medical philosophers, is now beginning to be generally acknowledged. For the cultivation of this magnificent pursuit, there are within the walls of the College of Surgeons materials not elsewhere to be found on earth. Even the celebrated collection of Cuvier is absolutely a trifle compared to that of Hunter.

It is impossible to view the latter with an understanding eye, without being lost in admiration at the amplitude of mind which could form, and the gigantic labour which could embody, so vast a conception. Unlike most other great works in science, it is no less an evidence of the splendid imagination, than of the vigorous reason of its author; as a fabric of natural truth it is one of the noblest efforts of philosophy; as a shadowing forth of divine power in creation, it is one of the sublimest visions of the human imagination.

And this monument of the finest intellect that ever adorned the annals of our art, this exhaustless mine of knowledge and of pleasure, is so jealously guarded as to be almost useless—it is a mere exhibition!

When is it open to the profession? Three days only in the week, between the hours of ten and four; that is, when it is impossible for gentlemen engaged in practice to resort thither. Another evil, though of less importance, is, that the gallery and the lower part of the museum are not accessible at the same time, so that many objects necessarily connected in science cannot be studied together; we have ourselves frequently desired to compare objects in different parts of the museum, and have been unable to do so on account of the arrangement above mentioned. What preposterous whim has led to such an arrangement we cannot tell.

In animadverting on these abuses, we beg leave expressly to exempt from all censure the two gentlemen who immediately superintend the museum: as far

as they are concerned, every facility is afforded to visitors; and all who address themselves to Mr. Clift or Mr. Owen, will be ready to acknowledge both the great extent of their information, and their polite and obliging manner of communicating it.

Such is the manner in which an important trust, reposed by government in the College of Surgeons, is fulfilled by the council. We will not now dwell on the fact that this grand collection remained for years a chaos for want of explanatory catalogues; nor on the fact that there are many pathological preparations, the history of which is known only to one individual—Mr. Clift, and which in the event of his death would have become useless and unmeaning. We will not dwell on these things, because the council, thanks to the *Lancet*, are now using all diligence to supply these deficiencies, and have confided the construction of catalogues to gentlemen who have already given very satisfactory proofs of their zeal and ability.

We conclude by entreating the council to let the museum be open all day and every day, and to let the whole of it be accessible at the same time—a very reasonable request, and very civilly made; which if they do not comply with at the re-opening of the College, we will lead them such a life that they shall wish the *London Medical and Surgical Journal* at the bottom of the deep sea.

—o—

NEW REGULATIONS OF THE APOTHECARIES' COMPANY.

—

WE have received numerous strictures on the new regulations of the Apothecaries' Company, and many complaints of the expense which they will heap on those apprentices, who cannot commence their medical studies before October next. We agree with our correspondents, that these regulations were too suddenly framed, and are oppressive and unjust towards those who entered the profession with pecuniary

means sufficient to enable them to obtain a qualification on the conditions that obtained when they were apprenticed. Had the legislators at the Hall proposed such regulations twenty years ago, and that in five years from that time, they should be complied with, there would be no just ground for complaint. But no, the rhabarbarians were blundering, year after year, with new regulations; and when on the eve of annihilation, they fruitlessly attempt to ward off the blow intended for them by the legislature, by framing a code of regulations according to the recommendations of the most eminent members of the profession, before parliament. They suddenly increase the expense of medical education, regardless of the means of a majority who expected it on more moderate terms. The Solons of the Hall cannot scarcely expect that the professors of the different branches of medical science, should give double the number of lectures, and for double the present period, for the present remuneration. It is to be recollected that most of the teachers in London and throughout the empire, are actively engaged in public and private practice, while some of them are solely dependent on teaching; and yet it is proposed that they shall devote double the length of time for the same remuneration they receive at present for half the period. According to this logic, the examiners at the Hall are bound to examine for double the time they now do for their present remuneration. It is not, however, stated in their manifesto, that they intend any such thing. They, considerate mortals, say to professors, and the medical officers of hospitals and dispensaries, we expect you will allow students to attend your instructions for double the present curriculum on the present terms. Whether this modest proposal will be received by the teachers, remains to be proved; and should it be declined, which is most likely, students will have to thank the rhabarbarians for a longer pull at their purses.

Hospital Reports.

WESTMINSTER HOSPITAL.

Medullary Sarcoma of the Liver and Aortic Lymphatic Glands, Tubercles of the Lungs, Spleen, Bronchial Glands, &c.

THOMAS YEARN, aged 31, was admitted under the care of Mr. White, March 25th,

1835, having been long ill with a tumour of the liver. He had lived as servant in a gentleman's family, and it appears that he has uniformly been of temperate habits. The disease had of late proceeded rapidly, despite all the treatment employed by his medical attendants; and pulmonary consumption having become developed in addition, and threatening a speedy fatal termination, he was received into the hospital, with the view rather of adding to his comforts, than to any particular treatment.

The tumour in the abdomen was very evident in the right hypochondriac region, reaching almost to the umbilicus, and it was a matter of doubt in the diagnosis, whether this depended upon a chronic abscess in the organ, or on some new formation. The auscultation of the thorax, in relation to the lungs, gave puerile respiration, mucous rattle, and bronchophony over the surface of the chest in general; with the exception of the clavicular and interscapular regions, where the respiratory murmur was deficient, and in the same regions the sound was dull on percussion, being clear in the remaining parts of the chest. What was remarkable, the action of the heart, as indicated by its sound and impulse, was not perceptible in the præcordial region, and the patient stated that he has not for long been able to distinguish it himself.

Since his admission into the hospital, he has obviously declined daily, the expectoration becoming more profuse, and the hectic symptoms more severe, and on the 5th inst. he died with no other symptoms than those of exhaustion, rendering him incapable to expectorate the frothy mucus, which had accumulated in the air passages.

Inspection of the Body, Thirty Hours after Death.—A white, ragged, and deeply excavated ulcer was found on the mucous membrane of the back of the pharynx, which had been noticed during life, and might have been taken for one of syphilitic origin. The larynx, trachea, and bronchi, contained a large quantity of frothy mucus, such as had been expectorated during life. The mucous membrane lining these tubes was considerably inflamed. Upon raising the sternum and cartilages of the ribs there was found at the point of articulation on the right side, and growing either from the costal cartilages, or their pericondrium, a morbid growth of an irregular and flattened oval shape, of the size of a large egg, of a dense cartilaginous-like structure, and of a yellowish white hue.

On the right side there were very general adhesions of the pleura, not of a very recent date. Externally, the lungs appeared very healthy and crepitated, throughout the greater part of their extent. The same was found to be the case upon cutting into them, with the exception of their being engorged with a quantity of frothy mucus, and that some of the air-cells were somewhat dilated.

Both lungs, however, and more especially the right, in the situation of their roots and apices, were studded with tubercles in various degrees of development, some having become merely softened, and the cysts of others having become evacuated. The tissue of the lung surrounding the tubercles was in the condition of sanguineous engorgement, and in some places apparently hedatized. In the apex of the left lung the tubercles were arranged in the form of concentric circles, the outer circle having a diameter of about an inch and a half, the surrounding lung being somewhat consolidated, but only slightly sprinkled with tubercles. Some of the bronchial glands were considerably enlarged, from the presence of numerous tubercles. One of the œsophageal glands was converted into a dense hard tumour, which presented a smooth regular surface when divided, and was beautifully mottled with green, white, and grey.

The heart was somewhat diminished in size, and flabby, being, if anything, smaller than the fist of the individual, who, however, it must be remembered, was highly emaciated. Its walls were in good proportion, and its valves healthy.

In the abdomen the liver was found extending beyond the cartilaginous margin of the thorax, and encroaching upon the epigastric and chondriac regions. Its convex surface was lobulated, from the presence of some subjacent tumours, which existed in two or three places.

On cutting into the liver there were found three or four roundish masses, one larger than an orange, in the right lobe, and the others smaller, in the left. The substance of these tumours was tolerably firm, resisting, and lardaceous, and of a white colour, having a tinge of yellow. The substance of the liver in which these tumours were embedded, was tolerably healthy. The aortic lymphatic glands, seated around the cæliac axis, were converted into a tissue closely resembling that of the hepatic tumours, and constituted a large lobulated mass just above the pancreas, which, however, was not itself affected. The spleen contained many yellowish scrofulous tubercles, and was larger and softer than natural. The kidneys were healthy. The mucous membrane of the stomach was of a somewhat increased degree of redness.

MEDICOBOTANICAL SOCIETY OF LONDON.

Tuesday May 12th, 1835.

Thomas Everitt Esq. in the chair.

DR. SIGMOND, the senior secretary to the Society, read a letter from Dr. Mones, the Professor of Toxicology, apologising for his absence and inability to deliver his introductory lecture.

Dr. Sigmond then observed, that he

would deliver a lecture on the subject, which he did with very great credit.

Mr. Allsop, a chemist at Chelsea then introduced a new minim glass, the value of which will be perceptible from the following particulars.

The Syringe Minim Meter or improved Drop Measure.—This useful little instrument, being graduated so as to measure with great accuracy to a single minim, is calculated to render the use of the more powerful medicines both convenient and safe. In the administration of prussic acid, laudanum, &c. perfect accuracy cannot be attained by the measures hitherto in use; and this may therefore be considered indispensable, not only to apothecaries and chemists, but also to accompany the medicine chest in private families. The entire uncertainty attendant upon the use of medicines by drops, will be shown by the following statement of experiments made for the purpose with various fluids, and dropped from bottles of different sizes to show the two extremes; from which it appears that drops may vary in size, *from less than half a minim to six times that quantity.*

Number of drops required to measure a drachm.

From a large bottle.	Ditto small.
Of dilute sulphuric acid . . . 24 drops .	84 drops.
—Prussic acid (Scheele's) 35	70 ———
—Distilled water 38	54 ———
—Liquid ammonia 40	48 ———
—Laudanum 84	135 ———
—Rectified spirit 100	130 ———
—Tinct. muriate of steel 100	150 * ———

It is necessary in using the measure, that the piston should be kept moistened with a little water: then raise the handle about the eighth of an inch, and dip the syringe into the bottle containing the fluid to be measured; draw up the required portion or rather more, and expel a drop or two until it mark the exact quantity, which may then be transferred to a phial or wine-glass; the tube being held between the thumb and middle finger of the right hand, and the piston pressed down by the fore-finger. After a little practice this will be done, in less time than would be occupied by dropping.

To cleanse the measure after use, draw up a sufficient quantity of water: apply the finger to the point or opening, press the handle down to the utmost and then raise it again, the finger still closing the orifice. Thus the water will be forced up through the packing of the piston, and descend through it again, so as to wash it perfectly clean.

Convenient and elegant stands for these measures, are provided for shops.

R. A. has also constructed a new description of syringe in glass, for general purposes; which is found highly preferable to those of bone or metal; and is now provided, in neat japanned cases, at a very moderate price.

* These are rather exaggerated proportions
ED.

The new instrument consists of a graduated glass tube with a piston, of which the above is the description.

—o—

ROYAL INSTITUTION—THE APPROACHING COMET.

DR. LARDNER has delivered some interesting lectures on the time at which the approaching comet will be visible in this country, which have given rise to some controversy.

Friday evening, in a lecture at the Royal Institution, on the path of Halley's comet, Dr. Lardner took occasion to contradict a paragraph which has been extensively circulated in the public journals, stating that a letter has been received from Sir John Herschell, announcing that the comet, having altered its course, would not be visible, and to which he scarcely considered it necessary to give a contradiction. He observed, that Sir John Herschell knows nothing more of the causes which would influence its return than any other astronomer, and that the statement attributed to him was pure fiction. The only circumstances which can prevent its making its appearance at the period stated are, that there may be existing beyond the orbit of Herschell some other planet with which it may have come in contact, so as to cause it to alter its direction, or that it may come into juxtaposition with another comet in the realms of space, and that their combined attraction may have caused them mutually to vary their course. Mr. Lubbock has calculated that it will make its appearance on the 31st of October; M. Damoiseau's calculation makes it the 5th of November; and Poncelet the 8th or 14th November. On the 10th of November it will probably be at its nearest distance to the earth, and will then most likely be visible amongst the three last stars of the Great Bear, both after sunset and before sunrise. Whether it will be visible or not will depend upon circumstances of which astronomers can have no knowledge, because they cannot predict the exact position in which it may be. It is now probably about the orbit of Saturn. The only difficulty presented in the calculation arises from our not knowing exactly the mass of the planet Herschell, and in proportion as that is above what is computed, so will there necessarily be an error in the period of computation. The number of comets known within the solar system, is between 500 and 600, whilst of these the paths of 137 have been closely examined and described. Of the above, 30 are known within the orbit of Mercury, although this is probably not one half of what actually exists within that space. Taking the number, however, as 30, and computing the quantity existing in a relative ratio between the estimated differences of a sphere, the diameter of the orbit Mercury, and that of

Herschell, it will give the total number of 3,529,407 within the limits of the solar system, and as the number above assigned within the limits of the orbit of Mercury is probably not half of what circulates there, the total number in the planetary system may possibly be upwards of 7,000,000.

This lecture has led to a correspondence between Dr. Lardner and Mr. Lubbock, in which the former made a most satisfactory defence of statements.

—o—

INTRODUCTION OF VACCINATION INTO THE NAVY.

It is not known, though it ought to be, that Dr. Veitch, of Chelsea, and formerly a medical officer under the renowned Lord St. Vincent, is entitled to the merit of having first introduced the blessings of the great Jennerian discovery into our navy. The following note, for the authenticity of which we can vouch, sets the point at rest. It reflects the greatest honour on the memory of the renowned and gallant associate of Nelson, the Earl St. Vincent, and is eminently entitled to record in the annals of medicine. It has come into our possession by chance, but well deserves to be rendered imperishable.

"Royal George, August 1, 1800.

"SIR—I have received your letter of the 29th ult., requesting permission to inoculate with the vaccine matter several men on board His Majesty's Ship Magnificent, who have not had the small-pox, which suggestion does you much credit, in my opinion; and I have no objection to your inoculating those men as proposed, if it meet with the approbation of Captain Bowater.

"I am, Sir,

"Your most obedient servant,

"(Signed) ST. VINCENT.

"Dr. Veitch,

"Surgeon of the Magnificent."

Dr. Veitch claims, he believes with justice, the merit of having introduced the vaccine inoculation into the navy, under the sanction of Earl St. Vincent, when Commander-in-Chief of the Channel Fleet. The satisfactory promptness with which Earl St. Vincent replied to the representation of Dr. Veitch, reflects the greatest credit on the capacious mind of his lordship.

—o—

ON THE USE OF CASTOR OIL.

To the Editor of the London Medical and Surgical Journal.

SIR—Having been long in the habit of frequently employing castor oil largely and repeatedly in numerous diseases, I have often had an opportunity of observing not only the juvantia of the medicine, but also its lædientia; the latter of which, to those who, like myself, "to other purgatives in

several, and especially in most *puerperal* diseases, are well deserving of notice.

The first injurious effect which shall be here mentioned, as resulting from the free exhibition of castor oil, is an irritability of the mucous membrane of the intestinal canal; an instance of which came before me some time since, in the case of a poor woman who was suffering under intestinal irritation, subsequent to a hard and harrassing parturition. The bowels, previous to the labour, had been much neglected, and the symptoms of intestinal irritation were decided and severe. By my order she took an ounce of castor oil every morning for three successive days, and with the best result—the symptoms of intestinal irritation having by that time entirely vanished. But the oil produced, as I had frequently observed in other cases, an irritability of the intestinal mucous membrane, shewn by the stools becoming watery and losing their fecal appearance, the bowels being instantly disturbed by the taking of warm liquids into the stomach, &c., and especially by the change in the state of the tongue, which put on a dull red and glazed appearance on its base and middle, and a bright red around the tip and edges. A dose or two of the compound ipecacuanha powder removed like a charm this state of things.

Another hurtful consequence of taking castor oil largely is a more or less inflammatory state of the mucous surface of the intestinal canal, the diagnosis of which is so well known to all, that it needs not to be alluded to here, excepting that it may not be improper to mention the striking difference usually to be seen in the appearance of the tongue in this disease, from that of an irritability of the same part. The tongue is in this disease, dry, rough, and covered with a white fur in its base and middle, but around the tip and edges it is thickly spotted with bright red dots.

There is an almost latent chronic gastro-enteritis, which is known to most practitioners on account of its obstinacy of cure, or at least difficulty of removal; and in which it is common for the patient to have almost daily recourse to castor oil for the removal of one of its frequent attendants—constipation. But this practice causes too often the prolongation, or even aggravation of the complaint. A modification of the diete absolue of Broussais, leeching the abdomen if necessary, mild enemata, cold water beverage, &c. are, it is well known, far preferable means of cure in this disease to repeated doses of castor oil.

These remarks on a medicine in general use, may probably afford an inexperienced practitioner a hint not only to watch the course of a disease, but likewise the action of the remedy by which he is endeavouring to remove it. I am, Sir, your obedient Servant.

Gainsborough, May 12, 1835.

ROBERT EMINSON.

CASES OF BLINDNESS CURED BY OPERATION.

[We copy the following interesting cases from Neill's Clinical Report of the Diseases of the Eye, treated in the Liverpool Ophthalmic Infirmary, as redounding to the credit of the operator, and to the state of surgery in Provincial Hospitals.]

ELLEN MUCHIN'S CASE,

The Little Girl who was Born Blind.

THE first case which I shall relate has already attracted considerable notice.

Ellen Muchin, *born* QUITE BLIND, was brought to me in the summer of 1831. Her mother stated that she had previously had many opinions on her daughter's blindness, the chief of which were unfavourable to any operation being performed. Feeling deeply interested in the case, I made a minute examination into the state of my little patient's eyes, and general health. The result of the examination led me immediately to propose an operation for the removal of the cataracts which obstructed vision: it was cheerfully and readily agreed to.

In less than a week, this interesting child, then *eight years old*, who had NEVER seen the "*spangled heavens*," nor known the "*BLESSED LIGHT OF DAY*," was in possession of the most precious sense. Her father and mother, with a professional friend of mine, witnessed the first operation. The child was put under no restraint: she sat with her head resting on my friend's breast, her father sat at one side and held her by the hand, she uttered no exclamation, till the operation, which did not occupy half a minute, was completed, when she said, "Oh, is that all?"

On the 4th of October last, upwards of *three years* after the former period, in the presence of many persons, among others, our *amiable* and *INDEFATIGABLE Vice-President*, the Rev. T. BOLD, I operated on the other eye, in the *Ophthalmic Infirmary*. She made a similar observation as on the former occasion, and remarked that she experienced "hardly any pain." So much then for the "wondrous sensibility of the eye."

After the first operation, Ellen and her parents went to Ireland, where they remained till August, 1834, the date of their return to Liverpool. The family had not been here long (in lodgings), ere Ellen and her mother were seized with cholera, and taken to the Fever Hospital. Within a few hours only after their removal, Ellens's mother was a widow, and Ellen herself fatherless, cholera having destroyed their only support. The workhouse received Ellen's three little sisters, who were without friends or home, and this poor family are now beggars!

It was at this period of her distress that Mrs. M. called upon me; I took Ellen into

the Ophthalmic Infirmary as a temporary home, and that a cure might be completed by operating on the other eye. The issue of the second operation has also been gratifyingly successful, as the following notice of this little girl's case will show; it is extracted from the public journals:—

October, 1834.—“There is at present in the Ophthalmic Infirmary, under Mr. Neill's care, a case of very great interest. The patient is a little girl who was born blind. About three years ago, Mr. Neill operated on the right eye; the operation was successful, and she obtained sight; she was then in her eighth year. On Saturday last, the 4th instant, he operated on the left eye, in the Slater-street Institution, with a similar happy result.

“This little creature, born blind, and for eight years in darkness, is now in full possession of the most precious sense. She can distinguish colours, and the smallest objects.

“The knowledge of distance after the first operation was for a long time imperfect. The first object which was presented to the eye was a halfpenny; for weeks afterwards every circular object, no matter how large, or what colour, was called a halfpenny.

“When blind, her residence was in Dove Court, School Lane. She was then familiar with ‘every nook and cranny’ in the neighbourhood. When she obtained sight, she often used to lose her way, sometimes even close to her own door. The instant this would occur, she would shut her eyes, and feel round until some known object was touched, then with her eyes closed she would hurry home, guided by her accustomed sense of touch. She is a pretty, intelligent girl, and is a pattern of neatness.”

Cheselden's case, the memoir of which is detailed in the thirty-fifth volume of the *Philosophical Transactions*, and Ware's case, as detailed in the second volume of his work on the Eye, both materially differ from mine.

Cheselden mentions that his patient, “upon obtaining sight, was so far from making any judgment of distance, that he thought all objects touched his eyes as what he felt did the skin. ‘He saw all objects in proximity to the eye.

Mr. Ware is satisfied that “children from whom cataracts had been extracted, had a notion of distance the first moment they were enabled to see.”

Cheselden's patient and Ware's patient could also distinguish colours previous to the operation. Now my little patient could only tell the sunshine from night, or a flame from darkness. When she obtained sight, it will be seen how very imperfect was her judgment of size or distance: all objects appeared smaller and farther off than their form or position really were. This, however, was what we might naturally expect; for the want of a refracting body, such as the lens, would at once point out this imperfection in vision.

Mr. Ware “was astonished by the facility with which, on the first experiment, he (his patient) took hold of my (Mr. Ware's) hand at different distances; mentioning whether it was brought nearer to, or carried further from him, and conveying his hand to mine in a circular direction, that we might be better satisfied of the accuracy with which he did it.”

Mr. Ware also says, “In this case, however, and in others of a like nature, although the patients had certainly been blind from infancy, I could not satisfy myself that they had not before this period enjoyed a sufficient degree of sight to impress the image of visible objects on the mind, and to give them ideas which could not afterwards be obliterated.” In Mr. Ware's case this may have happened, but in the case of *the child*, which I am now relating, it had not taken place. She never saw; and her after sight proved that an early knowledge of the use of the organ had never been gained.

How is it that all my patients, who after cataract operation recover sight, see imperfectly? and that the imperfection chiefly consists in short sight, *the near object appearing to be small, and far removed*? It is because the lens is wanting, and when a false lens is supplied, the *far object approaches*, and the *near object is increased in volume*.

Ellen's surprise was most ludicrous when she first placed her spectacles on her nose. She had already acquired a three years' knowledge of the surrounding objects, and from experience had gained an intimacy with them; when she saw through her spectacles, her mind had flown to “*Brobdignag*.” “Oh,” said she, “your head touches the ceiling.” Her knowledge of distance was again lost, and nearness was the fault, but *habit* will soon accustom her to the use of her spectacles.

A week after the second operation I bound up the right eye, *the one first operated on*, and desired her to use the other; with it (the new eye) she could tell every object with as much accuracy as with the other eye, and she could also distinguish colours. In fact, she said she could see with equal power with either*.

Mrs. Savage's Case.—The case of Mrs. Savage, No. 2, Crown-street, two doors from Pembroke-place, is interesting, inasmuch as the age of the patient might have been considered a drawback to the success of the operation.

Mrs. Savage applied to me in May last; she was in her 68th year, and quite blind, having cataract in both eyes.

I extract the following note of the operation

* I have this day, Dec. 30th, received a patient having *Congenital Cataract* in both eyes; he is a fine boy, 10 years of age; and I intend to operate upon him in about a week or ten days.

from the *Liverpool Medical Journal*, in which it was reported.

"May 14th. Mr. Neill operated to day on the left eye. The straight flat needle was introduced into the posterior chamber, the capsule of the lens ruptured, the lens made to roll, so as to effect its disengagement, the flat side of the needle placed upon its upper edge, and by a gentle pressure downwards and backwards the lens were made to glide into the body of the vitreous humour.

"27th. Operation on the right eye. The belladonna having been previously applied, Mr. Neill passed the needle, as related above, in the operation on the left eye, and the lens was made to glide, as in the former instance, into the body of the vitreous humour. The patient expressed great astonishment at the freedom from pain during the operation, which did not occupy more than the fourth of a minute."

She can now (with the assistance of spectacles) read her bible.

Ann Rudd, aged 64, quite blind, was received into the Ophthalmic Infirmary on the 19th of July last.

Her residence is No. 7, Crosshall-street.

"The right eye had been affected with inflammation many years since. There is cataract, with adhesion of the iris to the capsule of the lens. The iris is immoveable.

"In the left eye there is hard lenticular cataract, and the iris lively. On Saturday, the 26th of July, I reclined the cataract of the left eye, in the usual manner, the patient expressing astonishment at the freedom from pain. She was discharged cured on the 8th of August, and with spectacles is able to read very small print."

Mary Morris, aged 67. Residence No. 2, Orford-street, Salthouse Dock, was blind in both eyes from cataracts. I operated on both eyes on the 18th of October last, and made her an out-patient on the 24th of the same month, six days after the operation. She is cured, and with spectacles is able to read the smallest print.

Ellen Murray, aged 21, had cataract in the left eye, the result of injury sustained by blow about twelve months since. As there were threatenings of amaurosis in the right eye, I considered it advisable to break up the soft cataract in the left eye, which I did on the 23d of August last. When the patient left the hospital her sight was very good. I have not seen her, however, for four months.

William Ablett, aged 9 years, at play, ran a fork through the cornea of the right eye, and punctured the lens. Cataract formed, and blindness ensued. I performed the operation on the 4th of October last. The boy has now excellent vision.

None of my patients complain of disturbed vision after the operation upon one eye. In fact, I conceive that this opinion, which has been occasionally advanced as a reason for declining the operation when one eye alone is

affected, is erroneous. There are very few persons indeed who, in health, see with equal power in both eyes; and yet we never hear of disturbed vision from this cause.

John Hughes, aged 26, in the employ of Messrs. Lutwyche and Co., No. 19, Carruther-street, was blind of the left eye, from hard lenticular cataract. I operated upon this patient on the 18th November. His sight is restored.

Mary Austin, aged 54, blind for three years from cataract in both eyes, and so very deaf that she can scarcely hear the loudest sound of the voice. I operated on both eyes on the 18th November.

She is restored to sight.

Mrs. Austin's residence is No. 38, Warren-street.

William Griffiths, aged 66, from near Dolgelly, in Wales, was placed under my care a few weeks ago by Sir Robert Vaughan, Bart., M.P. for Merionethshire, who has taken much interest in his case.

I operated on the right eye on Saturday, the 13th of December last; but I am not very sanguine as to the result. I fear that disease of the retina has co-existed with the cataract.

Joseph Joynson, the son of Arthur Joynson, groom at the Star and Garter Hotel in this town, a few days after birth, was seized with purulent ophthalmia; the extent of the disease was not discovered until too late, and blindness in both eyes was the result of this destructive complaint.

He was brought to me in October last, and was then in his sixth year. One eye was quite destroyed, the other retained its form, but the pupil of the eye was blocked up by the opaque lens, which had fallen forward, and become united with the iris.

By the formation of an artificial pupil, I have given this child sight, which, although it can never be what a medical man would call "useful vision," will enable him to see his way, and distinguish larger objects.

Of the many cases which have been under my care during the past year, only one case of cataract terminated unfavourably, and that unfavourable termination was the result of the stubbornness of the patient, who left the hospital too soon, and afterwards suffered most severely from rheumatic inflammation of the eye for many months.

In the month of October last, I operated upon eight different patients for cataract, from the age of 5 years up to 73; and every one terminated in complete restoration to sight! This, then, is my apology, for so strenuously advocating the needleoperation.

*Cures of different species of Mental
Alienation.*

During eight years, practice in the Charenton Lunatic Asylum, 1557 patients have been admitted. The proportion of cures to the admissions is as 1 to 3. If we withdraw from the number of those admitted, the cases of palsy (274 in number), epilepsy 62, and idiotcy 15—all cases allowed by practitioners to be incurable—the number treated will be reduced to 1205 individuals. And as the cures amounted to 516, the proportion will then be 1 to 2.33. Of these cures there were of monomaniacs, 23 men and 128 women—total 151; of maniacs, 160 men and 103 women—total 263; of demented, 1 man and 3 women.

Since the year 1811 the theatrical representations formerly so much had recourse to in the treatment of insanity, have been forbidden; M. Esquirol found that they did more harm than good. He even found music, though more harmless, only of transitory benefit in those instances where its effect was favourable at all.

During the prevalence of epidemic cholera in Paris, three insane persons entered the asylum, who dated their insanity from attacks of cholera, fear having probably produced its worst effects.

Extirpation of the Parotid.

M. Roux has lately performed this difficult and hazardous operation with complete success. The whole of the gland was cut out. He had previously placed a reserve ligature round the carotid, which was not however required. Palsy of the face existed previous to, and, of course, after the operation.

North London Hospital.

We are extremely happy to observe that the funds of the North London Hospital have been considerably augmented by a subscription entered into at the Thatched House Tavern. Lord Brougham in the chair. The subscription amounted to £1,250, including £834 collected through the exertions of Mr. Lionel Goldsmid.

Physician to the Westminster Hospital.

Dr. Burne has been elected physician to the Westminster Hospital.

Physician to the Bethlem Hospital.

Dr. Morrison has been elected, after a sharp contest, physician to the Bethlem Hospital. Few of the other candidates possess so much experience in the treatment of the insane. The Bishop of London was one of his chief supporters.

LITERARY NOTICES.

In the Press.

A Clinical Account of Fever, Gout, Rheumatism, Cholera, &c., and various Diseases of the Chest. By Dr. Aldis, Cantab., Member of the Royal College of Physicians, London.

A New Practical Formulary of Hospitals; or, a Collection of Formulæ of the Civil and Military Hospitals of France, Germany, Italy, Great Britain and Ireland, &c. By M. Edwards, M.D., and P. Vavasseur, M.D. Translated and Augmented by M. Ryan, M.D.

TO CORRESPONDENTS.

Crito.—The Rhabarbarians cannot save themselves—their love of science is shewn too late.

An Enemy to Empiricism.—The medical reform will protect the educated portion of the profession, though, we fear while our nobles foster quackery, it will continue.

A Student at the London University, A. C., I. K., and others.—The indisposition of Dr. Thomson has caused an interruption in the publication of his lectures, but we hope the speedy recovery of the learned Professor will enable us to resume them.

Dr. Fletcher's Lectures.—We daily expect a continuation of this elaborate Course.

Professor Burnett's Lectures.—In reply to several Correspondents, we beg to state that we are not able to continue the Lectures delivered by Professor Burnett at the Chelsea Garden, in consequence of the delicate health of that gentleman, which renders him inadequate, at present, to attempt the labour of correcting our reports.

Mr. A. Booth.—We request an interview.

Philo-Celsus, Democritus, and Celsus.—We shall be obliged by the communications.

Mr. Dewhurst.—We cannot insert the reply to the *Lancet*.

Ursa Major.—We are not such lunatics as to fill our pages with wild disquisitions on Comets; nor with such vulgar unmeaning trash as Dramatic Sketches—Cranium and Shin-bones. Neither should we introduce the name of a well-known brandy-merchant, Mr. Brett, of Drury-lane, among quacks, because he refused to advertise on our wrapper—nor should we praise Mr. Harrison Curtis' new operation of applying *lapis infernalis* every morning to a cataract, to obviate the usual operation, because he advertises with us and is a subscriber—nor could we laud Baillie's Breakfast Bacon, and somebody's Essence of Ginger, to secure their advertisements.

THE

London Medical and Surgical Journal.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XIX.

Evidences of the Seat of Irritability in the Ganglionic System of Nerves—(continued).

EVERY presumptive evidence, then, is in favour of the opinion already advanced, that the apparently simple nervous apparatus of such of the invertebrate animals as have a distinct nervous system at all, is no less compound than that of the vertebrate; and positive evidence to the same effect seems to have been afforded by recent investigators (a), who have found that in some insects, the chain of knots above spoken of as a main part of this apparatus, besides supplying nerves to the parts which minister to the organic functions in the manner of a regular ganglionic system, gives off distinct lateral nerves arising by single roots from the central parts, and distributed principally upon the respiratory organs, as well as others arising each by an anterior and posterior root, and going chiefly to the organs of voluntary motion and sensation, the whole constituting a perfect cerebro-spinal system as found in the highest tribes. The argument therefore of the earlier manifestation, as we ascend in the scale of animals, of the ganglionic than of the cerebro-spinal system of nerves, in favour of regarding the former as the immediate seat of irritability, must not be extended to all the invertebrate tribes, however applicable it may be to those which, without any concentrated and distinct nervous apparatus, still display traces of nervous matter; although it must be confessed that is not easy to say to which department, in the latter case, the isolated nodules in question correspond. The analogy however, so constantly observed in other respects, between the lowest animals and the human embryo in its earliest stages, is certainly favourable, as we shall find from the next paragraph, to the idea that such nodules belong rather to the ganglionic than to the cerebro-spinal system.

VII.—That the development of the ganglionic system of nerves, in the human embryo, precedes that of the cerebro-spinal, and that the first part of it, which becomes obvious is the cardiac ganglion, has been confidently asserted (b): and this circumstance taken in conjunction with the facts, not only that irritation precedes sensation, thought, and voluntary motion, but also that the heart—the *punctum saliens* of Harvey—is the organ of the body which first manifests such irritation, seems to be a strong corroboration of the doctrine which refers irritability to the ganglionic system of nerves, as its primary seat. It is further asserted, not only that the sympathetic nerve is remarkably distinct, and its ganglions perfect and of their usual colour, while the cerebro-spinal system is still very obscure, but also that all these ganglions are relatively larger and more perfect in the foetus than after birth, except the cæliac (c); all which very well corresponds with the hypothesis under consideration, since while the irritability of every organ of the body which ministers to the circulation of the blood, nutrition, secretion, and absorption, is unquestionably more in requisition during fetal than during extra-uterine life, that of those which minister to digestion and generation is as certainly much less so.

VIII.—Again it is abundantly well known how frequently mature human fetusses are

born with a defective cerebro-spinal system of nerves, or even altogether without a spinal cord or a brain (*a*); whereas such defects are said seldom or never to occur with respect to the ganglionic system of nerves, sufficiently indicating its paramount importance in maintaining that circle of vital actions which requires only irritability for its exercise. It is true not a few accounts are on record of monsters, born at the full time, without any appearance whatever of a nervous system of any kind; but, if we attend carefully to such accounts, we shall perceive that their authors have been in general employed in looking for a spinal cord and brain, and the larger nerves connected with them, and might easily have overlooked those smaller filaments which belong to the ganglionic system: and this suspicion seems the more probable, when we call to mind how long it was before this system of nerves, even in the most perfect examples of the highest class of animals, was detected, and how recently the presence of nerves in the heart, upon which some of the most conspicuous filaments of this system of nerves are distributed, was resolutely denied. It is not indeed improbable that when the monstrosity is excessive, the unformed mass may have its nervous system, as well as all its other organs, as is the case in quite the lowest tribes of animals, so generally diffused as to be invisible (*b*); but it is stated on good authority, and as the result of numerous and patient inquiries on the subject, that, so long as a human monster does not very considerably depart from the human form, the ganglionic system of nerves is in general, if not always quite perfect (*c*). It is a good illustration also, as well of the independence of this system upon the cerebro-spinal, as of its indispensability—whatever may become of the latter—to the proper vital functions, that in idiots, whose cerebro-spinal system had become diseased and atrophic, the ganglions of the sympathetic nerve have been found in general perfectly healthy (*d*).

IX. It might have been almost inferred, from the contents of the seventh section, that the ganglionic system of nerves would be relatively more developed in the young than in the aged; and it has accordingly been found that this development is, in all animals, generally inversely as the age of the individual in which it is examined (*e*), the ganglions in old age being paler, drier, and more attenuated, and sending out fewer filaments, than at any other period (*f*). It appears also that the ganglionic system of females, bears in general a greater relation to their cerebro-spinal system than that of males. These facts, coupled with the acknowledged greater irritability of children and females, in comparison with their sensibility, their faculty of thinking, and their power of voluntary motion, than of adults and males, are very corroborative of the hypothesis in question. Perhaps, also, it may be added, under this head, that the length of time during which the irritability of each organ survives apparent death, seems to be, *cæteris paribus*, proportioned to the number and size of the ganglionic nerves with which it is supplied; as is well exemplified in the auricles of the heart, as contrasted with the ventricles, and in the right side of the heart, as contrasted with the left (*g*).

X. It is further in favour of the doctrine that the ganglionic system is the immediate seat of irritability that it is similar in structure to the sensiferous; since it renders it probable that the ganglionic nerves, as they certainly do not communicate sensibility, communicate at least that property which is most nearly allied to it. This similarity is observable, first in the manner in which the grey and white matter are intermingled, in the former system, not only in all the proper ganglions, but in all the nerves connected with them, and in the latter in all the ganglions placed in the roots of the several sensiferous nerves; and secondly in the general character of the white matter, so far as it can be ascertained, in both. It has been already noticed, under the head of the nervous tissue in general, that in the ganglionic nervous tissue the grey and white substances are everywhere inextricably interwoven together; whereas, in the cerebro-spinal—including of course the sensiferous department of it—this intermingling is confined to the central parts, so that the nerves consist of white substance alone. In this statement it was of course intended to include the ganglions of the sensiferous system of nerves among the central parts, and, in these, the mutual relations of the grey and white substances are almost entirely the same as in every part of the proper ganglionic system; nor is there any visible difference in the manner in which the nervous cords appear to enter each ganglion of both systems, to be

(*c*) Lobstein alone, *De Nerv. Sympath.* 1823, p. 52 & seq. relates no fewer than six remarkable instances, in which the brain and numerous other organs were deficient, but in all which the ganglionic system

was quite entire, and in some even more developed than usual.

subdivided within its substance into more minute filaments, and to be re-united as they prepare to emerge from the opposite surface, although if we are to regard the ganglions—not only the insensible, as already stated, but also the sensiferous, as will be stated in future—as independent sources of nervous influence, it would be more correct to represent all the nerves connected with them as proceeding from them, and to speak of such nerves as beginning each by minute roots from the central parts of the organ, and proceeding thence in opposite directions. However this may be, the relative distribution of the grey and white substances is, in both sets of ganglions, the same (a); and when it is remembered that the structure, not only of the grey matter, but, in these two systems of nerves, of the white matter also, unlike what it is in the respiratory and motiferous systems, is plexiform and soft, the general structural similarity of the proper ganglionic and sensiferous systems of nerves will be sufficiently apparent, and it will not seem unfair to infer that, as the respiratory and motiferous systems of nerves, the structure of which is similar, are the vehicles of different kinds of stimuli, so the ganglionic and sensiferous, which are equally similar in structure, are the seats of different kinds of susceptibilities.

XI.—It has been already stated that certain agents, such as narcotic substances, which when applied to the central parts of the sensiferous system of nerves, diminish or altogether destroy sensibility, when applied to all appearance directly to parts possessed of irritability, have similar effects with regard to this faculty; and as this is a fair *general* argument that it is not immediately on these parts, but intermediately through some department

(a) The internal structure of the ganglions, insensible and sensiferous, has been investigated principally by Meckel, sen., Haase, Scarpa, Monro, Bichât. Wutzer, and Lobstein, the four first of whom, as already observed, regard the former as merely appendages to the cerebro-spinal system, and the three last as independent organs; and the general result of their inquiries appears to be that there is little or no perceptible difference in structure between the two. The investigations of Meckel (*Mem de Berlin*, 1745), were confined almost to the sphenopalatine ganglion; but those of Haase (*De Gangl. Nerv.* 1772), were more extensive. By means of maceration and boiling he found that, in the centre of the ganglions in general, the minute white filaments, of which chiefly they consisted, were apparently teased out into a kind of net-work, but that, towards the surface, more or fewer of them were united together at acute angles, and thus constituted the nerves supposed either to terminate in or to arise from the ganglions. These observations were confirmed by Scarpa (*De Nerv. Gangl.* 1779), and Monro (*On the Struct. and Funct. of the Nerv. Syst.* 1783), who further thought that they observed that the filaments of all the nerves supposed to enter a ganglion, after having been unravelled within its substance, were so distributed, on preparing again to emerge from it, that every nerve proceeding from a ganglion received at least one filament from every nerve which had apparently entered it; and it was in this observation that the celebrated hypothesis of these authors, which has been already alluded to, respecting the use of the insensible ganglions, originated. But it was not merely of these subdivided and re-united cords, as in a mere plexus, that the ganglions, whether insensible or sensiferous, were found to consist, since in the interstices of these, a soft semi-liquid substance, of a colour between yellow and grey, and which

by Winslow, Johnstone, and others, had been previously presumed to be analagous to the cortical point of the brain, was uniformly met with; and although, according to Bichât (*Anat. Gén.*, 1801), supported by Wutzer (*De Corp. Hum. Gangl.* 1817), the former substance differs in several essential particulars from the latter, in as far as its merely physical and chemical properties are concerned, yet it may still bear the same physiological relations to the nervous filaments of the ganglions, whether insensible or sensiferous, as the grey substance of the brain bears to the white substance of that organ. Wutzer, moreover, amply confirmed the observations of Scarpa and Monro respecting the manner in which the nervous cords appear to be unravelled, and their filaments again collected, in the ganglions of both systems; and has given plates of the internal structure of some of the chief ganglions of each, the appearance of which is almost precisely the same: it is unnecessary to repeat, however, that a very different view may be taken of the nature of these ramifications. By Lobstein, lastly, (*De Nerv. Sympath.*, 1823), the presence of the soft, greyish substance equally in the insensible and sensiferous ganglions was further established, with the additional observation that, the smaller the ganglion, in general the greater was the relative quantity of this substance which it contained; and he confirmed also the remarks of preceding authors respecting the intermingling of the nervous filaments in the substance of the ganglions of both sorts. The fact, therefore, of the similarity in structure of the two appears to have been abundantly made out by the concurrent testimony, as well of the opponents, as of the advocates of the doctrine, which ascribes to the ganglionic system of nerves a property analogous to that which the sensiferous system is universally acknowledged to impart.

or other of the nervous system, that they operate so, taken in conjunction, not only with the direct analogy of sensibility and irritability, but also with the striking similarity in structure of the sensiferous and ganglionic systems, it is a fair *special* argument that it is through the latter system that they take effect, and consequently that this system is the immediate seat of irritability.

The remarkable circumstance, also, that the stimulus of galvanism is not well conducted by either the sensiferous or ganglionic system of nerves, while by the respiratory and motiferous its conveyance is instantaneous, is a further proof of the functional analogy, as well between the two former as between the two latter, and has therefore an obviously favourable bearing on the hypothesis in question.

XII.—The last circumstance to be mentioned, as tending to the conclusion that the ganglionic system of nerves is the immediate seat of irritability, is that of the nerves of this system, while they are of a similar form, colour, and consistence, when distributed on parts the irritability of which is of the same character—that is to say which are liable to be excited in the same manner by the same stimuli—being quite dissimilar in all these respects, when they supply parts the irritability of which is different. Thus, while the filaments going from the ganglions to the several voluntary muscles, all which have one general character of irritability, are said all to display the same general aspect and physical properties, those which proceed from the cæliac ganglion, for example, respectively to the stomach, liver, and other organs, each of which has a character peculiar to itself, have these properties very distinct; those sent to the stomach being conical, white, and firm, those to the liver cylindrical, red, and soft, and similar differences manifesting themselves between the filaments respectively of the splenic, mesenteric, hypogastric, and other plexuses (a). This remarkable coincidence then, if generally admitted, of certain modifications of a common faculty, as displayed by different organs and corresponding modifications of a common system of nerves, as distributed to these different organs, seems to be a strong testimony in favour of the doctrine, that this general system of nerves ministers directly to the general faculty in question.

Such, then, are some of the principal evidences brought forward in support of the hypothesis which places irritability on the ganglionic system of nerves as its immediate seat: the principal objections, on the other hand, to this hypothesis, in addition to the supposed circumscribed distribution of this system of nerves, and some others which have been already incidentally answered, are the alleged facts—at first sight conclusive against it—first, that the application of stimuli to a ganglion has little or no effect in producing any display of irritation, either in the ganglion itself, or in the organs which it supplies with nerves; and, secondly, that the destruction or removal of a ganglion has little or no immediate effect in diminishing the irritability of those organs, the nerves of which are derived from it.

It has been confidently asserted by many experimenters (b), that the ganglions of the sympathetic system in general may be acted on either mechanically, galvanically, or, as they suppose, chemically, without either betraying themselves any irritation, or giving rise to any irritation in the contiguous parts; and although some have asserted that stimuli applied to the cardiac ganglion, for example, do excite the motions of the heart, as much as when applied directly to the heart itself (c), while others, again, have represented such stimuli applied to the cæliac ganglion (d) or hepatic plexus (e), as competent to excite, not only irritation, but also sensation, in the parts to which their nerves extend, perhaps it may be safely conceded that no manifestation anywhere of even irritation follows the application of stimuli to a ganglion, without any compromise of the doctrine that it is in the ganglionic system that irritability is primarily seated. It is true, when the central parts of the sensiferous system of nerves—between which and the ganglionic system there is so close an analogy—are so acted on, the result is sensation, acute in proportion to the intensity of the stimulus applied; and it is highly probable, that when such stimuli as those just alluded to are applied to a ganglion, the result is irritation in the part immediately acted on, but such irritation may exist without any *manifestation* of it. It cannot be evinced by any expression of pain on the part of the animal on which the experiment is performed, for irritation is without consciousness—it is “*perceptio*,” but not “*perceptio perceptionis*,” nor can it be evinced by any perceptible motions on the part irritated, for a ganglion is without muscular fibres, and has not therefore the physical structure requisite to such motions. Nay, it is by no means certain, as already stated, that irritation may not exist without even imperceptible motion, although in as far as it does so, it cannot be regarded as quite synonymous with life—but whether or not any insensible motion takes place when a stimulus is applied to a ganglion, it is obvious that we cannot recognise irritation by this means. Whatever irritation may exist, therefore, it is impossible that there can be any manifestation of it in the ganglion itself, and it is highly improbable that any

(e) Haller.

such irritation will be extended elsewhere. The nerves supplied by the ganglions to the contiguous organs, if they communicate any thing at all to them, as acted upon through the ganglions, which is very doubtful, can be conceived, in conformity with the doctrine now under consideration, to communicate only an increased susceptibility of action on the application to the organs themselves of the requisite stimulus, not a stimulus capable of exciting the susceptibility already resident in them; and without this stimulus no irritation can, in any instance, take place. It is a very different thing when any extraordinary stimulus is applied to the root of a respiratory or motiferous nerve, the office of which is to convey stimuli in general to the organs in which they are distributed, and which, furnished as they are already from another source with the second necessary condition of action, namely, irritability, immediately obey such stimuli and manifest irritation. But doubling or trebling the latter condition of action, if it were possible to do so, by stimulating the ganglions, would not supersede the necessity of the former, which, in this case, must be wanting; so that whatever irritation were thus excited, it might *à priori* have been conceived likely to begin and end in a part in which any display of it was impossible. It is hence probable, that when the heart has appeared to be called into action by a stimulus applied to the cardiac ganglion, it was by means of some filaments of the pneumogastric nerve, with which the proper ganglionic nerves were associated, that the stimulus was conveyed in the same manner as when pain has appeared to be excited by such stimuli applied to ganglions, it was by means of some sensiferous filaments, with which the proper ganglionic nerves had become amalgamated, that the sensation was effected.

Nor is the fact, that the destruction or removal of a ganglion does not immediately entail any diminution of irritability on the organs to which the nerves from this ganglion extend, at all militate against the doctrine that it is in the ganglionic system that this faculty is primarily seated. It is unquestionable, that the destruction or removal of any portion of the central parts of the sensiferous system of nerves—so analogous to the ganglionic—entails a corresponding failure of sensibility on the organs which are supplied with nerves from this portion; but if a similar effect be anticipated with respect to the irritability of the heart, for example, from the demolition or abstraction of the cervical ganglions (*a*), or even of the cardiac ganglion (*b*), it must be by one unacquainted with the facts already insisted on, first, when speaking of the non-interruption of the irritability of a muscle by the division of the principal nervous trunks with which it is supplied, by the removal of the brain, or even, for some time, by the total separation of such muscle from the rest of the body, and again, when speaking of the fatal effects of withdrawing the central parts of the nervous apparatus of the invertebrate animals, as a proof of their corresponding rather to the cerebro-spinal, than to the ganglionic system of the invertebrate—that, from the intimate interweaving together, in every point of every ganglionic nerve, of grey and white matter, every such point is a focus of nervous influence to itself, and quite independent, therefore, at least for a time, on any common centre, for the continued display of the peculiar faculty to which it ministers. On the other hand, the sensiferous nerves, consisting as they do of white matter alone, must be regarded, not as sources of the characteristic faculty to which they are subservient, but merely as chains of communication between the organs on which they are distributed, and the sensorium; so that instantly, upon the latter being injured or withdrawn, the former are paralyzed throughout their whole extent. We may liken, if we please, the individual ganglionic nerves to wires composed of zinc and silver, and the ganglions connected with them to a voltaic pile: the former, perhaps, under ordinary circumstances, act principally as conductors of a power generated in the latter; but, upon being separated from it, are still competent to afford a certain quantity of the same power generated in themselves (*c*). Hence the division of the large vessels going to a limb, with which principally perhaps its ganglionic nerves reach it, has no immediate effect in impairing its irritability; and what effect it has, after a time, in this way, is pretty certainly to be ascribed, as already remarked, rather to the defective supply of blood to the parenchyma of the limb, by which the ganglionic nervous matter therein contained should have been renewed in proportion to its exhaustion, than to any obstruction of the ganglionic nerves in their course. A knowledge of these facts might have led us to expect an almost entirely negative result from the experiments just alluded to; and we cannot therefore, from such a result, infer anything prejudicial to the hypothesis now under consideration.

Upon the whole, the doctrine which regards irritability, not as inherent in all or any of the organized tissues of animals, independently of the nervous, but as immediately seated in the latter, and that, not in all its departments, but in the ganglionic department alone, seems to be as well entitled to credit as any doctrine, resting upon presumptive evidences alone, can be. The fact is not indeed demonstrated, nor is it perhaps susceptible of de-

(*a*) Bràchet, Sur les Fonctions du Syst. chet, &c.
Nerv. Gangl., 1823.

(*c*) Dr. Lovell Phillips, On Inflammation, 1833.

monstration; but he who determines to wait for demonstrative evidence on all, or almost any point of physiology, must make up his mind to halt on the threshold perplexed, and stationary in this perplexity. Upon every subject of physiology, and in every stage of our progress in the science, one opinion must be better supported than another, and any opinion founded on the best information which the present state of knowledge affords, and taken up, not more as a resting-place for the present, than as a stepping-stone to the future, must at least be better than no opinion at all, since it rather invites than opposes itself to further investigation, and while it spares us much heart-sickening and hopeless confusion at first, often enables us, by working with our previous conclusions in future speculations, to arrive rapidly at truths for which we might otherwise have waited in vain for ever. Let us not mistake, as is too often done, the vacillation of the timid, the indolent, or the incompetent for the caution of the philosopher, nor the decision of those who have boldness, industry, and talent enough to come to the legitimate decision for the rashness of the visionary. It has been admirably remarked, that he who dares not form an opinion must be a coward—he who will not must be an idler—he who cannot, must be a fool. Let us have an opinion upon every thing; but let us take up such opinion only after mature and dispassionate consideration of all the established facts which bear upon the subject, and be ready at once to qualify or to resign it, should any new facts occur to stagger or to overthrow us. It is no reproach to any one to be wiser to-day than he was yesterday; but it is a severe reproach to be from first to last an irresolute waverer, from a silly affectation of seeking for positive evidence in a science where such evidence is often unattainable, and a captious and fidgetty habit of starting difficulties, which a more powerful mind would either have disregarded as frivolous, or at once have dismissed as imaginary.

With respect to the manner in which irritability or vitality, presuming that its immediate seat is, at least in all the higher tribes of organized beings, the ganglionic nervous tissue, may be presumed to be extended to the other organized tissues, so that each appears to be *per se* possessed of it, very little needs be said. In the case of sensibility; the immediate seat of which is the sensiferous nervous tissue, there is no difficulty in at once admitting that this is the exclusive seat of the property in question, and that the comparatively few other tissues which appear to be *per se* possessed of it are, except in as far as they contain this, entirely insensible. But, with respect to irritability, we have more hesitation in confining this to the ganglionic nervous tissue, since irritability is, unlike sensibility, not merely an adventitious, but an essential property of organized beings, and seems therefore to be necessary, not only to every organ and every organized tissue, but also to every point of such tissue, in order to effect its molecular actions. But we must remember that there is no point of any organized tissue which does not contain ganglionic nervous matter, such matter being essential to its organism; and, consequently, there is no point which is not possessed of the property in question, which is accordingly—as has been from the first insisted on—the result of such organism. It is true, unless every organized tissue be one uniform mass of ganglionic nervous matter, there must be interstices of some other matter.

Thus there must be spaces in the ganglionic nervous matter occasioned by one or other of those peculiar aggregations of matter which go to form respectively the cellular, dermoid, mucous, serous, fibrous, vascular, osseous, cartilaginous, or muscular tissues, wherever an organized tissue presents itself; but the spaces thus occupied are so infinitely minute as to be perceived only by the mind's eye; and we may, therefore, without doing much violence to preconceived opinions, deny that they have direct participation in irritability or vitality. As merely a property, it can never be directly transferred; and if it be immediately, it must be exclusively that of the ganglionic nervous system (a). But such in-

(a) It was the opinion of Galen, although he knew nothing about irritability, that the nerves, as the immediate receptacles of his Πνεύματα, vivified, as it were, all the parts in their vicinity, καθάπερ ὅταν ἐπιτῶν περιέχοντος αἴρος ἐκ τῆς ἡλιακῆς αὐγῆς ὁρμηθῆῖσα τις ποιότης; (De Placitis Hipp. et Plat.); and a somewhat similar notion has been propagated in recent times by Reil, Humboldt, Aldini, Heineker, Lobstein, and others, who speak of a nervous halitus, gas, or atmosphere, an organic ether, &c., as the immediate source of the vitality of all the tissues of the body. "Statuo," says Lobstein, "materiem subtilem, imponderabilem, incoercendam, magnetico, vel electrico-galvanico fluido analogam, a pulpa nerva se-

cretam, evolutam atque transmissam, solam actuosum, quod nervis inest, principium constituentem. Admitto istam materiem mobilissimam, et summam nobilitatis gradum assecutam, circa nervorum funiculos atque ramos, tum et circa carnem muscularem, efformare atmosphæram—eam sensibilitate esse præditam, id est facultatem habere stimulum percipiendi, atque, ope organorum e quibus emanat, contra eum reagendi." (De Nerv. Sympath. 1823, p. 123). Dr. Lovell Phillips has lately endeavoured to illustrate the subject by comparing the changes effected by the property derived from the nerves in the organized tissues in general, to which this property gives, as it were, a new mode of being, to

ferred foreign substances, thus destitute *per se* of irritability or vitality, are not, nevertheless, in the condition of merely inorganic matter—of a mere “solidum mortuum,” with respect to either their structure, their composition, or their actions. It is never otherwise than as combined into a whole with ganglionic nervous matter, that they actually exist; and although the former alone perhaps has a structure and composition which can be strictly called vital, and is susceptible of strictly vital changes, still the latter are not less *sui generis* in these respects possessing, as they must do, such physical and chemical characters as qualify them to co-operate in these changes, and thus to temper and modify, in every part, the resulting phenomena. It is easy to conceive that, if a flame be applied to a mixture of combustible and incombustible matters, the former alone will burn, but the latter may still be competent to undergo, each according to its peculiar character, such modifications of expansion, liquefaction, vaporization, incandescence, and so forth, as will materially qualify the nature of the combustion, and may even be essential to it. It is in a similar relation that the substances occupying the interstices of the ganglionic nervous matter, in the several organized tissues, appear to stand to the nervous matter itself—they have *per se* no irritability or vitality, nor are the phenomena which they display strictly vital; but they are nevertheless such as no merely inorganic matters could have presented, and such as not only temper and modify vital action, but are perhaps necessary to render such action available.

those effected by the matter of heat in water, which is thus converted into vapour, and distinguished afterwards by characters quite distinct from any which it previously possessed. (On Inflammation, 1833). All these attempted explanations, however, seem to

proceed upon the presumption that irritability is a substance, and as such actually communicated by the nerves to the tissues with which they are associated, instead of merely a property, and therefore quite incapable of being so transferred.

LECTURE II.

The Fluids in Disease--Debilities--Inflammation.

THE fluids may be variously modified: they may be retained in the vessels and give rise to congestions. Obstacles may present themselves to the course of the blood, and these constitute a considerable class of important diseases, which I believe I was the first to mention as distinct from others, and which I was formerly in the habit of describing in the first place, though the clearness and precision I would desire to establish oblige me to leave for after consideration. These diseases in fact may disappear, and I by no means intend to say, that all the alterations on which they depend are incurable; nature is not without the power of relieving them.

The fluids then may be retained by the different affections denominated inflammations, neuroses, sub-inflammations, and organic alterations. They may be eliminated from the vessels constituting hemorrhages and fluxes; they may be depraved in their composition, and this is most frequently the case. In the next place, the fluids being retained, decomposed, and altered in the diseased parts, those of the remainder of the system may also become altered and decomposed: hence drop-

sies, œdema, the effusions consequent on and caused by inflammation.

Debilities.—Next to the alteration of the fluids come the debilities; these are sub-excitations, which have as certain an existence as super-excitations. But neither of these have any thing to do with those of Brown; for I point out to you many intermediate stages between the first and last degrees of inflammation, whereas Brown divided diseases into two series, one with augmentation, and the other with diminution of the vital power abstractedly considered, and not in relation with the organs. This power he regarded as an entity which at one time increased, and at another curtailed the energy of the whole body in an extraordinary manner. In fact, Brown's was a system of ontology.

I shall proceed to give you an idea of the nature of these sub-excitations, in order that you may understand the terms of which I make use, and that you may form a precise notion of all that will pass before us, not in an abstract manner, but in their immediate application to the living matter. When I began to teach the doctrines that I profess, I was in the habit of first laying down the general principles: I subsequently tried the method which takes its start from particular facts. Having consulted, on the choice between these methods, those of my hearers who appeared to be gifted with a discriminating spirit, and having myself revolved the point, I came to the conclusion that the latter, although analytical, was not equal to the former. Indeed, particular facts are so numerous, the details so multiplied, that it be-

comes an immense and even endless task to insist upon a knowledge of them all on the onset. It is better to commence with their common points of resemblance, taking the chance of not being perfectly understood. After a few lectures we are much more likely to be understood than if we had commenced with the details of isolated facts, while the latter are readily applied to the general or common notions, as soon as the lecturer develops them—in other words they are often recognised beforehand.

Sub-excitation or vital action in a degree beneath the normal state is, in the first place, exhibited after irritations: this is the most ordinary event. Every part that has suffered from inflammation, and when the latter has recovered is weaker than it previously was: the body exhausted by an effort, by a fever, remains debilitated, even though no blood shall have been drawn, and no abstinence observed. All convalescence is accompanied by weakness, which is an actual pathological state, worthy to be particularly attended to, and which has been truly denominated a secondary disease. In fact there is a debility to be managed, and it is of no small consequence to avoid changing it too rapidly into the contrary excess of strength. In the next place, whenever an excess of action occurs in any part of the nervous system, all the organs dependant on it are in a state of debility. If this increase of action has taken place in the brain, the functions of the muscles under its influence are weakened, as are also the sensitive and intellectual functions: this is the case either when there is inflammation, or when a sanguineous effusion in the brain matter has occurred, or a foreign body exists in it, or when there is serous effusion on it: in all these instances you behold debility follow super-excitation: you also behold it after any irritation that has existed in the medulla oblongata, in the spinal cord and in the nerves. It is of greater or smaller extent, according to the number of functions that the nervous apparatus affected has under its influence.

Thus it will be found that debility is equally important with irritation: but it should only be treated of after that condition; and you may find the reason for this in the fact that the majority of debilities are caused by super-excitations. After inflammation you have debility; after neurosis, debility; after hemorrhages, debility, and so on. It is connected, as a consequence, with all irritations, and is the common termination of them. You will ask me wherefore I speak of it in particular now, when it is my intention to mention it under each of the irritations? Because when I come to speak of inflammation, or neurosis, 'sub-inflammation, and organic alterations, your attention will be so rivetted on each of these phenomena, that you will have no thought of the consecutive states. and debility is so important that it will be necessary to return to and consider it atten-

tively. Meantime, care must be had to distinguish consecutive from primary debility, of which I shall also take occasion to speak.

Inflammation.—Inflammation is the principal phenomenon of pathology. Enter into any part of any hospital, and you find it at every step you take. You rarely meet with asphyxia, syncope or other similar affections purely asthenic and ab-irritative, but almost always with inflammation or its consequences, sub-inflammations, organic alterations, decompositions of the fluids, extravasations, &c. Go to the origin of all these affections, and you will almost invariably trace it in inflammation. Strictly speaking, therefore, this is the most important phenomenon of pathology, and that with which we ought to commence.

I will not undertake to give you a definition of inflammation, inasmuch as definitions for the most part only imperfectly represent the things they are intended to give an idea of. I prefer to offer you a summary idea of the state in question, and then proceed to its history, doing this however sufficiently in detail, that you should not be confined to purely theoretical data nor a limited review of particular facts.

Inflammation of the exterior surface of the body is recognised by four phenomena—pain, tumefaction of the affected part, increase of heat perceptible to the person suffering from it, and even to the observer, in comparison with the surrounding parts, and by redness beyond the natural degree. But we must not be confined to these four phenomena: we should also take advantage of the light thrown upon the subject by anatomy, and proceed further with our investigations. If we incise this inflamed point, we behold a sanguineous congestion of the vessels, which are now numerous and more filled with blood than in the normal condition. If we endeavour to ascertain how the circulation in it is going on, we find the following appearances: there is in the first instance augmented activity of the circulation of the injected vessels: subsequently a stagnation of the blood takes place in the centre of the tumour, and if an attempt is made to throw an injection into it, an obstacle will be found to it. An extravasation of blood into the areolar tissues of the part, if there are any—and there almost always is—is effected, the blood being not only extravasated, but mixing with the lymphatic (partly albuminous and partly fibrinous), the serous and the mucous matters. The activity of the circulation in the immediate neighbourhood of the inflamed point meantime continues: the surrounding cells also fill, the central ones with pure blood, the others with sanguinolent exudation. As the distance from the centre of inflammation increases, the infiltration is less bloody, and finally is altogether lymphatic and serous. In analysing the different parts of the tumour, it will be found that the central extravasations or exudations, contain more fibrin and albumen

than those of the circumference, in which gelatine and serosity predominate.

But how does all this terminate? If the inflammation be not excessive, and its cause ceases to operate, the fluids no longer go on accumulating around the inflammatory nucleus; the absorption of those that have been extravasated, commences in the areolæ of the nucleus, and of the surrounding parts; the stagnation of blood disappears; the effused blood is absorbed, the whole part again passes to the healthy condition, the resolution is completed, and no organic alteration remains behind.

But if on the other hand the congestion has been excessive, and all the cells of the part fill freely with blood containing no fibrin and coagulating, a motionless state ensues, the communication between the part and the current of general life flowing through the nerves is cut off, the fluids are no longer changed, the part dies and falls into gangrene: this last is limited by an inflammation which is for the most part defined.

If the congestion is not so great, the inflammation, after a certain time, losing its activity, a pure and simple resolution does not take place, but in lieu of it a resolution with decomposition of the fluids: pus is formed; so soon as this occurs the inflammation diminishes in intensity. If the part is permeable and has excretory canals it is frequently evacuated by those routs; if it is not, the pus collects into a centre, forces a solution of continuity and abscesses. Sometimes when the inflammation exists in mucous tissues, the secretory apparatus of the inflamed part is endued with the irritative action, and secretes a copious puriform mucus in order to the resolution of the inflammation.

Suppuration, however, is not always the termination, as may be seen when the inflammation existing in two opposite surfaces, the matter that exudes becomes organized, and establishes a continuity between them: this is one species of resolution. But if during the organization of this matter a fresh afflux of fluid takes place, the process is interrupted: a liquid, limpid, or turbid from the detritus of the exudation, sometimes purulent, separates the surfaces and forms an effusion. At other times, while the inflammation is continued during the absorption of the serosity that has been separated from the exudation, the solid matter of the latter may become dense, compact and organized in the shape of a false membrane, whence a true cicatrix arises.

Lastly, extravasation and incomplete stagnation of blood may occur in the areolæ of a part, without the total isolation of the effused fluid from the circulating mass that happens in gangrene; this is red induration, a kind of phlegmasia that becomes chronic if the individual survives.

Inflammation frequently leaves behind it

various kinds of alterations, such as superficial red granulations, false membranes, chronic effusions, vegetations, &c. Within the inflamed part fibrin is retained which becomes organized, and produces different kinds of organic alterations, such as hypertrophy of the whole organ, an alteration of the secretory apparatus, which instead of its natural fluid gives out pus or its own fluid in a depraved condition—either decomposed or sanious—and forms foreign bodies. Sometimes demolition of the organ ensues, which from a chronic inflammation suppurates, and in doing so is disorganized, and produces a kind of ulceration; the prolongation of acute inflammation generally has some such result as this.

Inflammation may also, without destroying the organization of the parts, leave their tissues in a state which deranges their functions: leaves, for instance, their nervous capillaries or papillæ in a pathological condition that induces particular phenomena: leaves the ganglions and the areolar and lymphatic tissues in a state of irritation, which after appearing to commence in the blood vessels during the acute stage, remains in the secondary tissues, and becomes chronic. *This constitutes sub-inflammation*, which in this case is only degenerated chronic inflammation—though such is not always its origin, for it may be primarily established. In fact, we are so organized, that irritation may be developed in the lymphatic, areolar, secretory and excretory systems, establishing therein an abnormal movement that tends to a deranged nutrition and the decomposition of our organs, without its ever rising to the degree of inflammation. This irritation is, however, always ready to rise to that degree, and we may indeed affirm, that every chronic irritation has a tendency to become acute, or even that every such *will* end in acute inflammation, unless it be properly treated. This is one of the most important truths of the physiological doctrine, and without a recognition of which it is impossible to be a judicious practitioner.

Such is a summary idea of inflammation viewed in its local character. But other considerations are attached to the subject; this inflammation influences the organs, it rarely enjoys a purely independent progress, unless it be extremely limited as in the instance of a very slight eruption, a passing erythema, a sty, or a simple pustule; while he who has had an inflammation in one part of the skin is liable to its re-appearance in some other part of it. Inflammation then, is rarely absolutely isolated; a simple prick of a pin often causes disorder at some distance, influencing the neighbouring organs by the propagation of the inflammation it induces; in this case there is a degree of pain which connects the movements of these organs. Suppose a woman seized with violent inflammation of the vagina; she would be consti-

pated, for the rectum would no longer dilate with the same facility. Is there inflammation of the pleura, immediately you may remark the immoveability of the intercostal muscles. Hence the origin of numerous phenomena; first there is propagation of inflammatory action in the immediate vicinity, and then, in consequence of pain, immoveability of the neighbouring organs whither the inflammation tends.

Thus, you observe one first influence of inflammation on other organs than those in which it is seated. By what medium is this influence exerted? by the medium of the nervous system. Does any moderately active inflammation involve the nerves of a part, those of the neighbouring parts communicating with them transmit the pain from one to the other; if one of your fingers is inflamed, the next fingers pain; if you have the tooth ache, more or fewer of the teeth also ache; is there an irritation of the nipple, the secretion of milk is altered; or of the bladder, the functions of the kidneys is disordered, and the urinary secretion depraved; if of the mouth, the salivary glands will cease to furnish the same healthy saliva as before. Influences such as these may be exerted on the neighbouring parts by means of nerves, without any disturbance of the powers, and without the participation in them of the brain and spinal cord. But if they become more intense, the disturbance may include the whole system; the nerves propagating to a considerable distance the stimulation of the morbid part, the spinal cord becomes the chief conductor of it, and the brain itself will be involved in the circle of transmitted stimulus. How are we to prove that such is the mode of proceeding? this is not difficult to do. You have only to divide the principal nerve of an external part, and then induce inflammation in it, and you will find that it remains purely topical and is no longer transmitted; you have only to disperse the congestion of an important organ in a state of inflammation, and the sympathetic phenomena will soon decrease and be finally extinguished. A man comes to me with a violent inflammation, producing an action on the brain and spinal cord, and causing subsultus of the limbs; I attack the inflammation and the twitchings disappear; the following day this patient commits some error in diet—immediately the subsultus returns. Facts of this kind are numberless. But this is not all; when irritation is thus disseminated by the nerves, other disorders than those of transmitted pain and of convulsions and spasms are produced. The heart contracts once or twice more rapidly than in the normal condition; the whole animal economy is deranged, and what is called fever is lighted up in a degree proportioned to the extent and vitality of the inflamed surfaces. The more nerves and vessels that are attached to an organ, and the more close and immediate the communication with the nervous centres of

transmission is, the greater is the disturbance. You see this in pulmonary inflammations, in phlegmasiæ of the digestive canal, which is seven times longer than the body—no wonder that a new disorder is induced.

The acceleration of the progress of the blood causes all the organs to receive more of it than ordinary. The respiration is necessarily precipitated in order to effect a more frequent oxygenation. If there are organs in a fit condition to retain it, the blood forms congestions in them that irritate them, as we see in individuals who previously had latent inflammatory points, and who in other respects were in tolerable health. When such persons are once involved in the febrile state, the points that were hitherto but slightly congested, become gorged, and suddenly inflame in consequence of the more vehement nervous excitation, and the more rapid current of blood; so that though they were passably well a few days before, having several latent, circumscribed phlegmasiæ, they are suddenly hurried on to the last degree of danger. Unless the physician who witnesses such apparent anomalies is accustomed to apply his powers of mental analysis to disease, he can never succeed in clearing up the chaotic disorder of it.

Further, the whole muscular apparatus is out of order; all the secretory actions are deranged in their action, and furnish diseased fluids—a circumstance that led the ancients to believe that the blood was corrupted in fever—and in fact all the chymical combinations are then overthrown; the whole economy is changed on the advent of any extensive or vehement inflammation. At the commencement, the process of nutrition in the inflamed organ is augmented, and when it has arrived at a certain point, disorganization takes place, it takes a retrograde course, and finally stops altogether. Should the organ be an important one, it deranges the composition of all the others, and nutrition is languid throughout the system; the process of decomposition predominates in the shape of excessive evacuations and disorder of the great viscera, emaciation progresses, and the patient slides into marasmus.

Such then are the principal phenomena of inflammation.

The influence of inflammation on other organs than that in which it is seated is, as we have seen, referable to four means of transmission.

1. By propagation: this is the most simple fact.
2. By community of nerves; pain and the immoveability of parts supplied by the same nerves is the first consequence.
3. By compression on the neighbouring parts; this may produce extravasations, disorganization, new tissues, &c. &c.
4. By transmission and dissemination by

the medium of the nervous system, which is indeed the means of communication between the vital phenomena of movement and sensation, just as the vascular system is that of circulation of the blood. I call your particular attention to this fact, for I believe that reflexion on it has caused the formation of the majority of judicious observers and most able physicians.

We have seen then how inflammation in the first place transmits irritation to a short distance by the nerves: of this I gave you several examples. In all these transmissions there is a remarkable phenomenon that ought not to be passed: it is, that at a certain degree of intensity, they cause an augmentation of the quantity of fluids furnished by the secretory organs, while, at another and stronger degree, they suppress them. In slight or incipient cystitis there is a more copious flow of urine: when it becomes intense it is suppressed. The same obtains in gonorrhœa. Inflammation of the stomach augments or arrests the flow of saliva, according to its intensity. Such is also the case in inflammations of the digestive canal: if slight they induce a more abundant flux of bile to themselves; if vehement, they stop its secretion. I have seen individuals that were subject to a considerable secretion of semen in whom an urethritis altogether put a stop to it.

In the next place, inflammation is transmitted throughout the entire system by the nerves; and when this is the case, the nervous centres take a part in the transmission; the stimulation then travels along the nerves, is reflected on the encephalo-spinal apparatus, and produces its various effects. One of the foremost of these is the increase of the heart's action or fever, which is by no means a necessary phenomenon in inflammations; for when these are limited, they pass through their phases without causing, without inducing any fever; and if, when they are extensive, the physician reduces them within certain limits, the movements of the heart cease to be hurried, and the fever stops. Thus it is only a sympathetic effect of inflammation, the only exception being the instance when the heart itself is inflamed.

The irritation once arrived at the great nervous centres, and spread thence over the organism, producing increased frequency of pulse, the process does not stop there. It turns off to the muscular system, and causes lassitude thereof, as may be proved by the possibility of diminishing or increasing the latter at will, by merely diminishing or increasing the activity of the inflammatory focus. On the other hand, it re-acts on the secretory parts, and causes the changes of fluids already mentioned. These changes vary according to a multiplicity of circumstances—according to the quantity of blood collected in the secretory organs, the proximity of the focus of inflammation, according

as the organ itself, or a portion of it, is the seat of that phenomenon, &c. &c.

Inflammation moreover re-acts on the two great functions of digestion and respiration. When an inflammation is sufficiently intense to affect the whole body, digestion suffers, and the appetite diminishes even though the stomach be not the seat of any inflammation whatever. Digestion may however go on if the influence be not too powerful: in the contrary case, digestion and appetite are arrested, and the stomach may even become inflamed. This takes place with varied rapidity, and the same stimulus deranges it more rapidly and more seriously in some than in other individuals; hence you see some who labour under inflammatory affections retain their appetite much longer than others similarly situated. What has been said of the stomach is applicable to other organs, to the lungs, as I have said, and to the brain. When the circulation is accelerated by the impulse of some centre of inflammation, and the nervous irritability is augmented throughout the nervous system, in consequence of the dissemination of the irritation, many organs that were not previously irritated become so, and you will see two, three, or four intense inflammations ensue upon a single inflammatory point.

In consequence of all these re-actions, and of this general disturbance, nutrition is deranged, because there is less reparation and more loss than in ordinary circumstances. The body becomes thin, while the inflamed part hypertrophies; but this hypertrophy does not continue beyond a certain degree of irritation, and thickening, suppuration, effusion, and every kind of disorganization follows it. Yet it is not less certain that if only a moderate degree of stimulation prevails in the organ, it undergoes an actual augmentation of volume without disorganization, and at least with a very slight alteration.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS,

FROM BIRTH TO PUBERTY.

BY DR. RYAN,

Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho; Session 1834-35.

LECTURE XXXVII

Petechiæ—Cyanosis—Lentigo—Ephelis—Chloasma—Aurigo or Icteritia—Kironosis.

GENTLEMEN—I shall now proceed to refute M. Andry's opinion that the fœtus in utero cannot labour under small-pox or other contagious diseases.

In an essay entitled "Observations on the Effects of Variolous Infection on Pregnant

Women," by George Pearson, M.D.F.R.S. Physician to St. George's Hospital, from the *Medical Commentaries*, vol. xxix, p. 213, will be found ample evidence, which I shall quote at length.

In April, 1793, I was requested to direct and attend the inoculation of the poor people in Weybridge, Walton, and other places adjacent to Oatlands. On this occasion I had under my care 215 patients, who were inoculated in May and June last, by Mr. Norman, Apothecary to the family of His Royal Highness the Duke of York. I attempted to avail myself of this opportunity to make observations, with a view to determine the circumstances which render the inoculated small-pox more or less severe; for the most experienced and judicious physicians do not agree with respect to many of the circumstances which have been generally alleged to influence this disease. But the observations in the present paper relate only to the small-pox in pregnant women.

The action of the variolous matter on the animal economy, is an interesting object of contemplation to the cultivators of natural science as well as necessary to be understood by physicians. It is supposed that the following statement of cases and observations may tend to elucidate a part of this subject, which has been hitherto but little investigated.

Case 1.—Mary Sheers, twenty-five years of age, the wife of a labourer, a moderately strong and healthy woman, had borne four children, the youngest of which was two years of age. According to her reckoning she was now in the beginning of the eighth month of her pregnancy. Having been directed to abstain from much fermented liquor and much animal food for about a week, and having during this time taken a mildly operating cathartic, she was inoculated on each arm on the 7th of May. The patient was ordered to observe the regimen just mentioned, and also to expose herself much in fresh air. On the 11th of May, the fifth day, including the first after inoculation, both arms were inflamed in the manner they usually are when the infectious matter produces the small-pox. Although there was no complaint made, it was thought advisable to draw off ten ounces of blood, which was very sizey. On the eighth day after inoculation, febrile symptoms appeared, namely, sensations of coldness and heat alternately, great lassitude, pains in the head and back, and frequency of pulse. On the ninth day the feverish symptoms were more severe, and on this day also some eruptions appeared. The day following, namely, the tenth, the fever had almost entirely disappeared: a great number of eruptions were seen—the eruptions, in number perhaps 12 or 1400, gradually increased to their usual size, in the distinct and regular small-pox; then suppurated; and on the fifteenth day were almost all drying up. No fresh symptoms had supervened, except a little difficulty in degluti-

tion, and a slight sore throat on the twelfth, thirteenth, and fourteenth days after inoculation.

By the twenty-third day the scabs from the small-pox had fallen off, and the patient was quite well. Notwithstanding the number of pustules, the patient had not been confined to her bed for more than one day before the eruption: but I had reason to believe that she had not been obedient to directions, for she had kept herself in hot and confined air.

The subject of our observation continued well till the 4th of June, which was the twenty-ninth day after inoculation, and the twenty-first after the eruptive fever; and she was delivered of a full grown dead child. To judge from the woman's feelings, her *fœtus* had been dead four or five days before it was brought into the world. On the 6th of June Mr. Keate and myself were at Oatlands; and hearing that this child was born with the small-pox upon it, but that it had been buried two days, by permission we took up the body, in order to judge by actual inspection of the appearances of so curious a fact. Neither of us expecting the account given to be founded on any strong proofs, we were not a little surprised the instant we saw the *fœtus* with the numerous pustules upon its skin, resembling exactly those of the small-pox, about the fourth day after the eruption in the favourable kind. These eruptions differed, only in being flattened, from the small-pox in the living subject. There must have been I think in number about 400. Presuming that putrefaction had begun to take place, it seemed probable that the matter of these pustules would not be infectious. As no serious consequence was apprehended from the trial to inoculate with it, Mr. Keate collected a little of it upon a lancet. Mr. Keate informs me, that on Saturday, the 14th of June, he inoculated with the matter of the dead *fœtus*, a girl of about nine years of age, from 42, South Molton-street. There was not the least reason to suppose she had gone through the small-pox. Mr. Keate observed that inflammation came on in the part inoculated in two or three days, as it usually does when the infection produces the disease: and that on Wednesday, the 19th of June, the fifth day after the insertion of the matter, there was a pretty extensive circular inflammation, and a small vesicular tumour of the arm where the puncture had been made. Mr. Keate observed the inflammation and tumour to increase for several days farther. On Sunday, the 23d of June, the ninth day after the incision, the patient called upon me. I could not discover any disorder of the constitution in general; nor did I learn that she had been affected by the slightest febrile complaints. There was, however, a tumour as large as a pea, full of matter upon the part which had been punctured, and a circular inflammation about this pustule. The aspect of the arm was exactly that of a part infected by the va-

riolous poison where eruptions are present. On Tuesday following, now the eleventh day after inoculation, Mr. Keate observed the inflammation to be upon the decline, and the pustule beginning to dry, therefore he conjectures that the disease was at its height the day before—that is, Monday, the tenth day after the incision; for in a few days the patient got quite well; a crust of slough leaving a scar as after inoculation where variolous pustules had appeared. As there was no observable fever or eruption in this case, Mr. Keate inoculated this girl twice within six months afterwards, and at each time two other children with the same kind of matter on the same lancet. The two latter went through the disorder in the regular way, but on the former these inoculations had no effect. He also again inoculated the girl on whom the matter from the dead foetus had been tried, but, as before, no inflammation or swelling ensued: nothing followed but a red line or a red spot for a day or two, according to the scratch or puncture that was made. In course the remaining scar was from the first inoculation with the matter of the dead foetus. Mr. Keate observed that in several cases of inoculation in the beginning of June last, local effects only were produced as above described; he could not help suspecting that the air at that time, which was very hot weather, had some influence, in rendering the small-pox so mild. On inquiry of several practitioners, and from cases of natural and inoculated small-pox, which fell under my care during the hot weather last summer, I was well satisfied that this disease was not more violent, but perhaps less severe than usual, provided the patients admitted were exposed to a succession of hot air. Perhaps it may be just worthy of notice, that the husband of Mary Sheers, was inoculated, and two of their children at the same time with herself; that he had the disease slightly, having only twenty eruptions; that one of the children had also twenty eruptions; and that the other child had inflammation and suppuration of the part inoculated, but no eruption, nor, I believe, fever; but we have seen that the mother had a pretty numerous crop of pustules as well as her foetus.

Case 2.—Mary Spoon, thirty-two years of age. She had six children, the youngest of which was two years old; and supposed herself to be in the sixth month of her pregnancy. She was inoculated in one arm on the 4th of June. The same regimen and medicines were prescribed as for the above patient, Mary Sheers. The inoculated part became inflamed and swelled in the usual manner when the variolous matter applied produces the small-pox. And symptoms of fever appeared on the 12th and 13th of June, viz. on the ninth and tenth days of inoculation. The eruption began to come out on the 15th of June, or the eleventh day after the inoculation. She had a great number of pustules; at least, 1500

or 2000: but there was no secondary fever; and she went through the stages of suppuration and dessication without suffering considerably, or having any unusual symptoms. This woman enjoyed good health during the rest of her pregnancy, and was delivered in the beginning of October of a healthy full grown child. It was inoculated in both arms when about eight weeks old, by Mr. Norman, with matter from a subject in the same room with it. The arms were seen a few days in the manner they most frequently are when patients are infected. The child sickened on the 8th day; and at this time the parts inoculated were swelled, and there was a little suppuration in them. No eruption ensued. On the 12th day the inflammation had greatly abated, or almost disappeared. On one arm in the part inoculated there was a round hard scab; and on the other arm, a crust from the inoculated part had sloughed off and left a cicatrix. As there had been no eruption, and as unfortunately the opportunity was lost, of taking matter from the suppurated parts, no other way remained of determining whether the child had been infected, but that of again inoculating it. This I did with fresh matter applied to both arms on the 2d of January last. I examined the child on the 6th, but so far from any inflammation having taken place, there was scarcely a vestige of the punctures remaining; nor was any thing seen afterwards but a red mark in each of its parts pricked by the lancet. At this time the scars from the first inoculation were as distinct as ever, but no marks remained from the second inoculation.

The numerous records of inoculation for the small-pox, contain but little information concerning the effects of it in the advanced periods of pregnancy. And it seems highly probable, that not much would have been known of inoculation in the earlier periods of pregnancy, if the subjects had not concealed or been ignorant of their being in this state. The opinion, that it is most dangerous to inoculate in every stage of impregnation appears to be founded on reasoning and extensive experience of the fatality of the natural small-pox, during the whole of utero-gestation. But from a pretty considerable number of instances which I can adduce, it seems that the inoculated small-pox, within the sixth month of pregnancy, is very seldom fatal to the mother, although it very frequently kills the foetus. Hence, I apprehend that the practitioner who should not inoculate in these states of pregnancy, under the circumstance of unavoidable exposure to infection, would be deemed as unskilful or culpably timid, as he would be accounted ignorant or rash who should inoculate in the absence of the circumstance of present infection. On this ground the justification of my practice in one of the above two cases is founded; namely, in that of Mary Spoon, who was a little more than five months gone with child.

And with regard to the other case, in which the woman was in the eighth month of pregnancy, although I then knew of only one instance of inoculation at so late a period, viz. a case by Mr. Quier, which terminated favourably, yet I considered the practice to be justifiable, because in about twenty cases to which I can refer of the natural small-pox, under similar circumstances of pregnancy, the disease proved fatal to three-fourths, or four-fifths of the women, and to a still greater proportion of the fœtuses. These two cases then, may serve as useful data in practice, in judging of the propriety of inoculation in the two last months of pregnancy; with regard to the small-pox having taken place before birth. In one of the cases above related, the woman was delivered of a fœtus with eruptions upon it, exactly like those of that disease, and the effects of the matter of these eruptions on a person who had not had the small-pox, afforded a strong, if not an unambiguous proof that this infectious disorder took place before birth. I remained, however, in a state of hesitation with respect to the infectious nature of the dead fœtus, until I had well considered the circumstances of the case, and compared this case with those of the same kind which are on record, or have fallen under the observation of other practitioners. The evidences of a disease being the small-pox seems to be the following:—1st. Certain symptoms and appearances observed only in particular stages of the disease. 2d. Certain symptoms which occur in succession. 3rd. Scars in the skin after the disease. 4th. The constitution not being after the disease susceptible of the small-pox from the insertion of variolous matter. 5th. The matter of eruptions producing the small-pox in other persons.

Now, as the small-pox may take place, and the peculiar symptoms in succession not be present, nor scars be left, and as the other proofs are equivocal or not in every case present, it follows that cases may occur in which it is impossible to determine the question at issue beyond the reach of doubt. For even the last proof mentioned is sometimes undecisive, as I will make appear by two instances.

Case 3.—In the year 1713, Mr. Derham, F.R.S., upon the authority of a midwife, gave an account to the Royal Society (Philosophical Transactions, vol. xxviii, p. 165), of a woman who when in a very advanced state of pregnancy had the natural small-pox very mildly; but, while taking strong purgatives as soon as the disease was over, the fœtus, according to her feeling, died; and in five days after its death, she was delivered of a dead child, whose skin had upon it a vast number of the suppurated small-pox.

Remark.—The small-pox eruptions, when very numerous and full of matter, are so very unlike any other known disease, as not to be easily mistaken by a nurse or midwife; and the delivery took place after the disease in

the mother, consistently with the action of the infectious matter upon the fœtus, as in several other cases.

Case 4.—An account is given in 1749, by Dr. Mortimer, Sec. R.S. (Philosophical Transactions, vol. lxvi, p. 233), of a lady who, when within a fortnight or three weeks of her reckoning, had held a conversation at the distance of thirty or forty yards with a person then in the small-pox, in the state of maturation. In a fortnight after this interview, the pregnant lady was delivered, and her infant was in a day or two covered with eruptions, which proved to be the small-pox, of which it died, before the period of maturation. The mother had no complaint or eruptions; and she had the small-pox long before.

Remark.—I apprehend that practitioners in general, will not conclude that in this case the fœtus was infected in the womb; because many hundreds of pregnant women in England yearly, are exposed to the influence of the variolous infection, under much more favourable circumstances for its action, than in the present instance; and there is no parallel to this case, I believe upon record, nor has any parallel been heard of. Besides this, the eruptions had not suppurated, and perhaps were not numerous. They might probably be from a different disease; or if from the small-pox, the source of the infection was not that alleged. Much as this case stands in need of confirmation, the authority for it was so respectable as to require my notice.

MEDICAL REFORM.

—

To the Editor of the London Medical and Surgical Journal.

SIR—There is no engine more powerful, or of greater utility in the promulgation of opinions, or the advancement of literature and science, than the periodical press, particularly when directed by a master-genius, who permits not the trammels of prejudice to fetter his judgment, nor allows his noblest prerogative of reason to succumb to the ascendancy of factious opposition. To you Sir—one of the ablest and most independent conductors of one of the most powerful and independent medical periodicals of the present day—the medical profession (especially the class called general practitioners) owe a deep, a lasting debt of gratitude. You have contributed to raise them, as it were from a species of degradation in which they were enthralled, and your editorial labours in their cause, have opened to view a new and brilliant era in the annals of their history. They are at length dispelling that dark and drowsy stupor, with which the narcotism of ignorance had clouded their energies, and which had placed a spell upon the development of their mental faculties. They are

now occupying a prouder position in the estimation of society, and the present race of general practitioners may be justly pronounced to be among the most scientific and enlightened of any of the cultivators of medical science—yet it must be candidly acknowledged, that they are even now, much below what they ought to be. To you then, as the professed advocate of medical reform, I shall offer no apology for addressing the following humble remarks.

The reformation of existing abuses, Sir, has ever been considered among the most important duties of those who are interested in the welfare of society—to eradicate those rank and noisome weeds, which in their dark and malignant luxuriance, check the development of the beautiful flower and its growth to maturity, must be regarded as an occupation of no ordinary character. The medical institutions of this country seem to me to require a powerful remodelling agency, in order to adapt them to the advanced state of medical science, and the improved state of society. It appears to be a singular anomaly, and entirely incapable of demonstration on the ordinary principles of logical science, that a few self-appointed individuals should have the sole power and educational management of a multitude, their equals in rank, and frequently their superiors in scientific and general acquirements. It may be aptly compared to the hydrostatical paradox of philosophers, by which a small proportion of water is made to balance a quantity however large. *Sed hæc hactenus.* I would propose that there be established a consolidation of the English College of Physicians, Surgeons, and Society of Apothecaries, which might then be denominated the English College, Academy or Faculty of Medicine and Surgery. The same might also take place in Ireland, and a similar mode of procedure might be instituted in Scotland. The examiners of these respective academies, should be selected from the most eminent and scientific physicians, surgeons, obstetricians, and apothecaries of the present day, and should be chosen solely by their acquirements, which might probably be sufficiently ascertained by their individual literary productions, and the eminence which they occupy in the estimation of the profession. These are to possess the power of first conferring an incipient degree of qualification, before the candidate commences his medical studies, and subsequently the degree of doctor. I would further propose then, that the youth intended for the medical profession should leave school at about the age of eighteen. He should then be required to undergo an examination as to his proficiency in the Latin, Greek, French, German, and Italian languages, and the elements of mathematics, &c. If he be found sufficiently acquainted with these important accessories

in the acquisition of medical knowledge, he should be apprenticed for the term of five years to a respectable practitioner—I say apprenticed, for I am an advocate for the apprenticeship system. I think where the preceptor is a scientific man, and will carefully direct the studies of his pupil, and permit him to attend lectures during that period, that it is powerfully conducive to moral as well as professional improvement. After the expiration of his apprenticeship, and a prescribed course of lecture and hospital attendance, he might then present himself for examination, and if found qualified, might receive the degree of doctor, and might afterwards confine himself either to the practice of medicine, surgery, or obstetrics (for a division of labour should always be encouraged, as more calculated to improve the individual sciences), or all in conjunction, if he thought proper. The examinations for the degree of doctor might be held annually, and should be long and minute on the various branches of medical science. I would not only have our faculty or academy endowed with the power of conferring the degree of doctor, but also honorary degrees in medicine, surgery, and obstetrics, for which all qualified for the doctorship might compete if inclined, by public examination. We have our Wranglers and Optimes at Cambridge, and why should not our medical faculty have the power of conferring similar honours? I would have instituted three kinds of academical honours, viz. for medicine, for surgery, and for obstetrics, so as to give the candidates an opportunity of distinguishing themselves, in each or all of the most important branches of the profession. There should be a graduated scale of fees, and each doctor should be permitted to dispense his own medicines; for it is a point admitting of no controversy, that every practitioner should know that the medicine he prescribes is genuine. How can he tell that it is pure, especially in this age of adulteration, unless it be dispensed under his own superintendence? I believe this to be the reason why the prescriptions of the most eminent physicians are so often found to be inefficient—and this latter fact will completely substantiate the validity of my position. The limits of a letter will not permit a more minute expatiation on the most efficient plan of medical education and reformation, which might be advantageously adopted in this country; but I humbly think, that if a system constituted like the one I have recommended, were brought into operation, it would be greatly conducive to the welfare of humanity, and add considerably to the dignified character and respectability of the medical practitioner. Sir, the refinements of modern times, and the rapidity with which education is advancing, demand that a corresponding advancement should take place in the learned pro-

fessions—and especially in the medical profession, where every mental faculty is so frequently called into operation, and required to be exerted to its fullest extent. At a time too, when the lowly mechanic threatens to overtake the member of a more exalted stage of society, in the acquirements of science and philosophy—it is time that those who have been hitherto intrusted with medical education, should make wholesome and beneficial changes in their chartered institutions—that they should enlarge the sphere of scientific acquisition necessary to become a member and should render the avenues to the profession more difficult to pass through, by the establishment of a more rigorous and emulative system of examination. Sir, it is surprising that medical men are so well informed as they are, when we consider the almost monkish ignorance and darkness, which cloud these institutions, which are now the sole arbiters of medical acquirements, and which they are expected to regard with paternal veneration. These institutions, individually, are so deeply enveloped in the gloominess of barbarism, that it would be utterly impossible to support their pretension to the respect of the profession, unless it were attempted in that sophisticated garb in which a false and specious philosophy clothes its speculations. Still dark as the chaos from which they first sprung into existence—the sun of science deigns not to beam upon their portals. Sir, I am not one of those who would wish to behold all that is useful and venerable in our country sacrificed on the altars of change and speculation—oh no! I could not bear to view the giant hand of desolation passing through the land, and carrying destruction at its every grasp—but I wish to see effected such alterations as will increase the dignity and respectability of a profession which I hold in the sincerest esteem and veneration. It was a brilliant era in philosophy, when the rational inductions of a Bacon subverted the syllogistical mysteries of an Aristotle, and when the mighty genius of a Newton burst asunder the fetters which nature had placed upon the finite conceptions of man! It was a brilliant era in the science of astronomy, when the simple and sublime system of a Copernicus superseded the ethereal illusions of a Descartes—and it will be a brilliant era in the science of medicine, when it is placed upon a basis which has for its object the welfare of humanity, and the advancement of the education and interests of its professors. I am, &c.

A GENERAL PRACTITIONER.

St. George's in the East.

Foreign Medicine.

M. Rostan's Clinical Lectures on the Lesions of the Nervous Centres, continued from p. 504.

Lesions of Sensibility.

PREVIOUS to describing the different modifications that sensibility is liable to undergo, it is better to inquire, in the true spirit of organic medicine, what organ or what portion of an organ presides in the fulfilment of this important function; and first of all, it is necessary to ask whether any distinct organ for the evolution of the phenomena of sensibility exists.

Medical observers have in all times certified the possibility of movement being deranged without any affection of the sensibility, and that the latter may be annihilated while movement remains. Hence it may be deduced that a distinct organ for the phenomena of sensibility really exists; and numerous researches have been made for the purpose of detecting its position in the great nervous masses, which researches have led to the knowledge that the posterior portion of the spinal cord and the cerebellum communicating with it by means of the restiform bodies, are essentially concerned in the actions constituting sensibility. Very many facts support this idea, although contradictory observations are cited, which still cast doubts on the point in question. Yet, as it cannot be denied that there are nerves for sensibility as well as for motion, and that these nerves originate from a particular portion of the nervous centres, the admission is equivalent to that of the existence of a distinct organ for producing sensible actions.

After several exceedingly curious physiological reflexions on the brain, M. Rostan proceeded to consider the perversions of sensibility in disease. He stated that obliteration of movement is more frequent than abolition of sensibility, and called to mind that this abolition may depend either on a modification of the sensitive extremity of touch, on the conductor nerve, or on the centre of perception. In some diseases of the nervous centres, there is exaltation of sensibility, a phenomenon by no means rare in hypochondriacal subjects, hysterical females, &c., as well as in other cases. Thus, M. Rostan has been for a long time in attendance on a gentleman, who, though suffering from racking head-ache and hemiplegia, exhibits a remarkable exaltation of sensibility in the paralytic side, accompanied with obstinate redness of the skin of that side alone. Inspection after death will disclose in this individual some alteration of the encephalic matter; but with our present knowledge it would be impossible, from the mere exaltation of the sensibility, to point out, with any accuracy, the seat and the nature of this alteration.

The numerous modifications which sensi-

bility undergoes in cephalic diseases, are, however, occasionally sufficient to establish the diagnosis. Thus, lancinating pains of the head, and similar pains affecting the paralysed limb, may lead to the detection of congestion of the brain and its softening. The diminution and abolition of sensibility are always characters of a compressed state of the encephalon, and according as they are general or partial, the extent of the cerebral lesion may be determined. On this subject M. Rostan related the following curious case:—A young lady residing at Brazil fell from a horse, but had no recollection of the circumstances attending the fall. She was immediately seized with violent lumbar pains and distressing palpitations of the epigastrium: she also experienced a total loss of sensibility of the external surface of the right thigh. After in vain trying various means to obviate these symptoms, she came to France. The diagnosis of this case is very difficult: the mischief arises most probably from a complex alteration; and though it may be correct to attribute the main symptoms to a myelitis, the loss of the sensibility of the thigh seems to be more particularly attributable to some lesion of a nervous branch.

The lecturer then proceeded to consider the particular histories of the diseases of the encephalon, commencing with—

Sanguineous Congestion of the Nervous Centres.

This is the most simple of encephalic disorders, and consists in the afflux of a varied though considerable quantity of blood to the contents of the cranium. It has received various appellations, which however should not be used indiscriminately, for, be it remembered, the terms cerebral plethora, encephalic hyperemy, apoplexy, are not indifferently applicable to all the cases of encephalic congestion. Previous to 1812 this morbid state was confounded by the majority of pathologists with the other acute affections of the brain, whence arose considerable obscurity in the manner of studying them, and great difficulty in the establishment of therapeutical indications: subsequent inquiries have remedied this.

According to M. Rostan, at least two kinds of encephalic congestion should be admitted; one slight, temporary, of minor consequence—this is cerebral plethora or hyperemy: the other, more decided, sometimes long-continued, and of serious import—this is apoplexy (*coup de sang*), or congestion properly so called. This is by no means a scholastic and useless distinction, for it aids the investigation of the disease in question, and facilitates its treatment.

Cerebral plethora or hyperemy may be direct or indirect, simple or complicated, that is to say, it may come on primarily, spontaneously, independently of all remote organic modification, or secondarily, in consequence of an affection of some organ va-

riously distant from the brain. It is known by the following signs: its invasion is most frequently sudden, and characterised by the appearance of flashes or sparks to the sight, as well as other disorders of vision, such as vertigo, distressing and painful impression of light, and, according to some authors, the red colouring of all objects submitted to the sight: the existence of this symptom, however, the learned lecturer doubts. Peculiar sounds, whistling, drumming, noises of beating, synchronous with the contractions of the ventricles, and the diastole of the carotid arteries, incessantly distress the patient. A momentary deafness is also apt to occur, and to be complicated with blindness; sometimes, on the contrary, the slightest noise suffices to enrage the patient. Occasionally there is exaltation of the intellectual powers, but more frequently they are oppressed, and the patient falls into a state of actual stupidity, the slightest occupation requiring any attention being dreadfully fatiguing. Delirium can scarcely be said to characterize this disease. Motion is ordinarily laboured and difficult: the patient moreover has the sensations of creeping, pricking, and cramps of the limbs. In the majority of cases the tendency to sleep is manifest; sleeplessness is rare. The face is generally tumefied and red: the eyes starting and suffused: the lips red, enlarged, swollen, and shining. The skin has a vaporous heat: the subcutaneous veins are large, swelled, and resist pressure: the temporal artery beats with vehemence, and is greatly expanded to allow the passage of the blood: yet the thirst is but slight, the tongue is moist, the appetite tolerable; there is no pain of the abdomen, but the fæces are for the most part confined: the impulse of the heart's contractions is increased. Such are the phenomena of cerebral plethora or hyperemy.

In apoplexy and encephalic congestion, which may be preceded or not by hyperemy, there is complete, sudden, instantaneous suspension of the functions of relation; the patient falls into a decided state of general insensibility and absolute loss of motion. This mostly pervades the whole system; the face is swelled and livid, the eyes half-closed and fixed, the lips projecting and blue, the respiration stertorous. The skin is hot and injected, particularly about the head; the pulse strong and large; vomiting sometimes comes on, but it is only a sympathetic effect, for there is very rarely any other disorder of the digestive organs to accompany it. In some infrequent instances patients have remained in this apparent state of utter annihilation of relative life, and yet were capable of understanding what was passing around. Cerebral congestion is likewise sometimes accompanied with paralysis of the limbs of one side alone. In these cases M. Rostan thinks it very possible that the brain may be more strongly congested on one side than the other; for it may happen

oxysm, or occurring when no gout is present, general bleeding is to be employed as in any other case, according to the force of the symptoms, and the powers of the individual constitution. Also, if there be, at any time, well marked symptoms of congestion in any organ—in the brain more especially—blood should be taken away freely. If general plethora be very manifest, in conjunction with a strong pulse, indicative of good power in the system, bleeding may be practised, with a view to lessen the quantity of the circulating blood. This method of practice is to be distinguished, I repeat, from the use of bleeding as a remedy for the gout in the extremities, which it would rarely tend to remove.

“ Nor is local bleeding by leeches so successful as we might be led to expect. It is much more so in rheumatic inflammation. It is often disadvantageous, and occasionally even injurious, in acute gout; rather aggravating than relieving the inflammation and pain. I have sometimes seen much permanent weakness of the joint produced by the free use of leeches; and, now and then, very troublesome sores follow from the bites.

“ In some instances of chronic gout, when the symptoms have possessed a more than usual local character, I have seen benefit arise from the application of leeches.

“ How entirely the inflammation of gout in its primary character may be viewed as of a peculiar kind, and entirely as the offspring of internal causes, as also its very distinct nature from common inflammation, is shewn in the practice to which I have before referred, adopted in former times, of drinking Madeira, and covering the affected part with flannel (very improperly it is true, and with the certain consequence of prolonging the disease), without producing that injury and danger which we might expect to follow from such stimulating means.

“ *Of Emetics.*—I entertain a higher opinion than formerly of the advantages of producing free vomiting, and especially at the commencement of a severe attack. Unless there are particular contra-indications, I much recommend this as one of the first measures to be adopted; and more especially when, as so commonly happens, the stomach is greatly disordered; the signs of this appearing in a coated tongue, disagreeable state of the

palate, irregularity or loss of the appetite, nausea and sour eructations, and flatulence. I have often witnessed an immediate subsidence of the gouty symptoms from the operation of an emetic. I am persuaded also, that I have occasionally succeeded in averting the threatened paroxysm, by the use of an emetic, immediately followed by a mercurial purgative, and by regulation of the diet.

“ *Of Cathartics.*—When it is considered how almost wholly a fit of gout appears to result from congestion in the abdominal viscera, more especially from a surcharge in the circulation of the vena portarum (the great vessel which carries the blood from the intestines to the liver) and of the biliary pores, we are at once led by theory to the choice of this class of remedies, and no less confirmed in its propriety by practice. It is incumbent on us to persist in acting with freedom on the bowels from day to day, so long as the alvine discharges exhibit an unnatural character, more particularly as to darkness of colour, which marks a vitiated state of the biliary secretion; or if, on the contrary, the appearance be that of clay or of leaden hue, proving a torpor of the liver; also, when the urine continues to deposit on cooling the brick-dust sediment; always having due regard to the manner in which the patient bears the evacuating treatment; for the practice of medicine is not to be conducted upon abstract principles, but relatively to various circumstances, and to none more than to the powers and temper of each individual constitution.

The superior value of a mercurial purgative in stimulating the excretory ducts of the liver, and thereby causing a more or less free discharge from the biliary pores, is familiarly known. This kind of evacuation is of peculiar importance in gout, in which disease the functions of the liver are so materially concerned. A combination of calomel with compound colocynth extract agrees with most persons; and it is often useful to add a small dose of James's powder. With some, however, the pilula hydrargyri, or the pilula hydr. submur. compos. will agree better than pure calomel. In general, it is better to administer the mercurial dose at night, joined with a little extract of poppy or small proportion of opium, directing a purgative in

the morning; which in its composition must be suited to the individual, and the circumstances of the case; and, accordingly, be rendered cordial or saline, actively cathartic, or mildly aperient.

“The dense state of the urine, its deep colour, and the remarkable quantity of brick-dust or pinkish sediment, which sooner or later in the paroxysm it deposits on cooling, is a clear indication for the employment of diuretics as a part of the medicinal plan. The carbonate of potash joined with the spirit of nitric æther, and compound spirit of juniper, diluted with water and flavoured with some pleasant syrup, usually agrees well with the gouty stomach.

“Although on the present occasion, I wish to limit myself to very general statements, and to the laying down of principles, rather than repeat any of those details which I have given in my Treatise, I will mention that as a medicine happily combining the qualities of aperient, diuretic, and sedative to the gouty action, is the draught with magnesia, sulphate of magnesia, acetum colchici, &c. the formula of which will be found in my Treatise.”

The preceding remarks are in strict accordance with the standard opinions of all judicious practitioners, with the exception of the author's views on colchicum. In this particular he differs materially from the almost universal impression in favour of the efficacy of this remedy. We believe, however, that he is quite correct in his animadversions on the excessive employment of this valuable medicine, to the exclusion or omission of proper constitutional remedies. But the author is somewhat inconsistent in preferring the acetum to every other preparation, inasmuch as he spoke in as high, if not higher terms of liquor prepared by Mr. Battley, in his late work on colchicum, about which he is silent in the production before us. He enters into a full examination of this medicine in a subsequent article, and to this we shall refer our readers for his conclusions. We now proceed with his remarks on general remedies.

“I have to observe, of the use of mercury in gout, that due care should always be observed not to produce salivation, or go beyond just making the gum sensible of its influence in any case, and in general not to this amount. I have witnessed the most

inconvenient consequences arise from the excessive action of mercury, with an aggravation instead of relief of all the gouty symptoms. It is always important that the patient, when under the influence of mercurial medicine, should most carefully guard against exposure to cold—especially cold with wet—and that his diet and regimen should be regulated with more than usual attention.

“*Sudorifics.*—During the course of acute gout, it is highly desirable that the functions of the skin should be duly performed; and when there is heat of surface, we should endeavour to procure free perspiration at intervals, and especially in the night; for in the day time, when it is our still more important object to maintain a full action of the bowels, the action of sudorifics would be incompatible.

“In strong constitutions, and when there is great increase of the circulation, the combination of tartarized antimony with the aperient medicines, or with simple salines, according to circumstances, proves very beneficial. In some cases, small and repeated doses of Dover's powder are to be preferred. When there is great difficulty of procuring the desired relaxation of the skin much advantage will often be obtained by fomenting the stomach and abdomen by means of flannel wrung out of hot water; or by substituting a very large sponge. When exposure to cold has been the particular exciting cause which has brought on the paroxysm; when the heat of the surface is irregular, and particularly when together with the gout, flying rheumatism is troublesome, much benefit is sometimes obtained from the use of a vapour-bath, administered in the patient's chamber.

“*Narcotics.*—Sydenham, in his ‘Treatise of the Gout,’ affirmed ‘that pain in this disease is the disagreeable remedy of nature, and the more violent it proves, the sooner the fit terminates, and the longer and more perfect is the intermission; and so on the contrary.’ In these terms he made a strong appeal to the judgment of the patient, that he should bear his sufferings with fortitude, and forego the aid of medicine; but I must add that, according to my observation, it rarely happens that the reward of a shorter fit and a longer intermission is thus obtained.

agony of severe gout is such that few would consent to endure it, knowing that they could procure relief from treatment.

"I am a decided advocate for such employment of opiates as may be found necessary for the mitigation of pain, and the procuring of sleep at night; and it is better to combine a sudorific with the anodine, so that its influence may be less stimulating. We make our choice between Battly's sedative liquor with tartarized antimony; crude opium with James's powder; and Dover's powder. Some individuals, from peculiarity of constitution, are exceedingly incommoded by any of the usual forms of opium, and are kept awake instead of gaining the comfort of sleep. In these circumstances, the acetate or the muriate of morphia should be chosen, which medicine has, usually, a delightful power of calming the nerves. I am in the habit of using the acetate.

"It occasionally happens that a tension of the arterial system counteracts the power of opiates to produce relief from pain; and I have seen instances in which the largest doses, which could with propriety be given, entirely failed to afford material ease. Upon the reduction of the circulation being effected by one or more bleedings from the arm, moderate doses of opiate proved quite successful.

"*Colchicum*.—Upon the real merits of colchicum as a remedy in Gout, I am anxious, after many years' study and observation of its properties and effects, to record my confirmed opinion. I conceive that there is scarcely any question in practical medicine more interesting and important than this. Its great value as a medicine is unquestionable; but I cannot hesitate to declare, that, in the injudicious manner in which it is popularly employed, it carries with it much more of bane than antidote. Without entering into a discussion at the present moment as to the distinct or identical nature of the eau medicinale, Wilson's tincture, Reynolds' specific, and wine of colchicum, I shall think it sufficient to assert, that all these medicines act so similarly on the tissues of the animal economy, as to lead us to the necessity of concluding that they are agents of precisely the same character, although having different degrees of strength;

and this I believe to be in the order in which I have named them.

"The immediate operation of the eau medicinale was now and then so violent in its effects, as to raise apprehensions for the safety of the patient; but also it was found that, when most successful in removing the symptoms, which relief was produced as if by a potent charm, the cure was only of short duration. This remedy has been laid aside for many years.

"Wilson's tincture still has its advocates; but is no longer in general use. It is less violent in its action than the eau medicinale, and certainly does, in general, exert great power over the symptoms of the fit; but with much repetition it is an injurious medicine, and also disappoints the expectations of the patient; for, with but few exceptions, it interrupts the fits without curing the disease. On the contrary, the intervals become shorter in the ratio of its employment.

"Reynolds' specific was so manifestly a preparation of colchicum in rum, that, although it had its day of popularity, it was not long preferred to the wine of colchicum. That preparation, used and recommended by the late Sir Everard Home, was for a certain period preferred; but of late years the wine of the shops, either made from the roots or the seeds, has been the active preparation of colchicum in general use. In the first edition of my Treatise, published in 1816, and in the subsequent editions, I have recommended the acetum colchici, as being, on certain grounds, entitled to preference; and to this question I shall return.

"I wish now to criticise the merits of colchicum as a curative remedy in gout.

"Of its proper and well-considered use, I am as much disposed to bestow my approbation, as I am earnest to condemn its careless employment and abuse.

"A few, but, indeed, they constitute the large minority, are attacked with so slight and manageable a degree of gout, that a few doses, at the most, of the wine of colchicum, prove sufficient to subdue the immediate symptoms. Attention being paid to the digestive organs, the patient soon recovers, and extols the happy powers of colchicum. So long as this moderate use of the medicine exerts a curative power (by which expression I mean, that the return of the disease

does not occur at shorter intervals than usual) there does not appear any reasonable ground for disapprobation of the remedy. But I would ask, how many are the examples in which results so simple and fortunate take place? The general fact is, that the colchicum alone exerts only a palliative power in gout; curative, it is true, in more or less quickly removing the present symptoms, but not curative of the causes of these symptoms, which exist in the system. Is not this truth evident, when we so continually witness the quick return of the paroxysm in the very face of the medicine; and this often to such a degree, that at length the patient has every reason to feel convinced that his disorder is only suppressed, not cured? Hence, of late years, the public opinion has been much divided as to the pretensions of colchicum, and many of those who were its warmest approvers, are now equally loud in its censure. The irrationality of pursuing a method of treatment which ends in such disappointment, is so striking, that it might appear unnecessary for the pen of the medical critic to offer his protest against it; but I am led to my present task by having witnessed very numerous instances in which the error of continually suppressing the gout by means of colchicum, as popularly employed, has been carried on even to the production of danger and death.

“Without doubt, the use of hermodactyl (colchicum) was abandoned by the ancients, from their experience of the many bad consequences which it occasioned. Before and since the time of Sydenham, there was a long interregnum, during which very little medical interference with gout was exercised. And now arises the important question—Is it safe and proper to have recourse to colchicum in the treatment of a paroxysm of gout, or not? The disease is so painful, so enervating, and so disqualifying from all the duties and the pleasures of life, that it is most natural for the patient to desire the aid of those means which he knows will afford him the most speedy relief; and, when racked with pain, he is not willing to exchange physic for philosophy, even though there may be mischief in the draught.

“With respect to the use of any medicine, it is obvious that the smallest dose

with which we can accomplish our object is the best; so far, but no farther, I am an Homoeopathic! It is equally clear, that the mildest preparation of any particular medicine, when of sufficient efficacy in the case, is to be preferred to the strongest.

“I have, in my former works, dwelt on the remarkable mildness of that preparation in the Pharmacopœia, which is called acetum colchici, and must now repeat some of my statements. The College directs one ounce of the fresh roots to seventeen ounces of fluid—sixteen of diluted acetic acid and one of proof spirit. For the vinum colchici (so called) the proportion of the fresh roots is twelve ounces to twelve ounces of fluid—four of proof spirit and eight of water. Besides this extraordinary difference of strength, arising from the different quantities of material in the two preparations, we may consider that the acetic acid exerts a modifying power over the active principles of the colchicum, as it does over opium and squills, rendering its action on the animal economy milder.

“It has been my favourite practice to employ the acetum colchici in preference to any other preparation, joining with it magnesia, or the carbonate, and, usually, sulphate of magnesia, as I fully set forth in my Treatise; so that, in this mode of administration, I not only prescribe a very mild preparation of the medicine, but, by means of the aperient ingredients just mentioned, I prevent its stay in the stomach, and thereby save the coats of that organ from inconvenience.”

Want of space obliges us to stop here, but we shall conclude our notice next week. In the mean time, we are bound to state, that those who do not possess the author's Treatise on Gout, would act wisely in procuring this epitome of it. It contains all the author's opinions and conclusions on the nature and treatment of gout, and these have been long esteemed by the profession.

It is a cheap, concise, and useful work, both to the practitioner of medicine and the public.

The London Medical

AND

Surgical Journal.

Saturday, May 30th, 1835.

REFORM IN THE COLLEGE OF PHYSICIANS.

SOME time since, when a contemporary journal announced that the College of Physicians was about to place all its members on an equal footing for the future, and to admit all the present licentiates of a certain standing to the fellowship, we expressed a fear that the news was too good to be true.

We suspect the event will prove that our apprehensions were but too well founded, and that our contemporary was either very coolly attempting to gull the licentiates, or was himself misled by an *ignis fatuus*, generated from the fervour of his own free and enthusiastic spirit.

We understand that proposals were brought forward, at a late meeting of the College, for admitting a certain number of licentiates to the fellowship. The most liberal party were inclined immediately to admit fifty; those who could not conscientiously go so far were for letting in only twenty; while those whose moral feeling was of the first water, would not hear of more than ten.

Now, let not the fellows flatter themselves that any of these plans will answer. If there be any *selection*, no matter whether the number of the chosen be large or small, the licentiates will, if they have a particle of spirit, indignantly reject the proffered favour, since it will imply, not that the fellows are, as they ought to be, convinced of their own folly and presumption in supposing themselves superior to the rest of the profession, but that they graciously condescend, out of mere indulgence, to admit a few of the inferior order into their own august fraternity.

We tell them this will not do; if they mean to retrieve their reputation, they must cast off, at once and for ever, the ponderous puppyism, the dull and clumsy affectation, by which they now endeavour to support their baseless pretensions, and be content to take their place with their brother physicians, grateful if the latter are willing to receive them into their ranks, after they have so long acted in a spirit of self-sufficient and bigoted eclecticism.

There is only one kind of reform in the College that the profession will or ought to accept—that of placing the graduates of all respectable universities, British or foreign, on precisely the same footing. In short, the College must return to what it was in the days of its illustrious founder, and the memory of Linacre be no more insulted by the vulgar illiberality of those who profess to venerate his name, but who deviate in every particular from his precepts and example.

The present state of the College cannot long endure, for, setting aside the impending parliamentary proceedings, and the influence of public opinion, which is now beginning to bear powerfully on medical politics, the initiated and we among the number, are well aware that all is not going quite smoothly even within the walls of the College itself. The fact is, that liberal principles have become so extensively disseminated among the junior fellows, that the advocates for things as they are, have enough to do to keep them at bay, and the pressure from without is scarcely more inconvenient than the fermentation within.

Let Sir Harry take heed; he is really a clever fellow, and quite a magician in his way, but like others of that craft, he may chance some day to be torn in pieces by the once obedient ministers of his will.

NEW REGULATIONS OF THE APOTHECARIES' COMPANY.

T. H. RAMADGE D. GENERAL PRACTITIONERS.

SIR—The company of apothecaries seem to have no idea there is a great difference between alteration and improvement. In their zeal to prove themselves progressing with the march of the times, they have issued forth their new regulations—which shew how purely ignorant they must be of the real state of matters. An experienced architect, a man who knew his business, would surely never add a new story to a house whose foundation was crumbling to decay—and yet these men, professing to understand their business, have added to their falling structure. For what purpose? Is it that their fall may be a more imposing one? or, is it offered as an insult to the profession, which has tolerated too long the insolence of these “Jacks in office,” the very Dogberrys of medical justice?

No, Sir, the new regulations are not calculated for the times. The framers of them ought to know this: their cupidity, their impertinence, and their absurdities have been thundered into their ears by this and other journals for years past. They were told they must begin the work of reformation at the beginning; that the odious apprentice law must be repealed; that the certificate system, the parent of numberless evils, must be dispensed with; that talent must be properly appreciated; in short, that they must abolish the system as it now exists—a system the most injurious and tyrannical that ever was formed or followed.

A short time since, in your journal, I exposed the absurdities of the law regulating apprenticeship—its utter uselessness—the waste of time to a medical student in dispensing medicines for five years, and the necessarily great expense attending it. Why could not these sapient law-givers make the time of apprenticeship shorter? Do they mean to add falsehood to their other good qualities, and tell us that five years is necessary to attain a knowledge of the compounding of medicines; and that three years is sufficient for anatomy, physiology, materia medica, chemistry, and the other collateral branches of medical science? They

do tell us this by their very regulations. *Proh pudor!* ye law-givers—ye upholders of the respectability, the honour of the profession! *proh pudor!* ye have written yourselves down as knaves or fools—knaves, if you make this statement with intent to deceive—fools, if you know not its utter absurdity and baseness. But ye have more knavery than foolery in your composition, if your acts can be dignified by the title of knaveries; but I fear they are of too low a character in the scale of intellect to be so styled. Ye are too bungling for knaves, and yet too cunning for fools. Yours is the low cunning of taking care of the main chance, without the address of hiding the flimsy trickeries by which you procure your victims' money. You have the bravado without the courage of the highwayman; the meanness without the address of the pick-pocket. This is severe, but the case requires it. Why will you persist in making a *trade* of the profession? Why will you, who have the direction of these things, allow an impertinent fellow of the College of Physicians, to have the opportunity of calling surgeon-apothecaries the *trade*?*

C.

DUPUYTREN'S CLINIC.

CATARACT.

M. DUPUYTREN having determined on making comparative trials of two modes of operating for cataract, proceeded in the first case, which occurred by depression. An imprudence of the patient brought on intense ophthalmia, which was effectually combated by leeches, and ultimately the transparency was complete, and the sight re-established. The second case was operated on by extraction. This patient was in a less favourable state than the former; the eyes being much sunk in the orbits, and affected with chronic ophthalmia, characterized by lachrymation and slight redness of the conjunctiva. This affection was attacked by venesection, and the application of a blister to the nape of the neck; the blister being open at the time of the operation. The patient was placed on his back in bed—for in such cases Dupuytren always operates in the ward—in order to avoid the consequences which might flow from the patient's being shaken on his return from the theatre, if carried thither. A simple change of po-

* A fact! see last week's “Lancet,”—a letter from F. H. Ramadge.

sition in bed, after the operation, is sometimes sufficient to cause mischief. The upper eyelid having been seized and fixed, not without difficulty, by an assistant, the operator depressing the lower lid, approached the point of Richter's knife to the cornea, a little above the middle line. The puncture having been made, the instrument was carried on, a little obliquely from above downward, and so as to divide by sawing, and not by pressing. The aqueous humour escaped, but not a drop of the vitreous; and a slight pressure on the upper part of the globe was sufficient to expel the crystalline lens. The eye appeared perfectly clear, and the patient saw distinctly. After the operation, M. Dupuytren made the following general and practical observations:—

Previously to operating we ought to pay the greatest attention to the general state of the patient, and examine most carefully the nature of any concomitant affections. These affections, which frequently contra-indicate the operation, or at least demand its postponement, are rheumatism, of shorter or longer duration, pulmonary catarrh, and disease of the stomach or intestinal canal; constipation, hæmorrhoids, diseases of the skin, and many others, such as various cerebral affections, also contra-indicate the operation, or ought to induce us to delay it, because they may, more less directly, give rise to accidents with respect to the eye, already irritated by the operation. If rheumatism exist, for instance, the operation may determine its metastasis; the eye becomes painful, and a serious inflammation is frequently the result. Whether you explain this by metastasis, or by irritation, is of little consequence. It is never prudent to operate in such cases; for experience has demonstrated the ill results which may follow. The rheumatism ought first to be attended to; and if we decide on operating while slight, indistinct pains still exist, it will be prudent to apply a blister to some part at a distance from the head. If bronchitis be present, beside the determination of blood to the head from the cough, we run the risk (if we have operated by depression) of seeing the lens remount, in consequence of the shocks which the head sustains, in the act of coughing. If there be disease of the stomach, not only shall we have to fear the same mechanical accidents which result from a cough, and which may here be produced by vomiting, but also the various complications which may flow from the sympathy between the stomach and the eyes—for there are some affections of the latter which are altogether dependent on disease of the former. Further, if we operate while the stomach is disordered, however slightly, we must always observe a very low diet for a long period; and the difficulty is well known with which children and old persons submit to this. Nor, indeed, in the case of the latter, is it without danger. This diet pro-

duces, among certain of these old patients, a sour odour, which may be perceived as soon as the curtains are opened: it causes disgust, and brings the mouth into a bad state. The tongue becomes large, pale, and foul; and this condition is sometimes not removed without a great deal of difficulty.

Diarrhœa, when it exists, obliges the patient to rise frequently; and this may cause displacement of the lens. Constipation may give rise (from the straining) to the same inconveniences as a cough; and if produced by irritation, may have sympathetic effects. The existence of the hæmorrhoidal flux is a contra-indication; and although we may operate for the cataract when the flow of blood has ceased, we must then be on our guard against congestion of blood about the head, and its slightest symptoms must be met by the application of leeches to the anus. When the patient is afflicted with a skin-disease, the operation may cause the irritation to change its place, which will not fail to give rise to some affection of the eye, difficult to cure.

Having thus considered the various complications of cataract (and we are far from having passed them *all* in review), it remains for us to choose the mode of operating: and here we cannot too much insist on the irrationality of employing the same method in all cases. In surgery, as in medicine, the same methods of treatment are not always to be employed for arriving at the same end. Thus in cataract, the age of the subject, and various circumstances relative to the form and volume of the organ of vision and its appendages, will oblige the practitioner to have recourse sometimes to depression and sometimes to extraction. With respect to age, looking at the degree of energy in the absorbent system at the two periods, we should say it was better, in general, to operate on children by depression, and on the aged by extraction. In the case of the former, the functions of life are in all their energy; the processes of composition and decomposition are executed with astonishing rapidity; and the absorption of the lens takes place almost at the instant that, deprived of its natural connexions, it loses its conditions of life. Add to this, that at that tender age the crystalline is never so hard as in the more advanced periods of life, and that, consequently, it offers less resistance to the absorbing powers. In old subjects, on the contrary, nutrition and absorption are less active. The latter, especially, appears to have lost its energy; exhalation predominates, and, besides, the lens is frequently of a remarkable hardness, and, on that account, less amenable to absorption. In patients who had fallen victims to diseases unconnected with the cataract, we have found the crystalline lens perfectly untouched, although displaced for more than two years. Thus, looking only at the different degrees of

energy in the absorbing process, we conclude (as we said before) that it would be better to operate by depression on the young, and on the old by extraction. But there are other considerations which are strongly in favour of depression in both cases. Children are rarely sufficiently docile; and not knowing how to distinguish what is advantageous from what is hurtful, will not keep their hands from their eyes, or restrain themselves from all motion during the operation. Hence arises much difficulty if extraction be attempted; and even the evacuation of the crystalline humour may be the result. On the other hand, in patients far advanced in life, the eye is often deeply sunk in the orbit. The borders of that osseous cavity become more and more prominent, according as the cellular tissue placed behind the globe is absorbed; and in such cases extraction is pre-eminently difficult. Once more—we meet at every age with individuals in whom, in consequence of irregularity in the movements of the eye, or vicious conformation of its appendages, extraction becomes difficult in the extreme; and, without insisting further on the case of those who have the eye continually agitated by rapid, and, as it were, convulsive movements, we have observed, that when a patient has been deprived of sight for any long period, with the habit of *seeing*, he appears also to have lost the habit of *looking*. The movements of the eye no longer obey his will; and this circumstance greatly detracts from the success of the operation.

After these general and comparative details on the choice of the two methods, the Professor described the manner of operating, both by extraction and by depression. Two instruments, according to him, are sufficient; in the first case Richter's knife, and in the second Scarpa's needle, modified by M. Dupuytren. Richter's knife appears to him preferable to that of Lafaye, because it acts principally by sawing, and not by pressing, like the other. The methods in question are too well known to render it necessary for us to dwell upon them. We would only direct the attention of our readers to one point, in the operation by depression, which M. Dupuytren has cleared up with great ability. The illustrious Scarpa was of opinion that every cataract should be broken up. How much the Italian surgeon was in error will be perceived, if we remember, with the French surgeon, that for the lens to offer a sufficient resistance to the needle, its mass ought to be much greater. On the contrary, it is fixed in its place by connections which are fragile in the extreme. The parts which are to sustain the impulse of the needle offer much less resistance than the lens itself: slender capillary vessels, a cellular web the finest in the body—a membrane of extraordinary tenuity—is all that confines the crystalline lens, and it bears on the vitreous humour. If we add to this the

firmness of the lens in some instances, so that it is difficult to crush it between the fingers after extraction, we shall be astonished as well as M. Dupuytren, that Scarpa could have thought of breaking it up in all cases. Nevertheless there are some cataracts which ought to be broken up, and which it is even impossible to depress; such as the milky cataracts, and those in which the force of cohesion is not capable of resisting the least motion of the instrument.

After the operation, we ought to be on our guard against a tendency of blood to the head. Should this occur, we ought, in young subjects, to have recourse to the most energetic antiphlogistics. In patients of a more advanced age, and not of a sanguineous temperament, these means ought to be employed with moderation.

A single white bandage, and over that a green or black shade, are sufficient for covering the eyes. It is useless, ridiculous, and even hurtful, to load the eyes with lint by way of dressing. The practice gives rise to pressure, which favours ophthalmia, or even the expulsion of the vitreous humour, if extraction have been performed. M. Dupuytren has not, in our opinion, sufficiently insisted on the inconveniences of all those pretty bandages with which patients are dressed, and which by producing a tight construction of the head, cannot but give rise to congestion. This produces pernicious effects, which we often vainly attempt to cure, and which more frequently still, freely run their course.

Accidental Occlusion of the Vagina, forming an obstacle to Delivery. By C. Hoillemin, D.M.P. of Aux Cayes, Hayti.

—

MADAME — de —, when twenty-five years of age, had an exceedingly difficult labour, lasting three days; during which she had no other assistance than that of an inexperienced midwife. The external parts of generation, as well as the vagina, were attacked with violent inflammation, which was followed by an almost complete closure of the vagina, only a small opening remaining, scarcely sufficient to allow of the passage of a goose quill. She long suffered from incontinence of urine, and much difficulty in walking.

About June, 1830, Mad. —, then twenty-seven years of age, first consulted me. She was at that time suffering with nausea, loss of appetite, progressive increase of the abdomen, swelling of the breasts, &c. I immediately recognised all the symptoms of

pregnancy at the third or fourth month, and informed Mad. — of it, who replied that it was impossible for her to be pregnant, since she could not cohabit with her husband, because her parts were closed, “*ses parties sont fermée*,” (this was her expression). The husband, who was present, confirmed all that his wife had said. Nevertheless, I assured her that she was undoubtedly pregnant, and I did my best to tranquillize her uneasiness, for she incessantly repeated that it was impossible for her to give birth to her infant.

The 30th of December of the same year, Mad. — sent for me at midnight. Labour pains had just come on. On examination I found that the vagina was closed by a firm membrane, extending across it, and which was thickest laterally. Near the meatus urinarius, a kind of fleshy band originated, which was lost in the partition. In the centre of this last there was a round opening, scarcely large enough to admit a quill, and the margin of which was thick.

I proposed to Mad. — to divide the membrane closing the vagina, to which she consented. After the uterine contractions had continued for six hours, I took advantage of the moment when the membrane was pressed forward and downwards by the membranes and the head of the child, to divide the margin of the opening, and then inserting the index finger of my left hand between the head of the infant and the partition, with my right hand I passed the blade of a straight probe-pointed bistoury upon the finger which served as a conductor, and cut the membrane from within outwards, on the left side, to the extent of an inch, and then waited the effect of the renewal of the uterine contractions. After an hour, during which these were strong and frequent, the opening not enlarging, and the membranous partition being constantly pressed down, I made another incision from within outwards on the right side, so that these two incisions formed a triangular flap, the base of which was towards the sacrum. The umbilical cord immediately protruded; the waters, which were discharged, were black, and exhaled a strong and disagreeable odour. Mad. — became covered with a cold sweat; had repeated faintings; her pulse was almost impercep-

tible, and the uterine contractions were infrequent. Suspecting that the child was dead, from there being no pulsation in the umbilical cord, and having great fears for the mother, I hastened to terminate the labour by delivering with the forceps. The child appeared lifeless; its surface was livid, indicating cerebral congestion. After dividing the cord, I allowed three or four ounces of blood to flow; I employed dry frictions over the cardiac region, &c. and was not a little surprised to see the infant revive, as well as the mother, both of whom are at present in the enjoyment of perfect health.

Precautions were taken to preserve separate the parts which had been divided, and to prevent their reunion; the opening of the vagina was thus re-established in its natural state. The triangular flap resulting from the two incisions gradually diminished, and at the end of two years no trace of it remained, and Mad. — could cohabit with her husband without experiencing any inconvenience.

This case appears to me to be interesting in a double point of view, both as respects the delivery and conception. I submit it to the profession, believing it to be not unworthy of their observation. *Aux Cayes, (Hayti), October 29th, 1834.—American Journal of the Medical Sciences.*

—o—

Case of Malignant Cholera, in which Delivery at Term took place, during its advanced or collapsed Stage, and the Patient recovered. By Francis West, M.D. September 28th, 1824.

HANNAH CARPENTER, a mulatto female, aged 20, of sound constitution and previous good health, came under my medical care as a patient of the Philadelphia Dispensary. She was living in a cellar in Water Street, between Spruce and Pine streets, occupied by a large black family, and had been attacked some hours before I saw her with the symptoms of malignant cholera, which was at the time prevailing with frightful severity in her immediate neighbourhood.

I first visited her about noon of this day, (Sept. 28th); I found her as follows: She had been vomiting and purging since early in the morning, and was then discharging up-

wards and downwards very large quantities of a white, flocculent, rice-water fluid; she had most violent cramps in her arms and legs; her skin, especially of the extremities, was cold, damp, inelastic, and corrugated; her tongue and breath were perfectly cold; and her eyes, I remarked, as unusually sunken in their orbits; her voice was strikingly characteristic, being husky, stridulous, and very low; her pulse was very weak, thready, and undulatory, and she was tormented by insatiable thirst and great restlessness. I was told, too, that she was daily expecting to be confined, and with her first child. A large sinapism was at once laid over her abdomen, and blisters were ordered for her legs, and a powder to be given her every hour composed as follows:—*Rx.* Calomel, gr. j; Camphor, gra. xv; Opium, gr. ss. M. Dry warmth was applied to her extremities, and Cayenne pepper infusion was directed as drink. Dr. Bond, who had occasion to be in the neighbourhood, kindly saw the patient with me at four o'clock, P.M. The sinapism had caused excessive pain, and she had retained the two powders which had been given to her. It was agreed to continue the treatment instituted. In the evening she was better, though the diarrhoea still continued, and her skin was excessively cold, and inactive, with a very feeble pulse, &c. The cramps still continued. During the next day, notwithstanding her condition was improved, she still remained very ill, and her situation very critical. The blisters had slightly drawn. About six o'clock in the afternoon I was sent for in great haste, and when I arrived the patient was on her knees on the floor, in strong labour, and with the child half protruded through the external parts. I had her placed upon the bed as soon as possible, and quickly afterwards she was delivered of a still-born male child of full size, which apparently had been dead for some days; the placenta was long in coming away, but there was very little hæmorrhage either before or after its escape. The patient was much exhausted.

On Tuesday morning I found her better in all respects, and there was very little discharge. I directed the blistered surface to be kept sore, and allowed her barley water for drink, which was generally retained. On Wednesday she felt so much better as to wish

to sit up in bed. On Thursday, she continued to improve, and the next day she was sufficiently well to bear removal from the cellar, which the board of health had ordered to be vacated, and cleared as soon as she could possibly leave it. I did not see the patient for some time afterwards, when she called to say that she 'was perfectly well.—*American Journal of the Medical Sciences.*

Philadelphia, Dec. 10, 1834.

—o—

Case of Wound of the Genitals. By James B. M'Junkin, of Lexington, Georgia.

ON the night of the 14th July, 1832, J. A. æt. 39 years, was attacked by a ruffian, who, aided by two negroes, seized him while asleep in his own bed, held him fast, and committed upon him the inhuman outrage which I am about to describe.

Grasping the scrotum with his left hand, he passed his knife through it posteriorly, cutting it close to the body, on the right side. This incision, which was nearly transverse, divided the urethra and the greater part of the crura of the corpora cavernosa penis, leaving the anterior face of the scrotum attached to the under side of the penis unhurt. The point of the instrument was directed inward and upward in the right groin, and brought out a little lower under the left. The spermatic cord of the right side was severed at the same time just above the epididymis. A second incision was then made, two inches and a half in length anteriorly, meeting the former at the right of the root of the penis, and carried in a direction toward the superior spinous process of the right ilium; this was not deep enough to wound the left spermatic cord, but merely penetrated the skin. A small angular piece of integument was thus left undivided by the knife, on the left side of the penis. This was lacerated by dragging forward the scrotum; the skin of the penis was inverted over the glans, and the member denuded, and the right testis cut and torn off. The left testicle, now completely exposed, was retracted into the groin.

In this situation J. A. was found by Dr. Pond and myself, who saw him three or four hours after the receipt of the injury. Dr. Hull was also subsequently associated with

us in the treatment of the case. The patient had lost much blood, but the hæmorrhage had now ceased. He suffered much pain, which was, however, entirely relieved on our dividing the inverted fold of skin which lay over the spermatic cord and left testis, and in contact with the latter. The wound was so extensive that but a small portion could be covered by integument. A narrow strip of lint, spread with simple cerate, was rolled around the denuded penis, and the parts covered and protected with finely carded cotton. The daily renewal of these dressings was followed by great pain of the testicle, which would continue some hours. The escape of urine at the wound in the urethra also occasioned great irritation and suffering, the patient refusing obstinately to submit to the introduction of a catheter or bougie, which was urged upon him. About the fifth day the urine found its way through its natural channel, the edges of the wound having coalesced; but this union gave way again on the occurrence of nocturnal involuntary erections. A few days afterwards these ceased to happen, and permanent re-union took place; but, owing to some irregularity in the manner of healing, there still remains a degree of narrowness at that part of the urethra, and some obstruction to the free passage of urine. On the third day there supervened much febrile excitement, with stupor and soreness of the abdomen; but these threatening symptoms disappeared under the employment of the lancet and other ordinary antiphlogistic remedies, and the patient was discharged in a about ten weeks.

In J. A.'s present condition, the parts exhibit the following aspect. A pretty strong, smooth, elastic envelope now encloses the testis, supplying the place of the scrotum. This sac is destitute of hair, and is not at all rugous. The testicle having suppurated at one small spot, the sac is united to it by the cicatrix which formed on its healing, and in consequence of this adhesion is not permitted to descend, but remains near the groin; a situation much exposed to accident, and where it is often hurt. A tense, smooth surface covers the membrum virile, resembling a cicatrix from a superficial burn. The mucous fold of the prepuce having been detached

from its cutaneous prolongation, is coiled behind the glans, giving the appearance of a double corona or ring. Adhesions and contraction of the cellular tissue, especially at the posterior extremity of the penis, greatly prevent the erection and elongation of the organ. This is particularly obvious at the wound of the urethra and under the ramus of the pubis, where the penis appears as if tied down with a cord, occasioning irregular incurvation posterior to the place of the incision. A condition resembling chordee also existed for some time after the parts were healed, causing much pain and disappointing his attempts at copulation, but by dividing the frenum preputi, this impediment was much diminished, though not entirely removed.

He now enjoys a pretty good state of health, being able to attend to his usual avocations, but is easily liable to a sense of fatigue in the lumbar region. The propensity for venereal gratification is perhaps as strong as ever, but the actual enjoyment is much impeded by the state of the organs above described.—*American Journal of the Medical Sciences.*

Oil extracted from the Spirit of Wine of Potatoes. By M. J. Dumas.

PREVIOUS to rectification, spirit of wine whether it be obtained from malt or potatoes, possesses a peculiar taste and smell which is removed by distillation frequently repeated. It has been long known that these properties depend on a peculiar oil, and its presence was first detected by Scheele. Fourcroy and Vauquelin proved that the oil was not a product of fermentation, but that it existed in grain, and could be separated by treating it with water, and taking up the oil from the liquid by alcohol. M. Payen has shewn that the seat of this oil is in the tegumentary part of the fecula of potatoes. Those who have examined the oil proceeding from the spirit of barley, describe it as capable of crystallization, volatilizing with difficulty, undergoing alterations by distillation, and staining paper permanently. Pelletan found on the contrary the oil from the spirit of potatoes to be a true essential oil. Dumas examined a specimen from the manufactory of Dabrunfaut; it possessed a reddish yellow colour, and a very disagreeable smell.

When one breathes the air charged with it, nausea and head-ache are produced. Carbonate of potash diminishes the odour considerably, and when distilled with it renders it analogous to that of nitric ether. In order to free it entirely from alcohol, it is necessary to distil cautiously, and obtain a residue of pure oil boiling at 180 deg. (266 deg. F.) or 182 deg. (269 deg.) the alcohol passing over first. Dumas suggests, that although bearing some affinity to alcohol and ether, it may belong to the family of camphors. The density of its vapour is 3.147, or calculating from the composition 3.072. It consists of:

Carbon.....68.6
Hydrogen.....13.6
Oxygen.....17.8
(Thomson's Records of General Science).

Intussusception with Stercoraceous Vomiting, successfully treated by Inflation. By J. Wood, M.D.

Mr. G. aged thirty-five, a type-founder, of nervous temperament, was suddenly seized on the night of September 17th, with violent pains in the umbilical region: he has before suffered two slight attacks of rachialgia. A medical gentleman in the neighbourhood saw him, and prescribed purgatives and hot fomentations. My attendance was requested the next night. He had obtained no relief from the remedies administered during the day; stomach had rejected them. No dejection for three days; frequent retching; little intermission from pain; pulse small and regular. Superficial examination of the abdomen detected no peculiarity. An acquaintance with his previous attacks led to the presumption that the present was painters' colic: he was, therefore, directed to take a pill containing two grains of opium, and one drop of croton oil every two hours till relieved; and to have an enema every four hours, and bags of hot sand to the abdomen.

Sept. 19th. Has taken all the pills; less pain through the night, but since day-break paroxysms have returned with greater force and frequency, accompanied by violent tormina and tenesmus; dry retching, especially after taking drink; hiccup; slight but general tenderness of abdomen; pulse irregular, irritated; no faecal evacuation, but discharged

in the course of the day a little bloody mucus, and vomited, towards night, a large quantity of green bile mixed with feculent matter. After a careful examination, the precise point of obstruction was ascertained. At first, only an unusual fullness and firmness in right iliac region could be discovered: but the hand lying upon the spot, a paroxysm of pain occurred, and an elongated tumour was felt to rise with an erectile motion; immediately there followed a gurgling rumbling noise, and a rush of fluid downwards against the point of obstruction. After two or three surges against the tumour, the fluid receded towards the stomach; but again returned with renewed violence, until the spasm subsiding, it passed upwards, the bowels taking on an inverted action. The treatment adopted was copious bleeding, the administration of purgatives, as calomel, infusion of senna, castor oil, enemata of tobacco infusion, hot anodyne fomentations, and at night large doses of opium.

20th. Aggravation of all the symptoms. In the afternoon Dr. Morril saw him, and after a careful examination of the case and an acquaintance with the treatment pursued, he agreed in opinion that there were no grounds for hope. As a last resource, however, he proposed inflation of the bowels with atmospheric air. Placing the patient on his right side, the pipe of a pair of bellows was introduced into the rectum, and inflation cautiously begun. This succeeded but partially, owing to the imperfection of the instrument; yet to our surprise, he proclaimed himself much easier, and was irresistibly driven to the commode, where he passed a large quantity of air and a gill of very foetid bloody water. A more perfect pair of bellows having been obtained, the tube was again inserted, and inflation employed till the abdomen became tense. He had no recurrence of violent pain after the first inflation. Directions were given him to remain quiet in bed, and resist the disposition to evacuate the bowels; to take one drop of croton oil every two hours, and at the end of four hours an enema of mucilaginous fluid. He was visited six hours afterwards; had had no return of pain since inflation: within last hour two copious dejections.

21st. Had seven dejections since last visit; quiet sleep for three hours; somewhat fever-

ish, thirsty; countenance anxious; pulse 125, small; tongue red, dry in centre. Full vesication from blister applied yesterday. Pretty severe enteritis followed, which yielded to the usual remedies in the course of fourteen days.

The result of this case was extremely gratifying. With regard to the treatment finally employed, we had no very sanguine anticipations of success; yet it must be admitted, that there is more philosophy in it than in many other plans adopted to lessen the ills of life. Of the numerous enemata administered in the forty-eight hours preceding the inflation, but a small quantity was retained, and that but momentarily. The use of them was persisted in with the hope of effecting mechanically the dilatation of the gut. In similar cases, the enemata cannot be thrown up to any amount: what is injected immediately returns. The effect is totally different when air is used. Its levity, its freedom from all irritating qualities, its elasticity and expansibility, give it a decided preference over the enemata. The nature of the difficulty also warrants the view of its utility. The tendency of the peristaltic motion and of the ingesta, is from above, downwards; most cases of intussusception, therefore, are *progressive*, few *retrograde*. If then, we can dilate the stricture, the invaginated portion will escape from below upwards, and thus will be restored to its original situation. If the above explanation be correct, what remedy can compete with inflation? It certainly merits a trial, and is earnestly recommended to the consideration of the profession. —*Boston Medical and Surgical Journal and Med. Mag.*

—o—

Fresh Water formation in Greece with Lignites.

IN 1830, a report was very generally spread of the discovery of coal in Greece. M. Theodore Virlet, who was in that country soon after the coal was said to have been observed, proceeded to the spot for the purpose of examining into the truth of the report. He visited the *Sporades Septentrionales* or Devil's Archipelago, situated at the mouth of the Gulphs of Volo and Salonica, near the coasts of Thessaly and Macedonia, where it was

said coal existed. He found the islands of Skiathos, Skantzoura, and Diodelphia to consist of primitive rocks, those of Xero, Xera, Panagia, Jacoura, Piperi, &c. to belong to a calcareous formation. In the island of Skopelos the latter rests on clay slate, and in some respects agrees with the transition limestone, but the existence of a number of fossils and especially *Hippurites semicostellata*, proves its distinct nature. *Tornatella priaca*, and *Turritella antiqua* Desh are likewise met with.

Iliodroma is a long, narrow, mountainous island, which consists of three formations: 1. Mica-slate, clay-slate and lime-stone. 2. Blue and grey limestone. 3. A fresh water tertiary formation containing lignites, which occupies half of the surface of the island, and was mistaken for coal. The lower portion is situated 200 or 300 metres above the sea, and is constituted of blue or green marls with a great deposit of fresh water and land shells belonging chiefly to the genera *Planorbis*, *Paludina*, *Helix*. Over these marls lie thin strata of marly limestone without fossils, but containing an irregular bed about two feet (Paris) thick of lignite, in general mixed with clay and shells. Above the lignite grey marls occur, filled with the debris of fossil vegetables. The whole of the formation is about 190 English feet in thickness. Among the fossils obtained from this formation, the most numerous belonged to what M. Adolphe Brongniart, who examined it, has termed *Taxodium Europæum*. It has also been found at Comothau in Bohemia, and at Cœningen near the lake of Constance. It belongs to the order Corniferae, and is characterised by long slender branches, subglobose cones, with leaves spiral or sometimes arranged in three rows.

Virlet considers this formation more ancient than that of Cœningen, and contemporaneous with the dislocation of strata which produced the Dardanelles, and with the corresponding formation in Switzerland, and the marine deposit of *Gompholites* in the Morea.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XX.

Stimuli to Irritability.

IRRITABILITY is only one of the conditions necessary to life—it is only, as it were, the susceptibility of living, or as the French call it, *l'aptitude à vivre*—and other conditions are still requisite in order to give rise to those phenomena in which life, consisting as it does in the sum of the essential functions performed by organized beings, consists. We have done with the main or lowest wheel of the organized machine, as represented in the diagram already published, *considered at rest*: we have now to pass on to the horizontal train of cogs, by the hitching of which with the cogs of this wheel, the latter is set in motion—in other words to those stimuli from the action of which on irritability or vitality, irritation or life results.

These stimuli may be spoken of as either direct and primary, or indirect and secondary; the former acting *ab initio* on the irritability of the organs to which they are applied; the latter implying always a previous irritation of one organ, no matter by what means excited, and consisting in a translation of this irritation, so as to act on the irritability of organs at a distance. Thus, a pinch of snuff, applied to the schneiderian membrane, excites *ab initio* an irritation of that organ, indicated by the changes effected in its secretions; and this irritation may either go no further, or may be translated, by sympathy, to the abdominal muscles, and excite there a secondary irritation, indicated by the sneezing which so often follows: snuff, therefore, is an example of a direct and primary stimulus to irritability, and sympathy an example of an indirect and secondary one. It is of importance to remark, however, the then stimuli are not, any more than irritability on which they act, substantial, although, like irritability, they are necessarily attached to something that is so; and such substances, accordingly, in the case of the direct and primary stimuli, are, for the purpose of avoiding circumlocution, always put for the stimulus of which they are at once the source and the vehicle. It is obvious that if life be a non-entity, neither of its conditions—irritability, nor any stimulus by which irritability is excited—can be entities. When we say, therefore, that snuff, or any other substance, is a stimulus to irritability, we mean only that the substance in question possesses some power which acts in this capacity; and we specify the substance only as a summary way of indicating the power which it exercises. We recognize these powers as we recognize the property; on which they act, only by their effects—we know nothing of them abstractedly. They are, in every case, the result of the peculiar aggregation of matter in which they reside, in the same way as irritability is the result of organism; but they are certainly no more identical with the substance of which they are characteristic, than irritability is identical with the organized tissues of which it is the attribute.

Of the direct or primary stimuli to irritability, the chief are certain universally-diffused agents, to which organized beings, in common with inorganic matter, are more or less constantly exposed, such as *caloric*, *light*, and *electricity*; others, of which they continually appropriate a portion to themselves, such as the medium by which they are directly surrounded, whether *air* or *water*, and the solid and liquid substances which they use as *aliment*; and others, lastly, which constitute at all times a substantial part of themselves, such as their various *fluids*, whether crude, mature, or secreted. Of the indirect or secondary

stimuli, the principal are *sympathy* and *passion*, or *instinct*—the two latter of which appear to be merely varieties of the former—and *volition*. In addition to these, which may be regarded as more or less constant and salutary stimuli to irritability, and which, when neither excessive nor defective, constitute what may be called the exciting causes of health (a); certain others occasionally come into operation, the action of which, as well as that of any of the preceding, when either in excess or deficiency, is prejudicial, and it is of these that the exciting causes of disease consist; but with these we have nothing to do at present.

One of the most universal of the natural stimuli to irritability is caloric; which, in a sensible or latent state, is present in every form of matter, and is continually exercising a powerful influence on the actions of all organized beings. It is hardly necessary to observe that heat and cold are merely relative terms. We call it heat—sensible caloric—when the quantity of this principle is such, in relation to the capacity of the substance containing it, as to raise its temperature above that of the surrounding medium, and consequently to give off caloric to this medium; and, on the contrary, we call it cold, when the quantity of caloric is such, in relation to the capacity of the substance, as to allow its temperature to fall below that of this medium, and consequently to abstract caloric therefrom; but in all forms of organized beings, as well as in every form of inorganic matter, more or less caloric is always present, and in all it is constantly operating as a stimulus to their irritability, and producing irritation; nor is this more certainly the case with respect to those organized beings the temperature of which is generally above, than with respect to those in which it is below that of the air or water in which they live. It appears, however, that every organized being requires a certain definite quantity of caloric in relation to its capacity, under the operation of which alone its functions proceed with energy—that, in some cases this is so considerable, as to raise its temperature above that of the medium which it inhabits, and in such cases its office is, as the result of some of its most indispensable functions, to extricate sensible caloric, or, as it is commonly expressed, to generate heat; in other cases it is such as to maintain its temperature upon a par with that of this medium, when the calorific and frigorific processes going on within it are precisely balanced; while in other cases, lastly, it is so small as to reduce its temperature below that of this medium, when its business is to absorb sensible caloric, or, in other words, to generate cold. Thus, to confine the question at present to animals, most of the invertebrate tribes, with the exception of insects, as well as most fishes and reptiles—hence called cold-blooded animals—require only a quantity of caloric, in relation to their capacity, sufficient to bring their temperature to about 60° Fahr., while most insects, birds, and mammals, require sufficient to raise it to between 80° and 110°; and if they derive either less or more than this quantity from without, they must themselves either compensate for the deficiency,

(a) At the time when it was customary to regard life as something inherent in the living body, and *per se* competent to bring about all vital phenomena, it was the practice to speak of every thing relating to the structure and actions of the body, under the name of *naturals*; of which seven were generally admitted—namely, its organs, its tissues, or associations, its fluids, its principles, its properties, its powers, and its functions; the first five of which have been already spoken of in the order in which they are above enumerated. The error of this schedule consisted in including also the powers and functions of the body, which were represented as likewise inherent in it, instead of the powers being regarded as more or less adventitious agents, from the co-operation of which with the characteristic property of the body (i. e. irritability), the functions revolted. This, however, would have been to deprive the everlasting vital principle of its self-sufficiency; and consequently, all those agents which the patrons of the vital principle doctrine could not avoid observing very materially influenced vital phenomena, and which should have been included under the head of the adventitious powers aforesaid, were regarded as quite

accidental, and marshalled accordingly into a distinct phalanx, under the name of *non-naturals*, of which it was customary to admit six—to wit, air, aliment, exercise, the secretions, the passions, and sleep. Upon what principle the most natural things in the world, as remarked by Sterne, should ever have been called non-natural, remains unexplained; but a remnant of this ancient absurdity is still perceptible in the advice sometimes even yet given to valetudinarians, to take care of their non-naturals. It was reserved for John Brown to abolish this non-natural and unfounded distinction, by demonstrating that life, and of course all the functions of the body, in the sum of which life consists, depended solely on the operation of some of these non-naturals, in conjunction with many other agents more or less allied to them, but which the founders of this distinction, in the plenitude of the perplexity in which their untenable hypothesis respecting life involved them, had inadvertently omitted. But it is idle entering into any investigation of the merits of a system, which is not less loose and arbitrary in its detail, than it is, in its general principle, opposed to every thing like reason and common sense.

or carry off the excess. It is not, however, in all forms of organized beings that this power of counteracting external temperature resides to any considerable degree, or at any rate it is not all which exercise it with impunity, and indeed in few or none but man is it such as to be capable of resisting every ordinary degree of external heat or cold; so that while man, the natural temperature of whose body is about 98° Fabr., is found the inhabitant of every clime, from the temperature of 55° to 125° , or can accommodate himself to any point within a range of about 180 degrees, almost every other form of organized being has its fixed habitat, or a comparatively limited scope within which alone it is competent to exercise its functions. Thus, some plants, as mosses and lichens, thrive best in regions where no other tribes of vegetables could exist; and the pine and fir flourished where the oak, the elm, the beech, and the chestnut would fail. A slight increase of external temperature, however, answers for these, but a more considerable increase is required for the apple and the pear, the plum and the cherry, and a temperature still more elevated for the cedar and the cypress, the fig, the olive, the orange, and the lemon; while the palm, the date, the cocoa, the coffee tree, the bread tree, the banana, and numerous others, come to perfection only in the torrid zone; nay, some kinds of water-plants thrive abundantly well in water at a temperature which would have been sufficient to boil them, had they been destitute of vitality (a). In these cases, then, we must conceive that the power of extricating sensible caloric, or compensating for the deficiency of it from without, has gone on progressively diminishing, while that of absorbing sensible caloric, or carrying off the excess from without has gone on progressively increasing; but no one of these plants seems competent to do, indifferently either the one or the other, according to circumstances. The various degree of external temperature required by plants are beautifully exemplified in mountainous districts, the low valleys of which are frequently adorned with the vegetable products of the torrid zone, and the more elevated districts with those of temperate climates, while towards the summit nothing is met with but the meagre natives of the polar regions; and the lines of demarcation are sometimes so remarkable, that on the volcano of Teneriffe no fewer than five distinct zones, marked by the vegetable products which characterize different climates, are distinguished. In like manner, with respect to animals, among fishes, the cod (*Gadus*, 27), among birds, the eider-duck (*Anas*, 36), the albatross (*Diomedea*, 36), and the Lapland owl (*Strix*, 40); and, among mammals, the whale (*Belena*, 42), the seal (*Phoca*, 43), the walrus (*Trichecus*, 43), the rein deer (*Cervus*, 45), the Polar bear (*Ursus*, 50), and the Esquimaux dog (*Canis*, 50), are met with exclusively in frigid regions; others, as most of those animals with which we are familiar, and, among beasts of prey, from which we are happily exempt, the wild boar (*Sus*, 44), the brown bear (*Ursus*, 50), the wolf (*Canis*, 50), and the lynx (*Felis*, 50), thrive best in temperate situations; while others, lastly, as, among molluscos animals, the pearl oyster (*Ostrea*, 7); among insects, the mosquito (*Culex*, 19), the white ant (*Termes*, 22), and numerous kinds of butterflies; among fishes, the electrical eel (*Gymnotus*, 26); among reptiles, all kinds of serpents and lizards, the crocodile, alligator, and gavia (*Crocodylus*, 35); among birds, the humming-bird (*Trochilus*, 38), the bird of paradise (*Paradisea*, 38), the parrot (*Psittacus*, 49), and the toucan (*Rhamphastos*, 49); and, among mammals, the elephant (*Elephantus*, 44), the hippopotamus (*Hippopotamus*, 44), the camel, and dromedary (*Camelus*, 45), the giraffe (*Camelopardalis*, 45), the hyena (*Canis*, 50), the lion, tiger, leopard, and panther (*Felis*, 50), and the various kinds of monkey (*Simia*, 51), are confined to torrid districts. Nay, some fishes live, and move, and have their being in water, the temperature of which is only a degree or two below the boiling point (b). And the same inference is to be drawn here as with respect to plants, that, as the inhabitants of frigid regions excel principally in the power of extricating sensible caloric, so those of the torrid zone, habitually exposed to intense heat in any form, are calculated rather for absorbing a portion of that by which they are surrounded. Temperate districts are accordingly too hot for the former—for the function of the lungs, a principal indirect office of which is to extricate sensible heat, being no longer in the usual requisition, is in a great measure suspended, and that to the great prejudice of the animal, by that of the liver—while they are too cold for the latter—the lungs being now more than usually and equally injudiciously exercised; and it is a remarkable fact that, as the rein deer, the Polar bear, and the Esquimaux dog, when brought to this country, commonly die of diseases of the liver, or other affections of hot regions; so the camel and dromedary, the lion, the tiger, and the monkey, under the same circumstances, generally perish of consumption, or other diseases peculiar to cold climates. Man almost alone, of all forms of organized beings, is competent to strike, with comparative impunity, such a balance in the functions of his several organs, under all ordinary degrees of external heat and cold, as to maintain the temperature requisite to the healthy excitement of his irritability; and the only effect which a higher or lower external temperature seems to have upon him is in the establishment, according to the greater or less

(a) Sonnerat, Foster, &c.

(b) Clarke, Sonnerat, Humboldt, Bonpland, &c.

exercise of this or that organ in effecting this balance of what are called national temperaments. Into a consideration of the means by which he is enabled to effect this balance, or the process of acclimation, as it is called—important and interesting as the subject is—it would be quite out of place to enter at present. Suffice it to say, in conclusion of this subject, that to every action, molecular or sensible, of every organized being, in which its life consists—in other words, to every instance of excitement of irritability—a certain quantity of caloric, in relation to the capacity of this being—that is to say, a certain temperature—is indispensable; and that if it meet with either less or more than this definite quantity from without, it must either increase or diminish it, as a result of certain processes going on within itself, although it is only within certain limits that such processes are in general exercised with impunity. This, then, is the relation, and the only relation in which caloric, or heat, stands to life—it is essential to life, but it neither is, nor can be identical with it, as was in former times so vaguely imagined (a).

A second, and perhaps equally universal stimulus to irritability is light, which, like caloric, pervades every form of matter in either a sensible or latent form, and continually exerts, perhaps, a more powerful influence on the actions of organized beings than is commonly believed. It is, perhaps, difficult to conceive that such beings when in what we call darkness are still under the stimulus of light; but we should keep in mind that light is not in itself luminous, any more than caloric is heating, and that it appears so only when its equilibrium is destroyed—that is to say, when a portion of what is contained is sent off from one body to others. Light and darkness are, in fact, like heat and cold, merely relative terms, and an organized being in darkness is no more withdrawn from the stimulus of light, than a being, the body of which is as cold or colder than the surrounding medium, is deprived of the stimulus of heat. Nevertheless, it is sensible light alone the stimulus of which is generally acknowledged; and even this is commonly regarded as very circumscribed in its operation, if not on the irritability of plants—which certainly appears to be very much under its influence—at any rate on that of animals, the only parts of which generally regarded as amenable to this agent being those of the eye. This, however, is in all probability a mistake; the parts of the eye alone appearing to be stimulated by sensible light only, because they alone are furnished with sensiferous nerves capable of taking cognizance of the irritation so produced, and of converting it into sensation, but all parts so exposed, being in fact equally the seat of such irritation. It is probable that every plant and animal thrives best when acted on by a certain definite quantity of light, as well as of caloric, in relation to its own capacity; but it does not appear that organized beings in general exercise any power like that manifested with respect to caloric, of so destroying the balance of the light within them and that of the surrounding medium, as to produce either a sensible extrication or a sensible absorption of it. Many plants, it is true, both cryptogamic and phanerogamic, have been represented as extricating light under some circumstances; and, among animals, some polypi, as the sea-feather (*Pennatula*, 2), some acalepha, as the sea blubber (*Medusa*, 4), and many insects, as the lantern fly (*Fulgora*, 18), the glow worm (*Lampyrus*, 24), and the fire fly (*Elater*, 24), certainly possess this power to a very considerable degree, while innumerable others display more or less of it. It is in general confined, however, to a particular part of the plant or animal which possesses it, and is certainly exercised for a purpose very different from that of exciting their irritability, as a stimulus to which alone light falls now to be considered. Light is, perhaps, as essential to life as caloric; but it is unnecessary to say that it neither is, nor can be identical with it, although this opinion has not wanted advocates (b).

(a) It is quite unnecessary to recapitulate all that has been said concerning the supposed *Πῦρ καθαρόν*, the elementary fire, the Promethean heat, the calidum innatum, &c., as synonymous with life. The error consisted only in mistaking a necessary condition of life for life itself.

(b) Light, the first of created things, and the creation of which is described in the most sublime passage of written language, is spoken of, in almost every page of the oldest book in the world, as emblematical of

all that is excellent, and of life among the rest; and we have recently seen that Galen represented the influence communicated by the nerves to the contiguous parts, as something, if not identical with, certainly very analogous to this principle. Among the few modern authors who have entertained themselves with propagating the notion of the identity of light and life is Lamarck, who represents the latter as a substance composed of a kind of mixture of light and electricity!

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN,

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XXXVIII.

*Variola on the Fœtus in Utero—Measles—Pem-
phigus—Elephantiasis.*

GENTLEMEN—I shall now conclude the essay of Dr. George Pearson, as the facts and observations which it contains clearly prove that small pox may be communicated by a pregnant woman to the infant in her womb. I shall shew, in the next lecture, that persons who are contaminated with syphilis without any sores on the genitals infect, the infant in different degrees, and in some instances that seven or eight infants have been born dead and decomposed, between the seventh and eighth months of pregnancy.

The remainder of Dr. Pearson's cases are as follow:—

Case 4.—In 1747, Dr. Mead, in his treatise *De Variolis*, relates the case of a lady, who, in the seventh month of her pregnancy had the small pox. On the eleventh day of this disease she was delivered, and her infant, when four days old, had a fever with eruptions, which Dr. Mead concluded was the small pox, although it died the evening of the first day of the eruption.

Case 5.—Dr. Mead, in the publication just mentioned, informs us (from memory), that a woman towards the close of her reckoning (who had long before had the small pox, but after attending during pregnancy a person in this disease) was brought to bed of a dead fœtus, covered with pustules.

Remark.—For reasons given in the remark on Dr. Mortimer's case, this also stands in need of confirmation; and we have a better right to arraign the accuracy of Dr. Mead's, because in the same page in which he states this case, he misunderstands, or misconstrues, a case of Mauriceau, with regard to a child going through the small pox in the womb, as remarked already by Sir George Baker.

Case 6.—In 1747, Sir William Watson (see *Philosophical Transactions*, vol. xlv, p. 239) published the case of a woman far advanced in pregnancy, who had laboured under the small pox a long time before, who during this pregnancy performed the duty of a nurse to her servant in the natural small pox, and in a month after this attendance was brought to bed of a child that had about forty scars upon its body like those from the small pox. This child (a girl) and her brother were after-

wards inoculated at the same time. The brother had inflammation of the parts inoculated, eruptive fever, and eruptions as in the most ordinary small pox; and the girl, born with pits on her skin, had inflammation and suppuration in the parts inoculated, in the same manner as her brother, and a general indisposition as in the undoubted cases of small pox, but no eruptions. Sir William concludes that this girl had gone through the small pox before her birth; and Camper and Van Swieten coincide with him in this conclusion.

Case 7.—The next case I have to mention is also furnished by the observation of Sir William Watson. A woman, on the ninth day of the natural small pox, was delivered of a child, which, on the eighth day after its birth, had various eruptions: therefore the author concluded that it had been infected by the mother while in the womb.

Remarks.—This seems to be the most reasonable conclusion, because subsequent experience has shown, that, except by inoculation, the infection scarcely ever acts upon the constitution, in general in the space of eight days after its application.

Case 8.—Dr. Rosen Von Rosenstein, has related that about the year 1756, a child had crusts and scars of the small pox upon its body when it was brought into the world; for the eldest son had the small pox a little before this was born. All the other children got the small pox six years after that, except this, who certainly had had the infection already in its mother's womb. This case is so very ambiguous that I should not have stated it, if it had been related by a less respectable physician than Von Rosenstein.

Case 9.—Baron Dimsdale, in his *Treatise on Inoculation* in 1766, states that a woman with child was inoculated, and had a small crop of pustules; that in nine weeks afterwards she was brought to bed at the full time of a living child with distinct marks of the small pox upon it.

Remark.—Perhaps it may be regretted that our doubts were not removed by inoculating this child.

Case 10.—In December, 1776, the case of Mrs. Ford occurred, which is stated by Mr. Wastall, and communicated by Mr. Hunter, in the *Philosophical Transactions*, vol. lxx, p. 128. The small pox seized this woman when far advanced in pregnancy; and on the twenty-third day after the eruption she was delivered of a dead child covered with eruptions, which Dr. Leake, Dr. Hunter, Mr. Hunter, Mr. Cruikshank, Mr. Falconer, and Mr. Wastall, considered to be the small pox in the state of suppuration. Dr. Hunter it is stated, thought the eruption like the small pox: "that he could hardly doubt;" but said "that in all other cases of the same kind he had met with, the child in utero escaped the contagion." This case is very similar to that of Mary Sheers, which fell under my obser-

vation; but hers was the inoculated small pox, and Mrs. Ford's the natural sort.

Case 11.—Is that published in 1781 (*Philosophical Transactions*, vol. lxxi, p. 372) by Dr. Wright. A negro woman, a fortnight after the eruption of the small pox in the natural way, was delivered of a child with eruptions, like those of the small pox, on the eighth or ninth day, in favourable cases. The child had many eruptions, and died in three days. The mother had a very small number of pustules and soon recovered.

Case 12.—In 1781 a case was published by Dr. Bland in the *London Medical Journal*, vol. ii, p. 205, of a woman who in the seventh month of pregnancy had the confluent small pox. Six days after the turn, and eighteen days after appearance of the eruption, she was delivered of a dead child, covered with the small pox, full of matter, and seemingly arrived at maturity. The mother supposed her child had been dead five or six days before the delivery.

Case 13.—In 1784 a case was published in the *Medical Journal*, vol. v, p. 399, by Mr. Roberts, of a woman who was inoculated in November, 1783. She was in the ninth month of pregnancy. The infection with the usual appearances. When the eruptions were drying up, she was seized with rigor and other symptoms, and felt as if the child then died, of which she was delivered the day after, as was expected, dead, and also covered with seemingly variolous eruptions.

Case 14.—In a general inoculation at Painswick, in 1785, of which there is an account in the seventh volume of the *Medical Journal*, a woman nearly eight months gone with child had the inoculated small pox. In about four weeks from the time she was inoculated, she fell into labour, and brought into the world a dead child, with about thirty pustules upon it. The foetus, according to the feelings of the mother, had been dead five or six days.

Case 15.—The account of this case, by Mr. Lynn, consulting surgeon to the Westminster Hospital, was read at the Royal Society in February, 1786; but the committee not thinking proper to publish it, this valuable and perhaps only decisive instance of the small pox in the womb, would have been unknown by the public if Mr. Lynn had not printed his paper in August, 1786, as read at the Royal Society. The fact in this case is also truly satisfactory, because it is attested by a man distinguished for superior accuracy and skill in his profession. I shall give the account of this case in the author's own words, as any other representation of it would be less honourable to him, and less useful to the public.

In November, 1785, the wife of Mr. Eve, a coachmaker in Oxford-street, being then in the eighth month of her pregnancy, was seized with rigors, pain in the back, and her febrile symptoms. In two days' time the

disease showed itself to be the small pox; and though the pustules were of the distinct sort, yet they were uncommonly numerous. On the 11th day, they began to turn; and on the 22d day, her labour took place, which according to her reckoning, was a fortnight before the regular period; that is, when she was advanced in her pregnancy, eight months and two weeks. The child at the time of its birth, was covered with distinct pustules all over its body. They did not appear to be full of matter till three days after; at which time I took some of the pus upon a lancet, from one of the pustules upon the face. With this lancet I afterwards inoculated, on the 2d of December, 1785, a child of Mr. Chater's, in Church-street, Soho, in both arms. On the 7th, the inflammation began to appear in each arm, and continued daily increasing till the 11th of December, when the child sickened, and was affected with all the symptoms which usually precede the eruption. On the 12th, the sickness and fever abated, the pustules of the distinct sort of small pox made their appearance, and the child, having regularly gone through the several stages of the distemper, was perfectly well in three weeks. As in all the decisive cases I had collected, except Mr. Lynn's, the child was born dead or died soon after birth, I was desirous to see the subject whose case is just related; but on inquiry, I found it also died about the fifth day after its birth; an event which it was not thought necessary to notice in the account published.

Case 16.—In Dr. Hagarth's work on the small pox, lately published, mention is made of a woman who was seized with the small pox in the 9th month of her pregnancy and who, "not long after," was delivered of a dead child that had distinct variolous eruptions over its whole body.

Case 17.—By permission of Dr. Woodville, Mr. Wacksel Apothecary to the Small Pox, Hospital, was so obliging as to show me a foetus preserved in spirit, which has apparently variolous eruptions upon it. This child was born dead by a woman in the 8th month of pregnancy about a fortnight after she had got well of the inoculated small pox. Besides the above cases which are on record, or which I have seen, I know of several more of the same sort, which have been communicated to me by medical practitioners.

Case 18.—Dr. Ford of Bond Street informs me that the case of Mrs. Marsh of Bristol fell under his observation. When in the 8th month of her pregnancy she had the natural small pox very severely; and soon after she had gone through the disease, she was delivered of a dead foetus, with such appearances as no one among the number of practitioners who saw the child could doubt to be the small pox. The eruptions in this instance appear to have been dried.

Case 19.—Mr. Jones of Mount Street, on whose accuracy and fidelity I can safely de-

pend, saw the case of a woman who was inoculated when seven months gone with child. Soon after the eruptions, which were few in number, had dried up, she was brought to bed of a dead child that had a numerous eruption of pustules which were quite flat, but which he thinks, no one could doubt being those of the small pox.

Case 20.—The same practitioner had a woman in the natural small pox, with very numerous eruptions, under his care, who was in the 8th or 9th month of pregnancy. While the disease was going off, or in the stage of desiccation, she was delivered of a dead child with a number of quite flat eruptions, which he judged to be most certainly variolous.

Cases 21 and 22.—Dr. Hossack, an ingenious young physician from Philadelphia, (who was recommended to me by Dr. Duncan, and is now attending lectures in London with great assiduity), has favoured me with the two following cases in a letter dated London, March 22, 1794. "In the summer of 1791, the small pox was by accident introduced into the town of Alexandria, State of Virginia. As soon as observed, most of those who had not had the disease were inoculated; about nine hundred in all. Notwithstanding the great heat of the weather in the month of July (the thermometer, upon an average at 12 o'clock in the day about 90 deg.) the disease in general proved so mild that it became a prevalent opinion with several physicians, that summer, although it had been hitherto so much dreaded, was the most proper season for inoculation. Among other facts of importance upon this subject which presented, (and which will no doubt be shortly published by Dr. Dick, a present eminent physician at Alexandria) two cases occurred of the small pox affecting the fœtus in utero producing miscarriages.

The first was a lady, in about the 5th month of her pregnancy. As she was exposed to the infection, she submitted to inoculation. The disease as usual was so mild that she scarcely experienced any inconvenience from it; having but a slight fever, and very few pustules. Notwithstanding the apparently favourable termination of her disease, about a week after her recovery, as it was thought, that is, about four weeks from her inoculation, she felt a weight and uneasiness at the lower part of her abdomen; and the motion of her child ceased. In this state she continued about three or four days, when she was taken in labour and delivered. The child was dead, but had no appearance of putrefaction. The skin was thickly covered, but with distinct spots which every person who saw the child, (among others were two medical gentlemen) pronounced to be small pox. The mother experienced no bad effects from it, but in a very short time recovered.

The second case was a lady, who from an apprehension of danger both to herself and child, declined inoculation, expecting to escape the disease altogether. But she unfortunately received the infection in the natural way. She was in about her 7th month of pregnancy, of a good habit of body, and had enjoyed good health. The disease however proved of the confluent species, and very violent. In the last stage of it, when the pustules were drying away, she observed the motion of her child ceased, and felt it as a heavy weight, occasioning some uneasiness and a bearing down. Notwithstanding this unfavourable circumstance the mother continued to get better; was free from fever and the pustules dried away quickly. In short, so favourable was her situation that I still could not give up all expectation of her child's safety. In this anxious state she continued, (in the meantime, even attending, in some measure, to the offices of her family), until about three weeks from the time she first perceived the motion of her child to cease. She was then taken in labour, and delivered of a dead child. It smelled extremely fetid, and appeared to have been dead a considerable time. Its whole skin was thickly covered with small dirty coloured spots which could not, under the above circumstances, have been anything but the small pox; and which would have been pronounced such by every person who had ever seen the small pox in any of its forms."

Observations.—From the very small number of instances in which the fœtus in the womb appears to have been infected, amongst the great number of pregnant women affected with the small-pox, we may safely conclude that this disease, in such cases, very rarely extends to the fœtus. The proofs of the fact upon which this conclusion is founded, are from the children of those having the small-pox after birth; and from the absence of eruptions in abortions constantly before the seventh month of pregnancy; and generally, in premature births, at a later period.

From the very small proportion of persons who are supposed to be susceptible of the variolous matter, although their mothers, while pregnant, who had, already passed through the small-pox, were exposed to the influence of this poison, and from there not being a single satisfactory proof of this disease in the womb of such women, it may reasonably be doubted, whether the small-pox ever takes place in the uterus, except from infection generated by the mother.

In all the above cases of the supposed small pox in the womb, in which the disease appears to have been communicated by the mother's infectious matter, the time of the action of the infection in the fœtus may have been the same as in the natural small-pox in the air, which we may reasonably suppose to be the case: because, under both circumstances, the

variola is probably conveyed into the constitution along with the aliment, whether that be oxygen which enters by way of the lungs or animal and vegetable matter, which enters by way of the alimentary canal.

It appears from the above cases and others on record, that the natural small-pox in pregnant women is fatal in at least 19 out of 20 cases to the foetus in the womb, and to three-fourths or four-fifths of the women. Nor is there, perhaps, a single decisive instance of a patient going through the disease of the womb, and being afterwards, born alive. It is not even clearly proved that a child, born with the small-pox, has survived this disease.

On what circumstances this fatality to the foetus depends we know not; but it is obvious to suspect three, viz :—

1st. The foetus being immersed in a liquid.

2dly. The small quantity of oxygen taken into its constitution, and that only through the intervention of the mother.

3dly. The temperature of the surrounding medium of fluids and solids being 97 or 98 deg.

It is particularly worthy of notice that the foetus, in the womb, dies with a smaller number of eruptions upon it than scarcely ever happens from this disease after birth.

There are some facts to shew, that it is probable a very small proportion of pregnant women die by inoculation, although the foetus is generally destroyed. All calculation is liable to much inaccuracy in the present state of facts; but in about 40 cases of pregnant women inoculated in almost every stage of pregnancy which I could state on the authority of Sir George Baker, Baron Dimsdale, Dr. Ingenhouz, Dr. Woodville, Mr. Wacksel, and from the above cases one died, as stated by Sir George Baker to have happened in the sixth month of pregnancy; but, I am sure, not one in a hundred dies at earlier periods of pregnancy than seven months.

There is no reason to suppose that the mother's constitution is at all disordered by the small pox of her foetus, although premature labour and parturition are very liable to come on during the disease of the mother.

It appears from the above cases, that the disease in the mother and foetus are not always in the same degree; for that in some cases the mother has the disease severely and very numerous eruptions; but the foetus has a small number of eruptions. And on the contrary, at other times the mother has the disease slightly and few eruptions, but the foetus a great number of pustules.

If it be allowed that the above statement of instances of small-pox in the womb establish the fact that the foetus is not infected by the variolous matter that infects the mother, and that the foetus is never infected but by variolous matter generated by the mother, it seems highly probable that this fact will be frequently referred to in physiological and pathological reasoning.

Such are the facts collected by the late Dr. Pearson, one of the most eminent physicians of the last and present century; and I deemed his essay so valuable that I copied all the cases related in it. This I considered necessary in confirming the generally received opinion of the most learned physiological and experienced physicians—that certain contagious and other diseases as well as the moral and physical characters of parents are transmitted by them to their progeny.

Dr. Jenner inoculated a woman, May 6th, 1808, who was delivered June 11th, the body of her infant being covered with incipient small-pox. New pustules appeared on the following day, and the infant died of convulsions eight days after birth. (Med. Chir. Trans. vol. i.) There is a specimen of congenital variolous eruption in the Museum of Guy's Hospital in London, taken from an infant whose mother was a patient under the late Mr. Laird at the General Dispensary, Aldersgate Street. Ann Howard, aged 26 years, the mother of one child, and pregnant of a second, laboured under the eruption of small pox, August the 30th, 1805. She was admitted, Sept. 2nd. Numerous confluent pustules were observable on her face and arms. The eruption was distinct on the body and inferior extremities. About ten days after her convalescence, she felt the motion of her infant two or three times, but did not after that period. She was delivered on Sept. 28th of an infant aged about six months. It had been dead for some time, as there was desquamation of the cuticle of the abdomen and hands, and putrefaction had commenced. There was a well marked variolous eruption on the back, shoulders, and particularly on the superior part of the neck; the pustules were distinct, elevated, with a depression in their centre. Similar cases are recorded by Bartholin. (Epist. Med. Cent. 2, p. 682; Philos. Trans. abridged, vol. iii, p. 308; Hildanus, Dolæus, Fernelius, Castor, and Boheroave, according to Van Swieten. (*Variola*).

M. Rayer states on the authority of Vogel that infants have been born who laboured under measles. M. Duges has detailed several cases in his inaugural dissertation of cutaneous inflammations, observed in new-born infants at the Maternity of Paris. M. Billard has seen erythema in different patches on new-born infants, which closely resembled measles. Congenital pemphigus was observed by Mr. Lobstein of Strasburg (Journ. Complém. du Dict. des Sciences Méd. t. vi, p. 3); but this was supposed a syphilitic eruption, by M. Duges (*Op. Cit.*); but others agree with the former opinion.

Pemphigus.—The epidermis of the sole of the foot, toes, palm of the hands and fingers, is raised sometimes in the foetus by the slightest contact; more rarely is general desquamation of this membrane met with.

Dr. Joerg, has, nevertheless, met with it once in an infant, born at the natural period, and well in other respects. This disease, attributed by some to syphilis, is always accompanied with great debility, and generally causes the death of these infants which are affected with it, in a few days, from the pain and inflammation of the skin, which result from the denudation of this membrane. It is sometimes accompanied with an eruption of pustules, which are principally developed over the soles of the feet and palms of the hands, and which always resemble vaccine buttons at the thirteenth or fourteenth day of development. Gœckel and Ledel (*Mémoires des Curieux de la Nature*) have seen new-born infants whose skin, covered with pustules or vesicles filled with serosity, was afterwards completely excoriated.

It is easy to perceive, in the different affections of the skin, all the characters which are attributed to the true pemphigus of adults. Ohler has observed vesicles, of the size of a pea, which were developed over the whole of the skin, and especially within the intervals of the fingers and toes. At the commencement they were surrounded with a red circle, they filled in a short time with a serous liquid, which soon changed into pus; then they discharged. The course of this exanthemata was not more than forty-eight hours. M. Desermeaux (*Dict. de Med., Art. Œuf*), who has also related this case after Ohler, thinks that this eruption ought to be considered rather as a varicella than a pemphigus.

Elephantiasis.—M. Chaussier has seen two infants at the Maternity of Paris, with disease of lower extremities similar to the elephantiasis. This solid, indolent swelling occupied the feet, legs, and a part of the thighs, there was neither heat, redness, nor sensible alteration of the skin, pressure did not cause pain or pitting as in œdema; and the disease was circumscribed as if a ligature had been firmly applied round it. On dissection the thickness of the skin was not increased, but the cells of the subcutaneous cellular tissue were filled with a white compact fat, and their areola filled with a sero-gelatinous fluid, which was readily squeezed out on pressure. —(*Dict. des Sciences Medicales, Art. Monstruosites*).

Scales on the Skin.—M. Sallpart van der Weil, has seen a fœtus whose whole body, except the head, was covered with scales, and exhaled a most unpleasant odour. When the scales fell off, they were replaced by new ones; and when rubbed off the surface, bled freely. (*Cent. Poster. Obs. 35*).

There are various other cutaneous diseases which have been observed on the infants soon after birth; but as they occur at a future period of life, I shall describe them fully hereafter.

LECTURE III.

Inflammation—Causes of Inflammation— External Inflammations.

ANOTHER peculiarity of the phenomenon of inflammation, is its power of changing locality; and this takes place in various ways: either a series of organs are sympathetically stimulated by the principal focus, at the same time that one of them seems to attract to itself the entire nervous activity, the primary inflammation leaving the first point it occupied, and passing to that single organ, or else it is propagated, makes way, and meanders internally as it sometimes does externally, passes from one organ to another, ever in progress, ever changing its position, at one time intense, at another feeble—so that it is impossible to avoid the observation of these displacements in contemplating an inflammatory process that has not been put down in its commencement;—or lastly, the change of place occurs in an irregular and inexplicable manner, when the inflammation is extremely intense. Thus, it will be found that inflammation is not a fixed phenomenon, it is ever moving about the organism—a fact that should always be borne in mind.

In order to remember more easily the nature of these displacements, they may be classed as follows:—1. Passage in the same organ: here the inflammation tends from one point to another of the same organ: the instances are the skin and mucous membranes; 2. Passages to organs of the same character, but situated in different regions of the body; 3. Passage from the exterior to the interior by the cellular tissue, by the continuous membranes and by the nerves; 4. Passage from the internal to the external parts by the same routes.

The idea of inflammation should never be given up and its existence forgotten because it is no longer felt and pain is no more perceptible. In fact inflammation is never very painful except when it involves tissues wherein nerves of relation or the cerebro-spinal abound, and such instances are found principally on the external parts, in the skin, which is, as it were, our sensitive cloak; but even in pain it is exceedingly transitory, for early combatting with the inflammation soon dulls the exaggerated sensibility. At the same time it rarely happens that pain is so slight that inflammation of the dermoid tissue cannot be traced by it. Internally the phenomenon of pain is not so palpably manifested; our relations with our viscera are far less felt. These for the most part are only painful at the com-

mencement of inflammation: subsequently they are not felt at all. These relations, however, vary with individuals, some being naturally more obtuse in their visceral sensibilities than others.

When there are several inflammatory points they simultaneously transmit their influences to the brain: in this case there is a confused feeling, the patient can give no distinct account of his sensations, and describes them collectively as *malaise*.

Thus you may perceive that pain is by no means to be relied upon in detecting the precise seat of inflammation, when this is internal, and sometimes not even when it is external; for we shall see that it is not always in proportion to the intensity of the disease.

We have seen that inflammation may pass from one point to another, be propagated simultaneously in several organs and proceed from within outwards and vice versa. But it is never generalized, and on this fact I beg you to reflect. They often speak of general diseases, but it would be difficult to shew such. True, there are apparently general phenomena—for instance, when the whole nervous system is in an excited condition—but still there are always points in which irritation is more at work than in others. What generality is there in the decided febrile state? You may answer, the rapidity of the blood's motion. Yet this is not everywhere the same. Neither pain nor the circulation, nor the nervous system in a state of general disturbance, constitute disease in the majority of other cases. Inflammation may involve the entire skin, but then it spares other organs: it may occupy all the mucous membranes, but then it spares the parenchymatous organs: it may pervade the parenchymata, but then it avoids the serous tissues, and so on. The diseases which exhibit the most extensive inflammations are the eruptive phlegmasiæ, of which I make anticipatory mention in order to have facts to present to you.

It is then possible to have inflammation in all the tissues, but not in all at one time.

Inflammation sometimes disappears spontaneously. Frequently an irritation having the characters of inflammation and that appears likely to end as it does, suddenly ceases, is transmitted elsewhere, or passes away altogether with the morbid state. Subsequently it returns. This constitutes the intermittent irritations. This kind of irritation cannot be separated from the continuous, inasmuch as, first, it is observed in all cases where inflammation, sub-inflammation and other shades of irritation are possible: secondly, because an irritation at first apparently intermittent, as it acquires fresh activity, changes into a continued form and produces the same disorders as that form: thirdly, because an irritation absolutely continued changes its form after undergoing certain modifications, and be-

comes intermittent; fourthly, because a manifestly intermittent irritation is often so much kept up by a continued inflammatory irritation as that on the disappearance of one, the other is arrested. Inflammation and congestive inflammatory irritation are therefore nearly allied; they can neither be studied separately nor can they be formed into two distinct classes of diseases.

Inflammation always alters the composition of the fluids; in the first instance, in the part where it is situated, the fibrin and albumen being decomposed, making thus the decomposition of the solids and fluids in that part simultaneous; subsequently it alters them in the other parts of the body, as is remarked in the fibrin of the blood, the relations between it, and the cruor changing so soon as the inflammatory condition is established. But besides these changes others occur in the progress of inflammations. The blood always becomes less fibrinous and more serous; and when inflammation has yielded pus and caused effusions, congestions and decompositions of various fluids, some portion of their molecules is sure to be absorbed and to taint the circulating blood. This in no way militates against the principle of applying our modifying means to the inflammatory state itself and not to the fluids; for let their deterioration have been ever so great, so soon as the inflammatory action ceases, the laws of the system are quickly re-established in their healthy condition.

Causes of Inflammation.

We now proceed to examine the causes of inflammation, which you will never comprehend in any other way than by reflecting on the modifications they produce in the tissues. In this view the phenomena that accompany its development may be reduced to two principal ones, which—conforming to the ordinary language—we shall call the proximate causes; one is nervous irritation, the other sanguineous congestion.

Irritation of the nervous matter is indispensable to inflammation, but is not uniformly the first cause of it.

Sanguineous congestion is also necessary to constitute inflammation, but it is not the most common cause of it: the most ordinary is nervous irritation, which is developed and produces inflammation upon the operation of various causes. It may be induced—

1. By external violence. When a part has been incised, bruised, or dragged, the phenomenon is pain (we suppose the hemorrhage to have been arrested). After the pain comes congestion, an afflux of serosity and blood, the sero-sanguineous effusion. The serum disappears, the blood alone accumulates, and inflammation appears in the lips of the wound.

2. By the introduction of foreign bodies to the surfaces of relation, the respiratory, gastric, or genito-urinary passages. On such introduction there is first, augmentation

of the secretions, then sanguineous congestion. The true inflammation afterwards predominates, and by it the secretions are for a short space stopped.

3. By a forced augmentation of innervation without the existence of either of the preceding causes. If you keep an organ in constant play, you change its vital physiological elevation into a vital pathological elevation or inflammation.

4. By irritating molecules that circulate with the fluids. These molecules develop irritation in different points, in the brain, in the digestive apparatus, in the lungs, the genital organs &c., and to their history is referable, the absorption of all irritating matters.

5. By congestions. Blood accumulated in a part irritates it. In fact, that fluid may be, like the too great influx of nervous energy, an irritant to the body: for whether we call the nervous power electricity, galvanic principle, or biotic imponderable, it is no less a matter, which by its accumulation produces irritation. So also of the accumulation of blood in a part. Should the disposition to irritation be added to that which causes the blood to accumulate, you have a phlegmasia in which irritation is chiefly prominent; this combined action may be remarked in the changes of nervous influx and distribution of blood that occur repeatedly in the twenty-four hours. It is well known that when heat surrounds the body the blood tends to the external parts, the veins swell and the arteries beat more vigorously, and that when cold is applied the blood is repelled to the internal parts, and accumulates in the viscera. This species of swinging motion, which occurs repeatedly in the same day and with varied degrees of vigour and duration, of flux and reflux, or, if you please to call it so, this alternation of centrifugal and centripetal movements, fatigues and irritates the organs; and should an irritative tendency exist, inflammation is generated and receives from it more strength and obstinacy. But it is difficult to separate completely the phenomenon of irritation from that of congestion as the cause of phlegmasia. One of the facts in favour of congestion in that character is, that when vigorous individuals are in the habit of undergoing certain kinds of efforts, either from taste or necessity, they are attacked with spitting of blood, and immediately afterwards with inflammation. However the fact may be with regard to this priority of nervous irritation or sanguineous congestion in producing inflammation, it is still certain that in them we have the two fundamental causes of that phenomenon.

Having premised these considerations, we may without difficulty connect them with those of the hygienic modifiers and use them to assist us in investigating the causes of inflammatory diseases. You may thus learn that the difficulties of pathology are

not so great as they appear, and that to avoid them you need only follow the method indicated by the identity of causes, a method that saves much repetition and confusion. And it is not without cause that we attach so much importance to the consideration of causes, for the more we know of them the more easily shall we find the remedy; some deny this, but their's is a want of reflexion.

We arrange the causes of inflammation according to the order of the materials included in hygiene.

1. *Applicata*. These give us all the surgical inflammations, which should be referred to irritation.

2. *Gesta*. You already know how the forced action of an organ produces inflammation of it. Violent exercise that causes the blood to circulate with too much impetuosity always ends in the inflammation of some great viscus. No diseases are more serious than those consequent on long forced marches; and such are more particularly violent if the body, after the exertion, be seized with cold, or if, during the exertion, some vehement external stimulus, as heat, is operating.

3. *Ingesta*. Too much or too stimulating food determine, on their contact with the stomach, irritations upon which inflammations of the mucous surfaces or of the organs connected with them ensue. By furnishing a superfluous quantity of nutritive material they enrich the blood so as to render it irritant. They also act indirectly, by arousing the passions and leading to acts that disturb the economy. In food will be found one of the most common causes of inflammation, for with it, irritating and more or less acrid matter enter the body and light up organs that are but too ready to be acted on.

4. *Percepta*. Strained exercise of the intellectual faculties is a powerful incentive to inflammation, and no wonder it is so, since the matter that serves to innervation is itself a stimulant. Neuroses are frequently followed by inflammation; cut or tie a nerve, and an inflammation or abscess straightway forms in the part to which the nerve is distributed. Moral affections and the passions determine visceral congestions, disturb the order of the secretory organs, disorder the bile, saliva, &c. and even cause hæmorrhage and sanguineous secretions. I have seen anger produce phlegmonoid, and even gangrenous erysipelas.

5. *Circumfusa*. The atmosphere may be an irritative cause if it is too active, or if there is a necessity for its very frequent respiration. You may perhaps scarcely credit it, but it is certain that too pure an atmosphere is capable of producing an acute phlegmasia, or of communicating a greater activity to already existing inflammations. Like water and other media the air may cause disease by variation in its temperature. Cold air is an indirect stimulant which pro-

duces inflammation, either by repelling the blood to the interior of the body and causing congestion of the viscera, thus leading to their inflammation and super-secretion: or by a re-action, by which the inflammation seizes the part first attacked by the cold. If the impression is insufficient to produce this re-action, the skin is still more sensitive and even painful; this is seen in very frosty weather, when the sensibility of the whole body is increased. It is true that this sensibility decreases with habit, but that is a subject involving the theory of acclimations. The atmosphere, moreover, acts by the medium of the irritative corpuscles with which it is loaded, and which sometimes find entrance to the body.

You see then how multiplied are the causes of inflammation and the use of subdividing them: I have only stated them generally, because we shall return to them in speaking of the individual species of inflammation. But before dismissing the subject, we will consider them in another point of view, and divide them into two series—those that are ordinary, usual, and produce inflammation of a decided cast, easily recognised, and easily treated: and those that give the inflammation a specific modification by which its progress is so disordered as to render it less tangible, and less tractable by the physician than in the most ordinary cases. For the physiological physician makes what he pleases of ordinary inflammation when he takes it: *ab initio*, whereas when the causes in question have come into play, the scene is changed, either in consequence of the alteration of the fluids or the derangement of the principle of innervation by them. The inflammations that ensue upon this second series of deteriorating agents should not be considered in conjunction with the others, because if you confound them you thereby increase the difficulty. In proceeding from the more known to the less known, I shall first descant on the ordinary inflammations that bear the greatest similarity to each other.

After the causes comes the theory of predispositions by which inflammation is variously exhibited in different individuals; in the strong, well-constituted, powerfully digesting, inflammation has always an un-deviating and palpable progress that is not easily modified; in the feeble, ill-developed, who are excitable to all the causes of disease, and have been reared in a bad atmosphere and with improper food, the physiological state is actually pathological, and the inflammations they suffer from, have neither the appearance nor the true progress exhibited in the former. Important distinctions are also founded on the age and sex. There are likewise depraved conditions produced by previous disease, that should be taken into account.

We shall now, as before said, proceed with the examination of the ordinary in-

flammations situated externally, and whose existence is readily detected.

Cutaneous Inflammations.—The skin takes on three forms of inflammation, the erythematous, the furuncular, and pustular. We first speak of the erythematous in its primary character, and not as proceeding from an internal inflammation.

Erythematous Inflammation of the Skin, or Erysipelas.—The external and internal causes of this inflammation are those of inflammation in general, that is, every thing that accumulates irritability or produces plethora; youth, the sanguineous temperament, hot climates on one of moderate climes, vicissitudes of temperature—a very common cause—all kinds of cutaneous excitations caused by irritating rubefacients and frictions, proximity to great heat, &c.

Erysipelas presents the four known characters of redness, tumefaction, heat, and pain, and is one of the principal types of inflammation. The heat is sharp; the redness gradually diminishes, and is insensibly lost in the normal skin, disappears on pressure by the finger, which pressure leaves a white mark: this last does not take place, however, if the inflammation be intense. If the inflammation is still more intense, the subcutaneous cellular tissue swells and becomes phlegmonous; pustules appear on the surface; these, indeed, are seen in almost all kinds of, erysipelas, but more particularly in shingles (*zona*), which is true erysipelas, and should not be isolated merely from its peculiar form. You may tell me it is connected with gastric affections, but I have seen it primary and altogether independent in character.

Let us now apply what has been said of propagation and dissemination to erysipelas. In the first place it is propagated and extends without changing its locality, and in this manner sometimes covers a large surface. In the next place it changes situation and wanders over the skin, leaving its former positions clear. If simple, it may disappear and leave no trace; if phlegmonous it does not disperse, it suppurates, produces abscess, and occasionally forms an eschar or tissues rendered gangrenous by the excess of inflammation. It is for the most part difficult to assign any particular progress and spontaneous termination to erysipelas, for it is rarely left to itself, and always modified in some manner. But when no treatment is applied, what ensues? enormous deterioration of tissue. In the army I have seen cases left to themselves that proceeded with frightful stride, causing purulent deposits, disorganizations, mortified shreds, absorption of pus, and finally inducing fatal cerebral phlegmasiæ.

Regarding the manner in which the phlegmasia in question is disseminated in the system, you observe at its commencement malaise, tremor, inquietude, and then by a further step, loss of appetite, thirst, red

tongue, frequent pulse, gastric heat and sensitiveness, in a word, the development and addition of an internal phlegmasia, itself tending to extension and propagation through the viscera—as the erysipelas did in the skin—with a *cortège* of symptoms and disorganizations that it would be premature at present to detail. In such an instance you have a complicated and possibly fatal disease. Should it prove so, you may by dissection ascertain the existence of such external disorders, as redness and injection of the skin, the thickening of the dermoid tissue, infiltration of sero-sanguinolent fluids, pus and putrid sanies into the subcutaneous cellular tissue, collections of decomposed matters, gangrenous shreds, &c. On the internal appearances we shall dwell when treating of the visceral phlegmasiæ.

You see then that erysipelas is not so simple and indifferent an affection as might be imagined; for it shews you how it is that diseases succeed and are connected with each other. You have doubtless seen abundance of cases of erysipelas, and will be inclined to think it idle in me to rest so long on things you are so well aware of, though I have avoided the prolix details. But this is my own manner, and it will lead to the demonstration of the connection of the facts mentioned with other diseases, and shew you that no disease, however common, can well be passed over.

On what do we ground our prognosis?—You can answer for yourselves: on the degree of propagation in the skin and dissemination in the viscera. So long as erysipelas is simple, superficial, not phlegmonoid and slow in its progress, the prognosis cannot be unfavourable. But should its march be rapid, should it traverse the skin, reach the cellular tissue and become phlegmonoid, you may be sure that there will be dissemination into the interior, and that a consecutive inflammation of the digestive mucous membranes, and, perhaps, of the vertebral and cerebral membranes also, will be developed; the danger is then urgent, and death more than likely. The latter can only take place however in consequence of the extension of the inflammation into the viscera, for no one dies of external disorders—an incontestable and memorable truth.

Attend to the treatment of erysipelas.—When incipient, slight, and superficial, it is sometimes successfully combated by astringents, the salts of lead, cold lotions, and by the simultaneous application of narcotics and astringents. In this stage it may even be put a stop to and irritated with impunity by lunar caustic, mercurial frictions, or ablisters. This may be very well when the irritative impulse is not sufficiently forcible; but if it possesses a certain vigour and tends to pass the skin and become phlegmonoid, these means only precipitate its progress and hasten the inflammatory and nervous dissemination. For the rest, this increased tendency to dissemination in consequence of the inopportune use of such means is not pecu-

liar to erysipelalous inflammations of the skin: the same danger obtains in treating internal inflammations in a similar manner.—Mark this fact; for our doctrine is so coherent that all its truths are connected, and are, as it were, within each other.

The remedies alluded to are only proper in erysipelas in the degree of erythema, or that which Cullen called erysipelas from external causes. As to that which he considered as analogous to variolous eruptions, the mischief of treating it in this manner would be still greater. This is a most important distinction to be made in determining the treatment of affections of this kind. In fact, though there can be no doubt that an internal inflammation may cause the development of erysipelas, and give it a more rapid march, yet it does not follow that in all the severe cases of that disease there should be, as Stoll said, an internal disposition or gastric condition, either bilious, mucous, or inflammatory. Very serious and extensive erysipelas is observed without anything of the kind; and this fact allows us to present erysipelas as an example of a primary inflammation that is able to disturb all the functions by self-propagation and dissemination. In treating it therefore, we must not consider ourselves bound to be incessantly purging, vomiting, or bleeding the patient: it is only incumbent on us to take the fact as we receive it—if the erysipelas is slight you may try the arresting treatment mentioned above. But if it is intense and phlegmonoid, you cannot, it will be dangerous and you will be rash. Rather employ local bleedings, which are always useful, and general ones if there is plethora. Practice the latter freely and copiously, particularly if the inflammation, having passed to some internal part, pulmonary or cerebral congestion is present; in that case do not fear to repeat the bleedings as often as that congestion inclines to a renewal—it is the only condition of your decided success. If gastritis or gastro-enteritis is present, either in a primary or consecutive character, attack it in like manner, allowing, however, the local bleedings of the abdomen always to exceed the general. The drinks ought only to be demulcent and refreshing. Lastly, if the erysipelas has become phlegmonoid, suppurating, gangrenous, you are obliged to use means, the consideration of which makes no part of this course. During convalescence, prudence in regimen and other hygienic means constitutes the true treatment. However—and this should never be slurred in the treatment of all inflammations whatever—care should be had to restore any suppressed evacuation, menses, hemorrhoids, &c., or supply their place.

Furuncular Inflammation.—In order to bring together into one final point of view all the external inflammations, I shall now pass to the consideration of the second form of them, the furuncular or perpendicular inflammation of the skin. Its causes are to be found

in all prolonged irritations of the skin. It is impossible to say wherefore these irritations produce furuncular inflammations in some, and erysipelas in others; individuals so constituted however most certainly exist. In either case a relapse is to be dreaded.

The predisposition to boils consists in the irritability of the nervous and sanguineous systems; but we must materialize this irritability, otherwise it is vague. Those who have unusually irritable, nervous, and sanguineous systems also carry in the respiratory, digestive, and genital mucous membranes a shade of irritation which is ever ready to be raised to the inflammatory point, and which meantime causes an incessant inquietude of the nervous centres, maintaining in them a state of agitation proportionate to its own activity. Such individuals, whom a too stimulating mode of living places in this state of inflammatory irritability, are also liable to actual inflammation from the slightest causes: and boil is among the affections that this cause may induce.

A boil is a small, red elevation, limited around the skin, accompanied with sharp pain, itching, and subsequently with burning pain. A swelling rises round it, the redness changes to brown, a yellow point appears at the summit, where there is also an excoriation. An autopsy of the boil is one of the remedies, and if we practise it we shall find a head of cellular tissue traversing the depth of it, swelled, forcibly separating the fibrous network of the dermis, already in a state of suppuration, acting like a pin that is passed through the skin. The disease progresses until this cellular tissue, or core, as it is called, becomes isolated and detached by suppuration; it is like a worm, and may like it be drawn out, leaving an empty space behind it. After this abstraction, the swelling diminishes, and all returns to a state of quietude.

The above is the most simple form; for it sometimes happens that the cores or suppurated cellular shreds are multiple and confluent, and thus foment the intensity of the inflammation, the propagation and dissemination of which are then to be feared, whereby more or fewer of the phenomena displayed in erysipelas are produced. When at this degree the disease takes the name of anthrax or carbuncle. The cellular tissue surrounding this constricted group of cores swells, becomes phlegmonous and the inflammation by extension may produce erysipelas. Here then is a very evident propagation. Things may go sufficiently far to cause dissemination, but this is rare. More ordinarily, the disease, after causing fever and considerable pain, ends, and the portion of skin interposed between the small cores of cellular tissue fall into gangrene, and an actual eschar forms: in simple boils such do not form; it is only when several cores together distend the skin in a violent manner, and the excessive inflammation of the cen-

tre annihilates life there, that we have eschars. In these cases a loss of substances as large as your hand may occur, but once detached, every thing becomes quiet of itself. Not but that internal and very intense inflammations requiring active treatment may arise secondarily and in consequence of certain predispositions, for such may be observed in all diseases, inflammation being a phenomenon that can neither be considered exclusively nor isolated in any particular organ, its unceasing tendency being to communicate and come into complication whenever it has reached a certain considerable degree of intensity.

In the next lecture we pass to the other points connected with the subject of furuncular inflammation.

Abstracts.

Proceedings of the Hunterian Society, during the Year 1834.

We wish other Societies would imitate the excellent example of the Hunterian, and publish a similar Report to that before us.

It will appear by our extracts, that the names of speakers are not given—a proper proceeding, but merely the results of their observations. If this plan were generally adopted, it would cure many members of their *cacoethes loquendi*.

I. Affections of the Brain and Nervous System.

“*Brain, Abscesses in*;—a case which commenced in ear disease, and proceeded insidiously till it destroyed life. Such cases spoken of as rendered the more important from being not unfrequent.

“*Brain*;—instance of large deposit of fibrine at the basis of—spreading itself on the nerves and vessels, in which the difficulty of diagnosis was exemplified.

“*Brain*;—instance of scrofulous tumours. The patient was an infant, and upwards of twenty tumours were found, and resembled strumous tubercles of other parts. There was serous effusion into the ventricles. Nevertheless, there was remarkable diminution of symptoms before death.

“*Brain*;—degeneracy of structure—imputed to a blow on the head, received eight months before death, and from which injury the patient apparently recovered. Paralysis ensued, and the disease ended fatally.

Epilepsy;—which also arose from a blow on the head. In another case related, the epilepsy arose from a similar cause, and continued during two years, when on the super-vention of diarrhoea the epilepsy ceased.

“*Pedunculated bony Tumour*;—growing from the inner table of the calvarium, and dipping between the convolutions of the left hemisphere. There was sudden death, and a clot of blood was found in each ventricle.

“*Delirium tremens*;—numerous instances were related bearing chiefly on the treatment by opium or depletion. The preponderating evidence was in favour of opium, and solid opium was preferred to the liquid preparation. In one case, 36 grains were taken within 36 hours, in doses of four grains every four hours. In another instance, two or three ounces of laudanum, and forty grains of opium, within a very short period. A state of coma was induced, and the respirations did not exceed five or six per minute, yet the patient recovered. Circumstances were specified under which the combination of opium with ammonia was highly extolled; less opium appeared requisite to produce a given effect. The advantages of annihilating the imaginary object, and of substituting a real one, as a hat, &c. were attested.

“*Nervous System*;—a paper was read on the distribution and functions of those nerves said by Sir Charles Bell to derive their influence from the tractus respiratorius. The author adverted to the fact that the sympathetic nerve is formed before any other part of the fetal animal, so that at birth the functions of assimilation, circulation, secretion, respiration, and voluntary motion, are under its government. The author endeavoured to shew that the precise central origin given to the respiratory nerves does not exist, but that the peculiar powers of those nerves are derived from their connexion with the sympathetic. An interesting discussion, in which some experiments and physiological observations were adduced, in corroboration of the author's opinions, ensued on this communication.

“ II. Diseases of the Thorax.

“*Heart*;—instance of hypertrophy of, with ossification of the mitral valves. In this case, there was pulpiness of the mucous membrane of the stomach and bowels, and a loaded state of their vessels, which, with some suspicious circumstances preceding death, led to an apprehension of poison. It was shown, however, that such appearances in the ali-

mentary canal are not unfrequently observed after death from disease of the heart.

“*Heart ruptured*;—several instances alluded to, in some of which the patients lived 24 hours. In others, death was instantaneous. The rupture most frequently happened in the left ventricle.

“*Aortic valve*;—an instance of its rupture in a boy, from his being frightened at the report of a pistol. He instantly felt pain at the region of the heart, soon became dropsical, and died in a year and a half.

“*Lungs*;—a paper was read on the question whether the parenchyma of the lungs, or the lining membrane of the cells is the seat of pneumonia. The author believed that what is called inflammation of the substance of the lungs, or pneumonia, is not inflammation of the parenchyma, but of the membrane lining the cells. Also that the inflammation is of two kinds, the plastic and non-plastic, with intermediate varieties. In the former, organizable lymph is thrown out; in the latter, there is a grey secretion, which gives the diseased portion the name of grey hepatization, and is much like Castile soap. The products of this inflammation are unorganizable. These two conditions said to differ, ab initio, and to require different treatment—the plastic bleeding and mercury, and the non-plastic stimulants.

“*Larynx and Œsophagus*;—ulcerated opening between to the extent of an inch, in a young woman. There was stricture in the Œsophagus, with ulceration to some extent. For several weeks before death, it was evident, from the symptoms, that an opening into the larynx had taken place. One of the inferior cornua of the thyroid cartilage was denuded, and one of the recurrent nerves exposed. The female in whom these lesions occurred had been the subject of hysteria, and it was suspected that the sympathetic irritation of the parts in the throat had ended in organic change.

“*Œsophagus*;—instance of a pouch at the lower extremity, occasioned by a stricture near the cardiac orifice, so that the food, after remaining only a short time in the dilated portion, returned.

“*Dyspnœa and Dysphagia*;—an instance which arose from nervous excitement.

“*Bronchocele*;—a remarkable instance of,

in which iodine appeared to augment the swelling. Carbonate of soda was then given in the dose of a drachm, and repeated three times a day. The enlargement decreased. The iodine was again tried with the same effect as before, when the soda was a second time resorted to, and with a similarly good effect. Ultimately, however, the disease was removed by the ioduret of iron.

“ III. *Diseases of the Abdomen.*

“ *Stomach*;—instance of perforation by ulcer. A young female servant, in previously good health, was attacked with acute burning pain in the epigastrium. The pulse was 100, soft and compressible. She was bled and purged, and died after sixteen hours' illness. There were two round openings, with slightly inflamed edges, near the lesser curvature of the stomach, through which a quantity of food had passed into the peritoneal cavity. The gall-bladder contained calculi.

“ *Stomach*;—perforated by a woman who stabbed herself. The contents of the viscus flowed out of the wound. She fell into a state of collapse, but was sufficiently sensible to be alarmed at her own act. She endured total abstinence from ingesta for thirty-six hours. She recovered, but ascites followed in four months. This was also removed. It was remarked, that wounds in the stomach heal with greater facility than those of the intestines, from the less activity of peristaltic motion.

“ *Stomach*;—retention of undigested matter in—as carrots, celery, &c.—instance of their proving fatal.

“ *Intestine*;—case in which the duodenum was perforated by an ulcer. The patient had resided in warm climates, and was attacked two hours after supper with acute pain in the epigastrium, and about the right shoulder. There was scarcely any affection of pulse. The contents of the intestine and stomach had escaped. The differences between rupture and perforation were alluded to. It was stated that in rupture the mucous membrane invariably curls over the rent peritoneum, but in ulceration the lesion of the mucous membrane usually extends beyond that of the serous. Ulceration of the bowels was considered of frequent occurrence in persons who have resided in hot climates. Rest and opium were considered to afford the only chance of closing

the opening, whilst the inflammatory stage is to be relieved by venesection.

“ A few cases of ulceration of the duodenum were mentioned, in which obstinate vomiting had preceded death. Other instances were related in which the adhesive inflammation had limited the effusion.

“ *Intestinal hæmorrhage*:—with immense discharges of muco-purulent matter.—A case was related in which alum injections, and acid astringents by the mouth, had been serviceable.

“ *Hernia*;—an anomalous instance of, was related. A man, æt. 67, was seized with vomiting and purging. In his straining efforts, protrusion of the bowel took place. He was placed in a warm bath, and the hernia was reduced. The symptoms of strangulation, however, continued, and peritonitis supervened, but he had no pain or tension about the part itself. In the failure of giving relief, a consultation was held as to the propriety of operation, when it was decided, that as the hernia was not the primary disorder, and appeared to have been reduced, it was not justifiable. The man died. On examination, a small knuckle of intestine was found strangulated in the inner ring, and just within the abdomen a sac containing a larger hernia, also incarcerated, was found. It was thought that the smaller portion had come down after the sac had been retained, and that had an operation been performed it was not probable that the more internal hernia would have been discovered.

“ *Liver*;—a large hydatid cyst of, was exhibited to the Society. The female from whose body it was taken was sixteen years of age. It had been several years in formation, and hæmorrhage from the bowels took place before death. The cyst was attached to the right side of the liver. Its outer covering was formed of the peritoneal coat of the liver, and within this was a second cyst, which contained three hydatids.

“ In another case a young woman had enlargement of the right side. At length she began to expectorate small hydatids tinged with bile. This expectoration continued for three months, and then she recovered.

“ In another instance small nodules were felt over the hepatic region. They disappeared by purging. It was supposed that

they were hydatids, and had passed by the biliary ducts.

"The question of treatment involved considerations as to the safety of tapping, or of opening the cyst more freely. By some it was thought tapping would hazard great constitutional irritation, and, perhaps, suppuration and sloughing of the sac. When these cysts are near serous cavities, it was considered as, usually, better to let them alone, unless a free exit can be given to them. A case, however, was related of the successful removal of three quarts of colourless fluid from an hydatid cyst by trocar. The patient was greatly relieved for a year and a half. Then came on cough and expectoration, and he died. The liver was changed into irregular clumsy masses, so that with its greatly thickened peritoneum, its natural character could not be discovered. It was converted into two thick cysts, containing very numerous large and small hydatids, the lower cyst was firmly contracted on several dead hydatids, and in the upper cyst there were numerous living hydatids. This upper cyst communicated, by an aperture through the diaphragm, with the right lung, where there was a large abscess containing shrivelled hydatids.

"It was mentioned that spontaneous cure sometimes occurs. The hydatids shrivel up, the cyst contracts, and remains dormant unless inflammation be excited, when the whole cyst may slough. Two fatal instances of this nature were adverted to.

"Could it be ascertained that adhesion had taken place, it was thought it would be safe to open with a scalpel.

"The importance of correct diagnosis was pointed out, and in aid of this it was mentioned, that the specific gravity of the fluid of ascites is to that of hyatids, as 1014 to 1001, and that the fluid of hyatids contains no albumen.

"*Encysted Dropsy*;—the patient, in this case, was tapped, and only a few ounces of fluid drawn off. Some hours afterwards another cyst burst, and seven or eight pints escaped. Four days afterwards symptoms of collapse came on, and the woman died. There were many cysts arising from the peritoneum. The intestines were agglutinated, and the ovaries greatly diseased. The cysts were ascribed to peritonitis.

"*Ascites, with utero-gestation*;—the female

was in the eighth month, and with her eighth child. Fever and delirium came on, and a question arose in consultation, as to the propriety of tapping, or of exciting premature labour. The distressing symptoms had subsided, so that neither had been decided on. It was suggested that tapping was less dangerous before delivery than soon after, and a case of recovery from paracentesis, under such circumstances was referred to. Cases of dropsy disappearing after parturition, were reported.

IV. *Diseases of the Urinary and Genital Organs.*

"*Kidney*;—an instance of a cyst containing five or six quarts of purulent matter, and connected with the left kidney. The structure of the kidney was absorbed, and the ureter was rendered impervious by lymph at its renal extremity. The patient had been tapped under an idea of ascites.

"An instance of strumous ulceration of the right kidney was related; and another in which a quantity of caseous matter was deposited in both kidneys, in connexion with ulceration of the bladder.

"*Diabetes*;—an instance in which the serum of blood drawn from the arm was like fresh milk, containing not only albumen but saccharine matter—showing the constitutional nature of the disease, and its dependance on deteriorated blood. A cataract had formed in both eyes, from deposition of albumen, within the last eight months. A question arose as to the cataracts, whether they were coincident, or dependent on the morbid state of the constitution. The latter opinion preponderated.

"*Bladder*;—retention of urine, an instance of, in a case of concealed pregnancy. The male catheter did not reach the urine. The child's head was ultimately perforated, but the woman died of sloughing of the vagina.

"A case of ulceration of the bladder in a female, æt. 26. The left kidney had become almost absorbed. The urine had been acid and bloody; there had been pain in the loins, and frequent desire of micturition. She died ten days after parturition. It was considered remarkable that, in almost the whole of a considerable number of cases of ulceration of bladder, the left kidney was the one affected.

" **Calculus of the bladder**; an instance of removal by dilating, with rectum bougies, the urethra of a girl, æt. 18. Three weeks' dilatation succeeded, though with much pain. The urine could be retained afterwards. She died eighteen months after, of disease of the kidney. Cases were alluded to in which the urethra had been dilated by mistake, supposing it to be the vagina.

Uterus;—fungus mass at the mouth of. The uterus had become impregnated, and discharges of blood and offensive matter took place. The woman had passed the term of utero-gestation, with entirely broken down powers. Ultimately the membranes were ruptured, and an attempt was made to deliver, but the woman died immediately afterwards. It was urged that premature labour should be induced in such cases, as uterine tumours grow rapidly in the latter months.

" Some cases were mentioned in which tumours of the uterus had become absorbed after delivery; and a question arose as to the process of removal, whether by absorption alone; or by previous softening, as in pulmonary tubercles.

" Case reported in which there had been distressing pressure on the rectum and bladder, yet this distress was removed, and the uterus restored to almost its natural size, by quiescence and the recumbent posture, persevered in during eight months.

" **Abortion and Death of Fœtus in Utero**;—an instance was related in which deaths of the fœtus took place repeatedly in the same female—a lady of spare habit—and was imputed to uterine congestion. On one occasion, and near the completion of the term, the child died, and it, as well as the placenta, was submitted to careful examination. No cause of death could be discovered except the loaded state of vessels.

" A case was mentioned in which the uterine hyperæmia appeared attributable to the lady's anxiety to have a child, and occasioned her repeatedly having still-born children. Tonics till the period of quickening, then venesection and mild mercurials, enabled her to give birth to a living child.

" In another instance, from the immense quantity (between two and three gallons) of liquor amnii, and the shortness of the chord, the child hung in utero, causing great distress to the mother, from the sense of drag-

ging. The child died between the eighth and ninth months. There was considerable ecchymosis at the entrance of the funis into the abdomen.

" **Vagina**;—instance of contraction; in which conception occurred, and a crucial incision was required in parturition.

" **Puerperal Fever**;—circumstances were mentioned as indicating the erratic nature of the inflammation, and as giving an erysipelatous character to the disease. No adhesive matter was formed. It was thought to commence in some local injury, and then to spread itself to other organs, sometimes leaving that in which it originated free from disease.

" **Perineum**;—several instances of injury and operation related. It appeared that they had generally done well, but some cases were reported in which severe effects arose, and proved the necessity for caution even in simple operations.

" **V. Diseases of Blood-vessels.**

" **Aneurism of the Aorta**;—which burst into the right auricle of the heart. Here there had been anasarca, dyspnoea, a livid countenance, and bellows-sound pulsation on the right side of the sternum. Twenty-four hours before death, dyspnoea and other symptoms became exceedingly distressing. There was hypertrophy of the heart with dilatation of the left ventricle, and the ossific deposit on the aorta and its valves. The right auricle adhered to the aorta, and communicated with it by a ruptured opening.

" **Aneurism of the Abdominal Aorta**;—communicating with the vena cava by two openings, having rounded and smooth edges. The man had become anasarcaous, and died suddenly. The lungs were diseased, and there was effusion into both thoracic cavities. Questions arose as to the state of circulation, it being supposed that if much arterial blood passed into the lungs, it would occasion extreme distress of the respiratory function. It did not, however, appear that there had been great distress; and it was suggested that the two columns might balance each other. Had the openings been congenital, it was thought nature would employ all her resources in meeting the exigency. It was

remarked, in the discussion of this interesting case, that sudden death often occurs when aneurisms exist even when no change in them has apparently taken place.

"*Hæmorrhage from mucous tissues under severe accidents* ;—on this was founded the inquiry whether it may be attributed merely to the concussion. Some seamen were in a boat, within two yards of a cannon unexpectedly by them discharged for signal. One of the boat's crew was cast into the water to a distance of ten yards. He was taken out insensible. There was no broken bone, but the head was much swollen, and there was hæmorrhage from the eyes, nose, and ears. Against the opinion of their being the effects of concussion, it was related that an officer had a twenty-four-pound shot pass between his thighs, and tore off part of the coat without his being aware of the occurrence. It also was considered to disprove the assertion that the wind of a cannon-ball is destructive.

"*VI. Diseases and Injuries of Bones.*

"*Fracture of the pelvis and thigh, arm and jaw* ;—in a boy, æt. 17, who fell from a height. He was found in a state of collapse, and discharged urine involuntary. He quite recovered.

"The importance of passing a catheter, in all cases of fractured pelvis, to prevent extravasation of urine, was urged. A question arose as to the state of the brain in injuries producing concussion of the brain and collapse.

"Another case was mentioned. The injury was occasioned by a heavy waggon's passing across the pelvis, chest, and right shoulder. The woman was collapsed and emphysematous. The clavicle, ribs, and ilium, were fractured. Ten weeks afterwards sloughing occurred, and destroyed life. The fractured clavicle and four ribs were found un-united.

"Other cases of fracture of the ilium were mentioned, and it was reported that these injuries usually do well.

"*Fracture of the femur* ;—an instance in a person 108 years of age. The bone united but then the repairing powers failed, and the patient died.

"*Knee joint* ;—cases of extensive injury were mentioned, as showing how much lesion can be sustained if the skin remain entire. The joints were torn open, except the skin

and integuments, and the leg bent on the trochanter—the ligaments, of course, being lacerated: and yet the patients have done well.

"*Sternum* ;—fungoid disease of—the sequel of a case related last year. Not only had part of the bone perished, but there were fungous developments at the ends of the cartilages of the ribs, abscess in the lung, adhesion of the pericardium to the heart, ulcer in the bronchia and hydrothorax.

"Some cases of dislocation of the hip, and some of removal of substances of the knee joint, also occupied the attention of the Society, and brought before it the practice of different public institutions, as well as of private individuals.

"*VII. Materia Medica.*

"*Veratris* ;—some cases in which it failed to give relief, others which it had aggravated, and some in which it had proved beneficial; but the concurrence of testimony was, that its powers had of late been unduly extolled.

"*Colchicum* ;—an extract of the acetate was mentioned as deserving of high commendation; and the powder of the root, in doses of five grains, was reported as an efficient form of the remedy. The addition of quinine had been found available, when either apart had not succeeded.

"*Iodine* was brought under observation as a valuable remedy in secondary syphilis, and in affections of the skin and throat where mercury cannot be used. In one case of two years' standing, the utmost advantage had resulted from one grain of iodine and ten of hydriodate of potash, with sarsa, twice a day, for a month."

—o—

Nouveau Manuel Complet d'Auscultation et de Percussion ; ou Application de l'Acoustique au Diagnostic des Maladies. Par A. Raciborski, D.M.P.

A New Complete Manual of Auscultation and Percussion ; or the Application of Acoustics to the Diagnosis of Diseases. 12mo. pp. 302. Paris. June. 1835.

We have been favoured with an early copy of this very valuable manual, and hasten to lay its contents before our readers.

The author, who is physician at la Charité, and also a professor, was determined to pub-

lish a portable manual of auscultation and to introduce all the improvements made since the time of the great Laennec. He includes all the conclusions of the French and Germans, and Italians, of Dr. Hope, &c.

The author observes:—

“All elementary books, in his opinion, ought to be portable, not only because this form is most commodious, but because a science whose domain is determined, may be reduced to its proper limits.

“In his opinion, also, a manual if intended to be an elementary book, so far from giving a vague or inexact idea of the science of which it treats, ought to give a perfect account of all the facts known on the subject.”

It ought to embrace all the facts, so as to deduce all that are not doubtful, to assign a logical place to each, and to present in the exposition, a filiation of natural ideas, as lucid to the mind as advantageous to the memory.

“Without dismembering the order, we should separate by a judicious analysis, all that is not essential to our object, and the synthesis which we present of all the simplified facts, but not disfigured or mutilated, shews a clear view of each object of analysis.”

It is in works of this kind that we ought to concentrate the same expositions of generalization, and the results of all analysis and details.

The importance of auscultation and percussion is now generally acknowledged. We have no hesitation in avowing that without their aids, we renounce the practice of medicine. There is not a celebrated physician in France who is not familiar with these methods. Other countries, says our author, also recognize the utility of this part of diagnosis.

Auscultation and percussion, already valuable in the hands of Laennec, Avenbrugger, and Corvisart, have become much more advantageous by the labours of MM. Andral, Bouillaud, Louis, Piorry, Reynaud, &c.

“This branch of diagnosis is still further enriched by the discovery of new facts, but these are so dispersed through journals and new works which are not in the possession of every one, and which only benefit a small number. I have thought that a work which would contain all the disquisitions will be useful. If I add some new facts, I hope they will be fairly examined by my

readers. I intend the work for those commencing the study of medicine.”

Our author next gives a concise view of the utility of auscultation and percussion, which is worthy of citation.

“Auscultation and percussion are nothing more than the direct application of the senses to the diagnosis of diseases. These two methods, although distinct, present so many points of contact and analogy in their use and mutual succour, that I have not considered they ought to be treated of isolatedly.

“Auscultation, from the Latin, *auscultatio*, exploration by means of the ear, has for its object, to recognize, by the aid of the ear, the different sounds (*bruits*) which occur during the performance of the functions of the organs of respiration and circulation. Instructed then by the numerous observations based on the general laws of physics, that a bruit observed in an organ coincides with a certain pathological state, we can easily recognise, by aid of auscultation, the seat and nature of affections which modify functional bruits. It is in this way that we know by the results of experience, the *crepitating* râle indicates a pneumonia of the first degree, or an alteration in the pulmonary vesicles, and the *sibilous* râle denotes the existence of a catarrh, or an alteration seated in the bronchiæ.

“Percussion consists in shocks executed principally by means of the fingers on the surface of different regions of the body; it causes them to give different sounds, according to the different nature and state of their organs.

“It is exercised on a greater field than auscultation. This is only applied to regions which produce spontaneous bruits; while the first may be practised on all the surface of the body, but principally upon the parietes of the great cavities of the trunk.

“When we find a dull sound in a region which in a normal state gives a clear one, this abnormal sign indicates that the organ corresponding to the percussed region is seized with a morbid affection.

“It will be easy to recognize to which of the different organs this state belongs, by a knowledge of its respective position; and percussion becomes a valuable means of determining, in a precise manner, the variations,

whether of situation or volume, which organs undergo.

"Thus we know that the part of the hypochondriac region, situated under the borders of the false ribs on the right side, gives on percussion a clear sound in a healthful state. If, then, this part renders a dull sound, an affection is revealed to us.

"If this dull sound is prolonged towards the liver, we say that this organ is hypertrophied.

"If this dulness descends without interruption to the region of the right ovary, we know that it depends on a tumour formed in this last organ*."

If auscultation and percussion had no other result than that of contributing to enlarge our knowledge on the nature of the affections of the respiratory organs, and of shewing these affections in a new and true light, their value would be inappreciable.

In fact, before the perfection of the different modes of percussion, and of the discovery of auscultation, what inaccuracy prevailed in the diagnosis of the respiratory organs!

When intestinal gases were evolved in great quantity and pressed the diaphragm against the lungs, so as to impede them in the performance of their function, dyspnoea resulted, which was ascribed to a lesion of the lungs, under the name of peripneumony and of pleurisy.

At other times an organic lesion of the heart gave rise to dyspnoea; and there was no hesitation in attributing this affection to some disease in the lungs, or of their nerves.

Again, when dyspnoea and sanguinolent sputa were the principal characters of pneumonia, the true affections of the lungs were unknown, and ascribed to morbid states that did not exist.

Thus, in inflammation of the lungs in aged persons, unaccompanied by expectoration, but only with prostration of the vital powers, common to all the serious diseases that afflict them, it was supposed that an adynamic fever existed when these persons were affected with pneumonia. Such was the state

of medicine about the end of the last century, and even at the commencement of the present. Thus, what Stoll described under the name of peripneumony or bilious pleurisy, was nothing, as Pinel has since remarked with reason, but a gastric derangement complicated with bronchitis, and we can find even in the clinic of Pinel himself, many cases of adynamic fevers, which to us, were true inflammations of the lungs.

The prognosis could not be better established than the diagnosis, the defect in the positive indications on the nature of the disease, though they observed all the changes in its progress, the pulse, urine, alvine evacuations, with a view of prognosticating the termination; the ulterior signs so incomplete, so variable, and so inconstant, could not supply a correct diagnosis, and could not free the prognosis from incalculable effects of inexactitude and error. As our art possesses at present the means of positive diagnosis, and which accords with the determined sciences, the prognosis reposes essentially on the diagnosis, of which it is only the interpretation. When this is once established, nothing is more easy than to prognosticate the intensity of the affection, and the importance of the affected organs.

Thus, to give an example of the simplicity of prognosis as regards the respiratory organs, from two patients, the one affected with the first degree of a slight pneumonia, and the other with an entire lung hepatized, the latter is a much more dangerous disease than the former.

Behold a simple prognosis, and one evident to every body, or the interpretation of a correct diagnosis. Thus auscultation and percussion are equally valuable to diagnosis and prognosis.

The same difficulties and errors which we have mentioned in the diagnosis and prognosis of diseases of the lungs, are necessarily encountered in their treatment, and thence the most frightful and irreparable consequences—the imminent danger of abscesses and inefficient treatment.

In the pneumonias, mistaken for adynamic fevers, we commence by exhibiting stimulants to the patients (camphor, serpentaria, acetate of ammonia, &c.); stimulants, which in place of removing the intensity of diseases,

* Other tumours may exist in this region, which are not ovarian.

only hasten death, whilst a bleeding, acting against the morbid state, would diminish its powers.

On the other hand, the absence of positive signs to establish the indications of treatment, the progress of disease, or its amelioration; signs which cannot differ from those which have been necessary, and which have been wanting for the diagnosis. The ulterior absence of positive signs, complicates, in an extraordinary degree, the difficulties of treatment; it does not even leave to the practitioner the resource of the expectant method, whilst auscultation and percussion come to our aid, whether to change an injudicious treatment, or adopt a judicious one.

How often do we see patients who seem to have no chest affection, scarcely any cough or expectoration, who are nevertheless affected with serious disease. If such patients are allowed even ordinary diet, or commit any excess, the morbid condition is increased, and instead of being extinguished, becomes chronic, and is not arrested but by the tomb.

We have seen more than once, in the practice of M. Bouillaud, at la Charité, patients affected by pneumonia, who were bled and supposed to be cured; but who began to spit blood, and were again seized with cough, and difficulty of respiration.

Such is the cause of phthisis in most cases, which is the result of chronic inflammation of the lungs or bronchiæ, badly treated or imperfectly cured, for want of the use of auscultation and percussion. These expose the slightest traces of the pathological condition, and direct the practitioner to combat the disease with the same means which he employed at the moment of its invasion.

Let us now examine the results of these discoveries, relative to the diseases of the heart. It is to percussion and auscultation, united to the researches of modern anatomopathologists, is to be ascribed the analysis of the different affections formerly comprised under the general name of asthma. At present we distinguish in asthma, sometimes lesions of the heart, sometimes of the pericardium, sometimes of the pleura, and sometimes of the lung. It is by these two methods that M. Bouillaud has recognised different lesions in the centre of the circulation, which were

called, at other times, passive and active aneurisms (Corvisart).

These advances are not illusory; they do not at all augment the number of diseases of the human race, but they very much influence their treatment. It is not correct to suppose that it is of little consequence to distinguish the different diseases of the heart, or that all are to be treated alike. In fact there are some which require instead of depletions, the use of iron and quinine.

It is by auscultation that M. Bouillaud has discovered a particular sound, named by him *bruit de diable*, and previously observed in many arteries by Laennec, and which constantly exists in the carotids of chlorotics.

This sign accompanies chlorosis and anemia, and is valuable in medical practice.

Do not the abdominal complaints also find in percussion a valuable mode of exploration?

How often have pains in the epigastrium been mistaken for the signs of gastritis, until percussion discovered the seat in the left lobe of the liver?

How often have effusions into the right side of the chest been mistaken for hypertrophies of the liver, until explained by percussion?

In fine, one of the happiest applications of this last method of diagnosis, is that which is made in pregnancy. We know that the movements of the foetus, regarded as the most certain sign of pregnancy, may sometimes be wanting; and that at other times hysterical women have supposed they felt such when they were not pregnant. Auscultation enables us to detect two sounds, the beatings of the foetal heart, and of the placenta, so that we cannot fall into error.

Surgery has also derived advantages from auscultation. We hear much better the crepitation of fractures, by placing the ear near the injured limb, than at a distance.

In the same way, by placing the ear over the hypogastrium, we more distinctly ascertain the presence of stone in the bladder, than by the shock given to the sound.

We cannot conclude these general remarks without observing, that the physician, surgeon, and general practitioner, has gained much by the introduction of auscultation and percussion.

A Formulary for the Preparation and Medical Administration of Certain New Remedies, translated from the French of M. Magendie, with Annotations and Additional Articles. By J. M. Gully, M.D.

THIS Formulary has become a species of supplemental codex to the French, and Pharmacopœia to the English medical world. The translator appears to view it in the latter light when he says in the preface that "in beholding the parliamentary pace of our British Pharmacopœias in the official recognition and adoption of the numerous and active remedies which the chemists of France are continually sending forth, and her physicians assiduously making application of in disease, he sees every reason why such a publication as the present should be necessary to, and approved of by, the laudably curious and inquiring medical man." To this sentiment we entirely subscribe, and therefore cordially thank Dr. Gully for undertaking to reduce this, the eighth French edition, into English.

The present differs from the former editions in containing more modern and accurate chemical analyses of the substances treated of, additional data accumulated by the author since 1830, and in the announcement of several new remedies the medical application of which, dates since that period. Among the latter we notice Narceine and Meconine, Codeine, Labadilline, Veratrin, Hydrocyanic ether, the Iodurets of barium and arsenic, Bromine, Chlorine, Mannite, Salicine, Lactic acid, and the Volatile oil of the black mustard-seed. On these individually we do not pretend to dwell, but we recommend the perusal of their properties and modes of application to all practical men. Codeine more particularly appears to have been a most valuable remedy in M. Magendie's hands; and from his remarks on the volatile oil of black-mustard seed, we should imagine it invaluable in cases where a rapid counter-irritation was desired, in cramp, and gouty stomach, for instance.

Under the head of Additional Articles, the translator has given the chemical and medicinal histories of Creosote, introduced by M. Reichenbach de Blansko, and of the Ioduret and Hydriodate of iron, recommended by Pierquin and Andral, in France, and Dr. A. T. Thom-

son, in Britain. These articles are rendered exceedingly interesting—that on Creosote particularly—by Dr. Gully. Nor are the annotations appended to many of the articles of the original text, without point and practical utility.

In short, we consider the introduction of this Formulary a happy and even necessary proceeding, and looking to the entire absence of any work that includes the preparation, effects, and applications of the powerful remedies therein treated of, we hold it as certain, that the English medical world in general will appreciate and patronize it accordingly.

*The London Medical
AND
Surgical Journal.*

Saturday, June 6th, 1835.

CONTINENTAL OPINIONS ON THE STATE
OF SURGICAL SCIENCE IN OUR HOSPITALS.

It is commonly asserted by those who have the surgical care of our hospitals, that the strictures on the manner in which they perform their office, and of their capabilities of doing it at all, are ever the result either of personal dislike, splenetic envy, or an uncontrollable propensity to deviate from the truth. Now, however easy it may be for *us* and others to find fault, it is much easier for *them* to make such assertions—ininitely easier than to combat our accusations, by advancing contrary instances. A pickpocket, though detected in the very enactment of his calling, drops his prey, gives his accuser the lie, and defies him to prove that his hand was ever in his pocket; "if your handkerchief dropped on the ground," quoth he, "it is no fault of mine; you are likely enough to fix on the man nearest to you." For the outrage on common honesty in this instance, substitute that on common sense in the instance of our hospital surgeons, and the relative positions of those who

think as we do, and of the worthies in question, may be understood. Say the latter to us, "Somebody outrages your common sense as regards the conduct of the surgical practice of the hospitals, and you turn round upon us, because we happen to be the nearest on whom you can vent your ire; it is more probable that you tell a lie, than that we are deficient in capabilities—more probable that you had no common sense than that we outrage it."

Suppose we were willing to allow the validity of, this pickpocket defence; suppose we allow ourselves to be only of frail flesh, and they of infallible essence, and that mere spleen, and a longing for all that makes office dear, *does* actuate us in advancing our accusations—what then should actuate an individual to the very same proceeding, who can by possibility have no hope, can entertain no expectation—be things as they are continued, or be they changed—of ever moving one step towards the eminence from which these infallible essences "look down upon us little men?" Surely, one would say, *he* has seen, and has good proof of what he advances: grown men are seldom mischievous for mischief's sake: if not interest, truth must be their motive for making and using rods. Such an individual we beg to introduce to the notice of our readers, in M. Baumes of Lyons, himself the *chirurgien en chef* of one of the hospitals of that city, and not likely, therefore, to cast any sheep's eyes at those of our city. In an article in the *Gazette Medicale*, of the 16th of May, he commences what he terms a "coup d'œil sur les hopitaux de Londres:" and in the number of the same journal for the 23rd, he continues the same subject, with more particular reference, however, to the literary merits of our hospital surgeons; to this portion of the remarks we shall not at present advert, but we call attention to the opinion expressed regarding the practical powers displayed in the hospital

surgery of the metropolis. After recalling the tableau made by M. Roux twenty years ago of the state of surgical science in England, a picture drawn from nature—for our naturals and flats were unconsciously sitting for it.—M. Baumes proceeds to say: "If we seek to learn the mode of proceeding at the present time in the London hospitals, and compare the results with those traced in M. Roux's account, it will be easily observed that the art, as regards operations, has undergone scarcely any change; that it has in no way been enriched by the addition of the discoveries made in other countries; and that as regards the internal, the non-medical treatment of surgical diseases, not one step has been taken out of the apparently immutable track of English therapeutics." The writer then particularises, by quoting from Sir. A. Cooper's lectures, edition 1835, the modes therein laid down for combatting irritation, which includes "mercury to act on the liver, saline purgatives to act on the intestines, and antimonials to act on the skin," as also for the calming of the irritation of the nervous system, "opium and antimony, or rather opium, antimony, and calomel, to act at once on the skin, the liver, and nervous system." Of course this sort of treatment puts out of sight the possibility of any one point being the starting place of irritation to others.

But M. Baumes adds, that "he has seen different kinds of articular tumours, white swelling for instance, increase and aggravated with rapidity, ultimately rendering an operation necessary, when a rational treatment might have superseded it." . . . "Thus any one who has observed their practice for a given time, may readily remark that amputation is frequently had recourse to, in cases that in France, and other countries, would assuredly be cured by following the more rational means of pathological physiology."

Again, to shew how "the operation"

is alway uppermost in the mind of your conceited hospital surgeon, how much rather he makes a case an opportunity for the display of his operative powers, than of his conservative capabilities, it is only necessary to say that when M. Baumes observed the ill-placed treatments of these articular inflammations to several of those who treated them, the answer he got was that "if they put off the operation too long a time, that is if strong febrile symptoms supervened, the operation did not succeed;" whereas the very fever they feared themselves, originated with their calomel, their iron, antimony, and similar irritants ordered at a risk during one of their flying visits. "I have seen," says the writer in another place, "in several hospitals, patients affected with articular tumours, with caries of the bone, fistula, abscess &c. to whom amputation was proposed; and in the meantime, under pretext that a great degree of debility existed, wine, tonics and various cordials were freely administered, although it was at the same time evident that there was extreme irritation of the gastric organs, in great part consequent on the evacuant, aperient, mercurial and other treatment that had been employed for the purpose of getting rid of a complaint which they had thereby increased."

Here there are some nuts for our pure surgeons to crack; the writer does not get his information second-hand: what he relates he has witnessed "in the practice of the first surgeons in London"—*first surgeons!!*

Mr. Lawrence he mentions as an honourable exception to the general rule of ignorance and darkness in the progress of surgical science. "I can affirm," he says, "that I have seen him arrest a violent peritonitis, consequent on the operation for strangulated hernia in as short time as any French surgeon that has been accustomed to the rational therapeutical treatment of such affections, and this by his vigorous

antiphlogistic remedies. *Had the patient been in any other hospital, I do not think he would have escaped death.*"

In our next we shall give the same writer's remarks on the literary merits of our hospital surgeons; meantime we wish them all joy of his estimate of their therapeutical acumen and *operative* alacrity.

ON THE DISEASES OF THE GENITO-URINARY ORGANS.

THE diseases of the urethra are not only formidable in themselves, but they induce others which are most destructive to human life. Although the medical sciences have recently made the most rapid advances in this country, there is not as yet a complete treatise in our language on the diseases of the genito-urinary system. Many instructive works and essays have been published on some of these diseases, but no British author with whose work I am acquainted, has described the whole of them.

It is my object to give a full account of urinary and genito-diseases, and to commence with those of the urethra, as these are most commonly met with; and the whole urinary system comprehends disorganizations which are the prolific causes not only of the numerous diseases of the genito-urinary organs, but of many of the most fatal of the cerebro-spinal, circulatory, respiratory, digestive, and muscular systems. It would, however, be utterly impossible in an essay of this kind, to describe the numerous diseases in the different organs, to which urethral disorganization gives origin; and I shall therefore confine my descriptions to those that strictly belong to the urinary apparatus alone.

As great diversity of opinion exists with respect to the removal of urethral diseases, it appears to me that a concise description of the anatomy and pathology of the urethra should precede that of the treatment. I shall therefore adopt the following arrangement in this essay; 1st. The anatomy of the urethra; 2d. The pathology; and 3rd. the treatment of its diseases.

Anatomy of the Urethra.—The urethra is the excretory canal of the urine in both sexes; of the prostatic fluid and semen in man.

In man it extends from the neck of the bladder to the extremity of the virile member, passing above the inferior extremity of the rectum, under the symphysis pubis, behind the corpora cavernosa, and glans penis.

In the male subject the direction of the urethra is compared to that of the letter S, when the penis is relaxed, or when the rectum and bladder are filled with air. Br

M. Ammussat has clearly demonstrated that when the penis is elevated on the abdomen, there is but one curve, which almost entirely disappears on expelling the air, and that if there, the organ is carried before and upwards, that is to say, in an intermediate position to the two preceding, the canal becomes straight or almost so, directed obliquely from before backwards, and from above downwards. The facility with which straight lithotritic instruments are introduced into the bladder, confirms the truth of the statement that the urethra is nearly straight. The length of the urethra has been variously estimated by different writers. Whately, after a careful examination of forty-eight subjects states, that the length varies from $7\frac{1}{2}$ to $9\frac{1}{2}$ inches; Lisfranc from 9 to 10, and in one case of a negro 11; but it is usually estimated from 9 to 12 inches in European subjects, and still higher in negroes. Its diameter also varies in different parts, being about four lines wide in the greater part of its extent, and from two and a half to three at its orifice. Such is the estimate of Sir Everard Home, which is held to be too small by Lisfranc, and too great by Phillips; but the experiments hitherto made are too few in number to determine the point.

The average length of the urethra is about 9 inches, the prostatic portion occupying $\frac{1}{4}$ of an inch, the membranous, about $1\frac{1}{4}$ inch, the remaining spongy portion about 7 inches.

There are usually three dilatations of the urethra, one at the prostatic portion, another at the bulb, and a third behind the fossa navicularis; and there are generally three contractors, one at the orifice, which is about 1-5th of an inch in diameter, another at the membranous portion, about 1-4th of an inch, and a third outside the bladder at its orifice.

Anatomists divide the urethra into three portions, the prostatic, the membranous, and the spongy; some add a fourth, the bulbous; but this is generally considered a part of the spongy.

The portion which is continuous with the neck of the bladder, is the prostatic.

The space between the margin of the prostate and the bulb, is the membranous, and the remaining portion to the glans penis is the spongy. The bulbous portion is included in this division:—

1st. The prostatic portion (*pars prostatica*) is so called from its being surrounded by the prostate gland; it has the form of a cone, the base of which is turned backwards, the apex forwards; its length has been variously estimated. Bayer considers it from 15 to 18 lines; Ducamp from 12 to 15; Lisfranc from 8 to 11; but the general opinion is, that it is from 12 to 15 lines in length. It is larger in the middle than at its extremities, its parietes are thin, except when in connexion with the prostate, where they are thick and solid.

This portion of the urethra is surrounded by the prostate in its inferior three-fourths; the superior fourth being close to the arch of the pubis, and is frequently enveloped by muscular fibres. This part of the canal may be entirely surrounded by the prostate, when that organ is diseased. It is situated before the interior extremity of the rectum, about an inch from the anus in the adult, above and behind the small curve of the rectum, to which it is intimately united by cellular tissue, traversed by many blood-vessels and by the recto-vesical aponeurosis, which also connect it with the *vesiculæ seminales*. Above and upon the sides it is situated behind the arch of the pubis under the surface of the triangular ligament of the symphysis. It is attached to the ami of the pubis by the anterior ligaments of the bladder, which are the internal portion of the attachment of the recto-vesical aponeuroses. Above this portion of the urethra there are large veins and loose cellular tissue interposed between the bladder and nymphysis, and in this situation the oblique direction of the bladder forming a triangular space, circumscribed inferiorly by the prostate, anteriorly by the nymphysis, and posteriorly by the bladder. The prostate portion anteriorly, and on its sides is round, and it is united inferiorly to the *vesiculæ seminales* by an aponeurotic band. It is thin and insensibly confounded anteriorly with the commencement of the membranous portion. On the sides it is connected with a portion of the levator ani muscles. A great number of varicose veins surround it more, especially between the bladder and rectum; in old persons M. Ammussat has discovered that it is liable to numerous changes of position, in consequence of the length of the fibrous attachments and the mobility of the anterior part of the rectum with which it is connected, the direction will therefore be modified according to the fulness or emptiness of the rectum. When the intestine is empty it is directed obliquely from below upwards, and from behind forwards; when it is full, the direction is the reverse. In the middle of the floor or inferior surface of this urethra a narrow ridge projects from seven to nine lines in length, formed by an elevation of the lining membrane and subjacent cellular tissues, extending from the neck of the bladder where it is largest almost to the extremity of the prostate where it is pointed; and this is denominated by anatomists, the *caput gallinæ* or *verumontanum*. In the middle of its anterior part is an oblong narrow depression, designated the *sinus pocularis*, within the margins of which, the orifices of the two seminal ducts (*ducti ejaculatores*) are situated, one being on each side. On the outer side of this ridge there is a depression called the *sinus prostaticus* which is pierced by eight or ten excretory canals of the prostate, through which a viscid fluid exudes on compression. There also occasionally exist

two culs de sac on the verumontanum, which arrests the progress of instruments. Lisfranc has found a depression between the two lobes of the prostate, the antero-posterior diameter of which is two lines, the transverse 1 line, and the depth $1\frac{1}{2}$ line. This depression is rare, and is generally discovered at the right side of the verumontanum when this is deformed and inclined to the left. A catheter or sound may readily pass into these cavities, and we should bear them in recollection. Posterior to the verumontanum is a transverse projection which establishes the line of demarcation between the bladder and urethra, and these two elevations unite at a right angle, dividing the commencement of the canal on its under surface into two lateral depressions, in which instruments are more frequently arrested than in the lacunæ on the verumontanum. The superior surface of this part of the urethra is uniform, and offers no obstruction except at the point where it corresponds to the triangular ligament.

2nd. The membranous portion (*pars membranosa*) extends from the margin of the prostate to the bulb; its length is differently stated, by Boyer at 12 lines; by Ducamp at 9 or 10; by Lisfranc from 7 to 11; and by Quain from 10 to 12. It is composed of the proper membranes of the urethra only, its extent superiorly being about an inch, and inferiorly about 4 or 5 long; it is the narrowest part of the canal, and is covered by fibres from the deep perineal fascia, which is continued backwards around it and the prostate, and is supported by the terminal expansion of Wilson's muscles. It is of a cylindrical form, is situated precisely under the nymphysis pubis, and at the junction of the corpora cavernosa. Its muscle is named that of Wilson, which attaches it to the anterior ligament of the bladder, and to a dense cellular substance, as well as the triangular ligament of the nymphysis, at the space of the corpora cavernosa. Its connexion with these parts is closer when the virile member is raised towards the abdomen; it is in immediate connexion, inferiorly, with Cowper's glands and the acceleratores urinæ, laterally with its muscles, and with vessels and nerves which it derives from the corpora cavernosa, and superior to it is the triangular ligament of the urethræ. It is oblique from behind forwards, and from below upwards, similar to the urethra of the female, which it resembles in length, form, and direction: it changes its course according to the condition of the rectum and penis. It is much stronger than is generally supposed, as the muscle of Wilson surrounds and strengthens it, serves to elevate and compress it, contains a great number of vessels between its fibres, and presents itself before Cowper's glands: under this muscle the urethra possesses the same organization as the bladder; its fibres are longitudinal and circular, and

these are intermixed with each other. It would, in fact, be more correct to call it the muscular than the membranous portion, as this last term conveys false ideas, considering its force and resistance. It is sometimes pierced by the beak of the sound or catheter. It is this portion of the urethra that is incised on the operation for lithotomy, and in that for retention of urine through the perinæum. In the membranous portion, in its course from the prostate to the bulb, there is a curve, the convexity of which is towards the pubis. This curve frequently prevents the passage of an instrument towards the bladder, but the difficulty will be overcome by the surgeon elevating the penis to an angle of 45° , at the same time drawing it forwards, or by passing a finger into the rectum, and directing the instrument into the bladder. At the anterior extremity of this portion is the bulb, or commencement of the spongy portion.

The bulb is very distinct posteriorly, where it projects under the canal, but it offers no line of demarcation, and anteriorly is insensibly continuous with the spongy portion of which it forms a part. It is situated in front of the inferior extremity of the rectum, to which it is attached by dense cellular tissue; and, above all, by the sphincter ani. It is situated above the acceleratores urinæ, so that it can be felt across the perinæum by the finger. It corresponds superiorly to Cowper's glands, and to the termination of the membranous portion; still higher are the triangular ligament of the nymphysis, and the junction of the corpora cavernosa on its sides; it is immediately enveloped by the acceleratores urinæ, and by the roots of the corpora cavernosa; on its superior part there is a groove which receives the urethra, properly so called; this groove is continued anteriorly, with a canal formed by a spongy tissue, which envelopes the mucous membrane; posteriorly it presents at its origin a cul de sac, circumscribed by a band formed by a fold of the fibrous membrane which surrounds the spongy tissue.

3. The spongy portion (*pars spongiosa*) is more anterior and more extended, commences at the bulb without a line of demarcation, and terminates at the glans penis. The urethra frequently enlarges after the commencement of the bulb, especially on its inferior surface, and forms a sinus, supposed to be a reservoir for the semen and urine, which obliges the surgeon, in passing a catheter, to raise its point so as to ensure the sweep of it into the bladder. The length of the membranous portion is estimated by some at six or seven inches, by others at eight or ten. This part of the urethra is uniform in size, being intermediate in diameter, between the membranous and bulbous portion; but it dilates in the glands, forming a cavity called the fossa navicularis, and then narrows at the orifice of the urethra. The spongy portion is embraced by

the corpora cavernosa, which present a groove for its reception, and with these it is firmly united by a very dense cellular tissue and by blood-vessels. It is covered inferiorly and almost posteriorly by the acceleratores urinæ, and anteriorly by the skin alone. It presents in its middle a sort of induration when the penis is in a state of flaccidity.

(To be continued).

Hospital Reports.

—

NORTH LONDON HOSPITAL.

Quartan Fever with Scabies—Large doses of Quinine.

FRANCIS HAYES, labourer, aged 39, was admitted March 6th, under the care of Dr. Elliotson. Five months ago he was working for six or seven weeks in wet and marshy land near Rye, in Sussex, and at the end of that period was taken with all the symptoms of ague. At the first or second fit, he took a pint of pure brandy for the purpose of "bringing up the ague cake." Instead of this being attended with benefit, it very much increased the subsequent hot stage, and produced great head-ache and delirium. He afterwards took three pints of decoction of oak bark between the fits, daily. It was attended with no perceptible effect. On the advice of a friend he now got drunk when the fit came on, with ale. This also seemed as little effective as the oak bark, but did not increase the hot stage. He worked five or six days after the disease began, but did not see a medical man for about a month. When he did apply for relief, twelve small pills were given him; they were bitter, but did him no good. This was the last medicine he took. His symptoms on admission were, no pain in chest or abdomen, pulse 78, soft and weak; respiration natural except during the fit; bowels open. He has an eruption, which appeared eight days since, over the whole surface but the face.

Sulph. Quinine, gr. x; hora unamante paroxysm, sumendæ et rept. 8vo. hor.

It is worthy of remark that the paroxysm commenced at eight A.M. not as it usually does in the after part of the day.

7th. Paroxysm came on half an hour earlier, less severe than usual, lasting about an hour.

Mag. Sulphuris, ʒj; fricand per horam unam bis die.

10th. Paroxysm returned this morning, the cold stage was unattended with rigors. Slight pain in epigastrium, attributed to quinine. Cupped to ʒvj., in the region affected.

11th. Pain in epigastrium gone, eruption disappearing.

13th. Paroxysm very slight, cold stage

lasting only half an hour. The eruption to-day very irritable, and more defined on the chest.

22d. On the expected day no return of the paroxysm.

24th. Distressing head-ache, pain in epigastrium. Omit quinine.

27th. Head-ache gone, fluttering coldness in extremities and abdomen.

April 1st. Coldness gone, eruption dying away.

7th. Discharged, cured of both diseases.

Dr. Elliotson remarked of this case, that it is worthy of being remembered, as illustrating the fact of two specific diseases going on in the system, at one time, with the application of two specific remedies. The large doses of quinine were attended with no ill consequences, except on one or two occasions a pain in the epigastrium, which was removed by the abstraction of a small quantity of blood; had he discontinued the quinine it is probable the disease would have been protracted. He thought in severe cases like the present, large doses of quinine should be used; it was erroneous to suppose that you could always fix the dose of any medicine.

—o—

PARISIAN ANATOMICAL SOCIETY.

Encystment of the Liver.—One of the most curious alterations exhibited, is the conversion of the organ into a compact yellow mass more than thrice the ordinary volume of the liver, and throughout the substance of which, non-encysted points of a tissue that is evidently erectile were found. The encysted condition of the liver, either partial or general, is one of the most frequent changes that have been exhibited to the Society, and opportunities have presented of observing it in all its shades, from granular encystment in which each grain appears to have its own cyst, to the lobular encystment, or subdivision of the liver by fibrous bands which isolate variously sized lobules and give the whole organ the embossed appearance so usual in scirrhus. In one case you may have remarked the great thickness of the fibrous lamellæ that thus formed the partition of the hepatic tissue. You have also seen the general encystment of the organ in a case of ascites, in which the liver turned upon itself and, enveloped in very thick false membranes, seems to have been condensed by some powerful pressure. In all the cases of encystment, partial or general, you could not fail to remark the general or partial atrophy of the organ, as well as the alteration of the tissue.

To what is this singular tendency of the liver to encystment to be attributed? Is it owing to its anatomical texture or to the specific nature of its diseases? The fibrous septa are the result either of some new production or the consequence of an atrophy of

the glandular grains, or lobules, whose disappearance would allow the fibrous lamellæ, previously separate, to join each other; or lastly, they may be a consequence of the presence of the specific membrane, to which the name of Glisson's capsule is applied.

A rare and curious alteration of the liver was presented by M. Cezalia. It had a compactness, colour, and fracture, resembling those of yellow wax.

M. Stenski exhibited a scirrhus of the liver, with dilatation of the vena portæ.—*Archives Generales, April.*

—o—

VIREY ON THE GENERATION OF PLANTS AND ANIMALS.

(Continued from p. 239).

Alterations in the Reproductive Functions—Of Monstrosities, and Mixtures of Races.

EVERY one knows how much parents influence the product of generation. The vital power, for example, the duration of life, the temperament, form, degenerescences, and numerous other diseases, are hereditary. These are the vicious contrarieties of the power of life. The Jews and Mussulmans are circumcised for ages; but their progeny are born with a prepuce. Frogs and salamanders engender tadpoles with projections which they do not possess. The diseases which are transmitted by generation are the constitutional affections of the body, and not local diseases; a deaf, blind, hump-backed, or deformed individual rarely communicates his infirmity to his descendants; but epileptics, hypochondriacs, the gouty or calculous (those labouring under gravel or stone) perpetuate their diseases to their families. It is also the same as to the strong or feeble constitution of parents. Animals born of aged parents are feeble and languid, because they received a life enfeebled and exhausted. We rarely observe these facts in vegetables. There is also a resemblance between infants and parents, in their temperaments and hereditary characters, but these resemblances are most marked in proportion as love and the vigour of the generative power have been more considerable; and as the inferior animals follow nature better than men, their productions are more like themselves than infants are their parents. In fact, man and woman do not

copulate, too frequently, without exciting nature, and abusing their powers; they too frequently think of satisfying their desires than of producing sound and robust infants, so that the object of nature is neglected for pleasure. It is not, then, astonishing that they often form vicious and disfigured productions; besides, the irregularities of life, the passions, effeminacy, feebleness, diseases of pregnancy, have great influence on the offspring. Domestic animals, which enjoy a kind of life so opposed to the natural state, are equally subject to irregularities in generation. Monsters or monstrosities are more common, for this reason, in the human species and in domestic animals, than among the species which live according to the laws of nature. The weakness of the seeds, the effects of the abuse of amorous pleasures, cause imperfect infants, false germs, as moles or false conceptions, which are irregular fleshy masses, ordinarily containing the rudiments of the organs and limbs, which remain in the womb for a long time and harden. In fact, nature cannot engender more than imperfect infants, on account of want of time sufficient for the elaboration of the seeds; she endeavours, nevertheless, to perfect them, to give them life, and employs a longer time than in ordinary pregnancies, for moles have continued during the whole life of the woman who conceived them. Females who have borne moles or monstrosities sometimes preserve the power to reproduce them, by a habitude which their organs have contracted. Individuals who fear dishonour, which does not always defend them from seduction, produce moles; or, when chagrin and the secret desire to abort enfeeble the effect of impregnation.

There are many kinds of monsters where the organs are in excess, as infants with two heads, four arms, &c., or where the organs

the act of reproduction, and some are indifferent to the result, or have their minds occupied with other individuals, or other matters. It cannot be expected, under such circumstances, that there will be a marked parental resemblance. A friend of mine assured me, that, during coition, having fixed his imagination on a lady whom he once loved, that his child was a female, and remarkably like the individual on whom his imagination was fixed.—Ed.

* Few, perhaps, are entirely absorbed in

are defective, as infants without legs, arms, &c., or where there is a transposition of organs, or by alterations of forms. When two embryos are developed at the same time in the womb, they may grow together or be partially or wholly united; they may be, moreover, less imperfect; and the same thing is observed in eggs containing two yolks which produce chickens with double feet, &c.; and the same is seen in vegetables and animals which have several young ones, and these are more liable to have monsters than those that bring forth but one little one.

M. Virey is of opinion that tight lacing and strong passions contribute to the deformities of infants. Peasants who are robust generally engender well-formed infants, because they follow nature more closely than the delicate women of large cities. In proportion as we deviate from nature, we obtain products less natural and more deformed.

In the ages of superstition, the birth of a monstrous infant was considered a proof of sexual connexion with an evil spirit, or a sign of celestial vengeance, and the burning of the mother could alone expiate so great a crime in the eyes of the people.

It is from the venereal harmony and voluntary intercourse of the sexes that a good conformation of individuals results; for these enjoyments denied by the heart, these pleasures influenced by fear or violence, are sterile, or do not produce but deformed beings who bear the imprint of the hatred and discord of those who engendered them. Such are sometimes the adulterous mixtures of different species of animals, because such unions are not commanded by nature. The resemblance of infants to their parents equally depends on the concordance of the seeds and on the activity of their parts, which preserve their original type; but the defect of the energy of the seeds produces degenerate individuals, and these scarcely preserve any traits of their parents. Thus it is that domestic animals have less vigour than their savage species; they engender varieties, as we often see dogs, birds, &c., which races differ from the originals, both in colour, proportion, stature, and also most partial monstrosities. Animals which bring several young ones at one birth have great

varieties, while the uniparous, or those that have one at a birth, has it more perfect, as the elephant, mare, &c., whose offspring is seldom monstrous; but the multiparous species, as bitches, cats, &c., give birth to many varieties, which is caused by nature having to form many instead of one individual, and therefore she can give less perfection to many than to one.

When there are two or more infants in the uterus, they are less developed than when there is but one; when three or four in number they compress each other, so as to cause deformities. Women who bring forth monstrosities are less sound and vigorous than those who have well-formed infants.

We may refer to a similar disparity of action on deformed productions born of seeds unequal in vigour; for the sperm of those who are in the flower of youth is very different from that of old persons. When two individuals of different ages copulate, there is scarcely any harmony of love, and it is on this account that conception either does not happen, or they engender imperfect infants or monstrosities. The seeds which are best fitted for perfect generation are those of the same ages, and those who aspire more to be united; for the sperm of an old man renders old a young female organ, in the same manner that a young man fades with an aged woman; so that Love never retrogrades, and he wishes to unite to a young in preference to an aged woman.

In crossing the breeds of animals we obtain individuals much more robust, we improve the species, and augment the number of males; which always indicates a much greater vigour in the generative power. Among dioic plants, such as hemp, male individuals are, in general, less numerous than females, as we have already remarked.

The sexes engender the different sexes according to the inequality of power in their seeds; for when the male seed dominates it engenders male individuals; and females are engendered by an excess of power in the female seed, or in the germ, or the egg (ovum) in the ovary, which produces it. When the seeds are equal in vigour, one could not surmount the other, according to Empedocles, and individuals of both sexes, androgynes or hermaphrodites, which are incapable of engendering, result.

The sexual organs of animals and plants contain in their ovaries the germs of the new beings, but these cannot be vivified or developed before the males communicate a part of themselves, whilst the females furnish a portion also. The womb and the ovary of every animal and plant is endowed with a special vitality, especially at the epoch of generation; it has a separate existence—its desires, wants, appetites; it is an individual within an individual; it influences and governs the whole of the living being. The womb and its dependences, in the female, are, as Plato said, a species of living animal, which has its caprices, its affections, its pleasures, which governs the whole body, which extends its influence over all parts, so that it may be considered the root of the female—her original vital trunk. When the womb is impregnated by the male it influences every part of the body; the flesh is impregnated, which is easily discovered in the goat, the sheep, the heifer, &c., whose flesh has an unpleasant and peculiar flavour at the time of fecundation. So, also, has the flesh of the male at the season of reproduction. The odour of flowers correspond to that of the genital organs of animals during the rutting season. The nausea and the vomitings, changes of colour, and spots on the skin, which we remark in most women who have conceived, have no other cause than this action of the sperm on the whole animal economy, independently [of that which it exerts on the womb and ovaries.

All parts of the body concur in the act of fecundation—the shock is universal; life seems to be arrested in all the senses, and in all parts of the body to concur in the excretion or ejaculation of the sperm; and it is the same in woman—it is the climax of feeling.

The sexual organs have also intimate relations or nervous sympathies with the exterior of the body, with the skin, the hair, the feathers, the scales, and, in general, with the beauty of all beings.

Love depends very much on the vigour of health, on strength and courage, because the object of Nature is the perfect development of the species, and the perfect conformation of individuals. "She enforces against us," says J. J. Rousseau, "a law

like the the Spartan, which consigned to death the feeble and the delicate, and takes the greatest care of robust individuals."

The end or object of love is not pleasure only, as is generally supposed, but generation; for pleasure is not complete but when fecundation is effected, and then love ceases. Nature, therefore, has not pleasure alone in view, but the multiplication of the species. The presence of a pregnant woman does not excite the same affection in the heart of man as the aspect of a young damsel. This individual inspires love, that respect; thus Nature, superior to all human conventions, has ordained it. In love, kings are as other men; they have no more pleasure than shepherds, and Nature has equally divided all her gifts.

8.—*Comparative Power of the Generative Faculty in Plants and Animals.*

The generative power, that wonderful attribute of organized beings, is differently developed in vegetables and animals. In all the families of the agamous plants, or those in which the sex is unknown, as the truffles, algae, &c., as well as in the radiary animals, polypi, hydres, meduses, actinies, holothuries, &c., reproduction is effected by a simple division of the individual, which forms complete individuals, or by shoots, or by expansions of the procreative being when it has a superabundance of nutrition and life. Many of the most perfect plants, in which the sex is very apparent, as all the *aphanerogamous*, are capable of multiplying themselves by grain and seeds, by shoots, sprouts, suckers, portions of the root, twigs, &c. This is not so with animals of sex, which must couple to engender, as all the dioic species, or by themselves, as the monoic, such as the bivalvular molluscs.

Among the species provided with sex in the animal and vegetable kingdom, there is a great difference relative to fecundity.

Female plants seem more capable of multiplying, even without the intervention of the male. Thus, we observe females of dioic vegetables which are cultivated in Europe alone, as the *broussonotia papyrifera*; the *populus balsamifera* propagate by twigs, whilst all the male individuals of this class are more feeble, and do not multiply by the same means. Even some female plants pro-

duce male flowers; as Forster has observed in the islands of the South Seas. Spallanzani has seen the female of the hemp produce fecund grains. Again, the stamens are sometimes changed in flowers, while the female organs remain immutable.

In the animal kingdom, on the contrary, male individuals are more robust, and more capable of fecundating than females; and as to the proportion of the species, one bull or one cock is sufficient for a number of females, which is the inverse of plants, in which the stamens almost always surpass the number of the pistils.

The relative multiplication of plants and animals appears to be equally prodigious; and it is doubtful even if the animal kingdom has the superiority. A sprig of maize produces 2,000 grains; a sun-flower has double the number; a stalk of poppy affords 32,000 seeds, one of tobacco more than 40,000; an elm-tree furnishes 100,000 grains annually; a clove more than 720,000, besides those which produce double the number. These are immense, but if all the reproductive energy of a single vegetable was developed into new beings, the earth and the celestial sphere would not be sufficient to nourish them. But this is very insignificant, when compared to the reproductive faculty of animals. I do not speak of the innumerable multiplication of insects, or of the five or six thousand eggs (ova) which a frog supplies every year, nor of the gnats, nor of the locusts, nor of the insects in Tartary, which are so dense as to obscure the sun, and devour, in a few hours, all vegetable productions; nor do I cite aquatic animals, more especially fishes. I may observe, however, that, the smallest herring has nearly 10,000 eggs. Bloch found 100,000 in a carp that weighed only half a pound. P. Petit discovered in another, about four inches long, 262,820 eggs; and in another, weighing six ounces, 342,144. A perch had 380,000, and a female sturgeon was computed to have 7,653,200 eggs. Lewen Noeck calculated, in this manner, 344,000 eggs in a cod fish. This fish alone would, in a few years, produce millions of its kind; and if these reproduced in proportion, millions of millions would be engendered in turn, which shews the immense, nay, the incalculable fecundity of nature.

(To be continued).

CORRESPONDENTS.

Paracelsus.—What between mummies and star-gazing, Simon Pure must think his fifty readers confirmed lunatics.

The Westminster Medical School and its Prizes.—We have received six communications about the distribution of prizes at this school, all complaining of partiality on the part of the adjudicators. We inform our correspondents, that the same system prevails in every school in London, that resorts to the clap-trap system of offering prizes. House pupils, private pupils, and apprentices are sure to obtain them. It is on this account we declined noticing the distribution of prizes. We have the particulars of every school which has awarded them, and shall, if circumstances demand it publish them.

An Advertiser.—We cannot comply with the request; our publisher never deviates from the established scale of terms, which is 30 per cent. lower than that of some of our contemporaries—if he wants to see himself in print and be read by about six dozen nincompoops, and only pay the advertisement duty, the office for such advantages is in the neighbourhood of the Strand.

A Liverpool Friend, Edinensis, An Enemy to the Scratch Journal, and many other correspondents will see on the wrapper of the day the information they require.

Dr. Thomson's Lectures.—The Toxological part of Professor Thomson's Lectures consisted chiefly of chemical experiments which are to be found in any modern system of chemistry. For this reason we decline to publish them.

M. Broussais' Lectures were delivered last session, and will be regularly continued.

Dr. Corrigan's Lectures.—We owe it to our readers to state, that we used every effort to give the continuation of these valuable lectures. We wrote several times about them but have not as yet obtained them.

A Medical Student.—Quain's Anatomy, is infinitely superior to the Dublin Dissector, which is only fit for a novice, or a first year's student.

C.—Mr. Hughes is a gentleman in the fullest sense of the word, and gave us no information that was not proved by Dr. Tweedie in the Court of Common Pleas. Had we not the highest opinion of the integrity and veracity of Mr. Hughes, we should not have published his statement that Dr. Tweedie had refused to meet F. H. Ramadge, in consultation as advocate of St. John Long, and now advertising curer of consumption.

Berkshire Medical Association.—A Society bearing this title has been established at Reading to protect the interests of the profession against the conduct of the Poor law Commissioners. Every respectable practitioner in the county has joined the Society.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXI.

Stimuli to Irritability—(continued).

A THIRD stimulus to irritability, and one very analogous to the two first mentioned, is electricity, and particularly that form of it which is called galvanism. Like caloric and light, it pervades every form of matter; and although its existence is not perceptible, any more than theirs, till the equilibrium of its distribution is destroyed, it has probably, even in its latent state, a very considerable influence on the actions of organized beings. Positive and negative electricity, it is almost superfluous to remark, stand in the same relations to each other as heat and cold—as light and darkness—that is to say it is the former alone which has any existence, and in no degree of negative electricity are plants and animals quite withdrawn from the agency of this principle. It is however only in its sensible state that this agent can be recognised; and in this state there are few or none, except caloric, which can compare with it in universality of action, since every irritable organ appears to be subject to its agency, and none whatever is a match for it in power, since the results are more striking from this than from any other stimulus to irritability, and it takes effect long after every other has failed. It is remarkable, however, that it appears to exert no action on the irritability of plants, except when applied in the manner of a spark or shock (a); whereas on that of animals, from the leech up to man, whether suddenly or continuously transmitted, its action is most powerful and striking. As either applied directly to the several organs, or conducted to them by the respiratory or motiferous nerves, it excites the irritability of the respiratory muscles, and therefore may be made to effect respiration; that of the heart, and therefore circulation; that of the secreting and absorbing vessels, and therefore nutrition, secretion, and absorption; that of the stomach, and therefore digestion; that of the membranes of the nostrils, eyes, and ears, of the tongue, and of the skin, and therefore indirectly—the irritations so excited being taken cognizance of, so long as the animal functions are unimpaired by the respective sensiferous nerves—the sensations of smell, sight, hearing, taste, and touch; that of the voluntary muscles, and therefore various writhings of the features and contortions of the limbs; and it does all this more forcibly, and for a longer time after apparent death, than any other known stimulus (b), and may often therefore be substituted with effect for any of the ordinary stimuli, such as caloric, sympathy, volition, and so forth, by which these functions are naturally excited (c). It is probable that to every form of organized beings, a certain definite quantity of galvanism, in relation to the capacity of each, as well as of caloric and light, is essential to the healthy performance of all its functions; but it is very doubtful whether such beings are in general provided with the means of either extricating or absorbing it, as in the case of caloric, so as to render themselves, in this respect, in some

(a) Van Marum, Humboldt, &c.

(b) The most extensive series of experiments of this kind was performed on the victims of the guillotine, at Turin, by Nysten, who employed galvanism as the test of

the duration, in each part of the body, of its irritability.

(c) Hence its advantage, as a remedial agent, in asthma, dyspepsia, palsy, &c.

measure independent of the medium which surrounds them. It has been supposed, indeed, that plants develop positive electricity—that is to say extricate this principle—by night, owing to the exhalation from them of carbonic acid, formed, as is imagined, by the direct union of carbon and oxygen, and that they develop negative electricity—in other words absorb this principle—by day, owing to the exhalation from them of pure oxygen, and that it is by this means principally that the varieties of the atmosphere, with respect to its state of electricity, are produced (a); and that numerous animals have the power of at least extricating electricity is sufficiently well known. This is very remarkably the case with the electrical eel (*Gymnotus*, 26), the electrical silure (*Silurus*, 29), and the torpedo (*Raia*, 31), and many other aquatic animals possess the same power in a greater or less degree; but in all the electricity so developed appears to be confined to a particular organ of the animal, and to be extricated for purposes very distinct from that of acting as a stimulus to its irritability. The relation in which electricity stands to living action, or to life, has been above pointed out: but, not content with regarding this principle as the most efficient known stimulus to irritability, some physiologists have amused themselves, in the same manner as others have done with respect at one time to heat, and at another to light, with representing it as identical, sometimes with life, and at others with the so-called nervous energy. The doctrine is altogether so loose and untangible, that it is almost impossible to contend with it systematically—"Your true no-meaning puzzles more than wit"—but as it has attained, perhaps from its vagueness, an undue degree of popularity with a certain class of physiologists, it will be necessary to say a few words on the subject. And first, with respect to the alleged identity of electricity, or galvanism and life (b). Of course if the notion concerning life, already so fully inculcated—that it is not a substance at all, but a mere mode of being—be well founded, it is quite out of the question entering at all into the inquiry whether it be identical with electricity or galvanism, or any thing else; but admitting, for a moment, that life is a substance, what evidence have we that it consists merely in electricity or galvanism? We have seen already that the principal arguments adduced in favour of the existence of life, as an entity, are, 1st, that such an entity is essential to the organization of a living being; 2nd, that such an entity alone is competent to effect the characteristic actions of a being so organized; and 3rd, that our belief in a future state of existence hinges on the presumption of the existence of such an entity: and it is of course incumbent on those who contend for the identity of life, and electricity or galvanism—not indeed to apply these arguments to prove the existence of electricity or galvanism as an entity—for that is unquestioned—but to shew that the latter is competent to effect, and does in reality effect, all those phenomena from which the existence of life, as an entity, has been inferred. Now, in the first place, does electricity or galvanism organize substances into which it is thrown? Does the prime conductor of an electrical machine, or the positive wire of a galvanic trough, become organized in virtue of the electricity or galvanism which they receive; or do any other matters in which these principles are accumulated undergo organization as a consequence of such accumulation? The idea is absurd. Nevertheless, if organized beings became so solely in virtue of their substantial life, and this were identical with electricity or galvanism, any matters transmitting or receiving these principles must of necessity become organized beings. Again, do all matters by which these principles are conducted, or in which they become collected, manifest the characteristic actions of organized beings; or, on the other hand, are such actions excited, by these agents, only in those which are already possessed of the property of irritability or vitality, quite independently of their operation? The answer is obvious. Nevertheless, if life were nothing but electricity or galvanism, any matters into which these principles were thrown must necessarily display living action; and it must be equally correct to say that an electric or galvanic apparatus produces its phenomena by means of the life which it develops, as that a plant or animal lives and moves by means of its electricity or galvanism: further, if such were the case, we ought to be able, at any time, to stop the living actions of one body and to excite the actions in another—that is to say to withdraw and communicate life, precisely as we withdraw or

(a) Pouillet, Ann. de Chim. and de Phys., t. xxxv, Dr. Graves' Lectures, &c.

(b) That heat was life, that light was life, that air was life, that water was life, that every thing in short with which mankind was acquainted was life, had been successively maintained, and each occupant of the vital chair had been pretty satisfactorily in turn dislodged, when, fortunately for the lovers of an absolute monarchy in physiology, electricity was discovered, and electricity was at once promoted to the vacant

throne. The notion of the identity of this principle and life seems to have been promulgated for the first time, as already remarked, by John Hunter, and it was of course adopted by his popular pupil, John Abernethy: fortunately, however, the reputation of both of them is founded on a more solid basis than the propagation of this flimsy and shallow hypothesis. Lamarck, as we have just seen, represented life as a compound of this principle and light!

communicate the principles in question (a). And how can it be explained, upon the presumption of the identity of life and electricity or galvanism, that these principles cannot excite living action, even in organized bodies, beyond a limited time—life should surely always make live: nay, that excess of these principles should be immediately fatal to both plants and animals?—death should surely not result from excess of life (b). Is it not, on the other hand, evident that, in the former case, the electricity or galvanism, being a mere stimulus, becomes inert as soon as all irritability has departed; and, in the latter, that, in the same character of a stimulus, it destroys all irritability by the excess of irritation which it produces? Lastly, who will be so wild as to contend that the immortal part of our frame—that which leaves our bodies at the instant of death, and is destined to survive us to all eternity—is electricity or galvanism? Yet such must be the case if life, or the presumed “vital spark of heavenly flame,” and these principles be identical. But it is mere waste of time dwelling any longer on this rambling dream: not only is life nothing, and incapable therefore of being identical with any thing, but, were it anything, every view of the subject would demonstrate that it must be at least *sui generis*, and as distinct from electricity or galvanism as one thing can be from another. But are these principles identical, not indeed with life, under which term are jumbled together all kinds of susceptibilities and all kinds of stimuli in most admired disorder, but with nervous energy, as it is called; by which term seems to be, in this case, understood—for it has been used in twenty different acceptations—not a susceptibility of any kind, but all kinds of stimuli, which, originating in the body of an animal, are capable of being conveyed by the nerves. According to this doctrine not only has electricity or galvanism, as artificially extricated and applied, been made to excite all the vital actions, and become thus a good substitute for the natural stimuli when those are defective, as has been already stated, but it is electricity or galvanism which, as constantly extricated either in various parts of the body, owing to the mutual action of its several solids in general, and in particular of nerve and muscle (c), or in the brain alone, owing to the mutual action of the alternate layers of grey and white matter of which it is composed, almost in the same manner as a voltaic pile is of alternate plates of zinc and copper (d), and conducted by the several nerves, naturally excites these actions. It is upon this agent accordingly that immediately depend, it is said, not only respiration, circulation, digestion, and the other functions consisting in sensible motion, but, in a more especial manner, secretion, and the rest of those which consist in molecular motion; the nature of which, if this hypothesis be adopted, is no longer involved in any obscurity. It was noticed, in evil hour, that the blood, when withdrawn from the body, and subjected to galvanism, had its albumen coagulated, and its salts separated (e); and again, that the ingredients of a solution of muriate of soda could be made to pass separately through an organized membrane by the same means (f). It hence became established that it was electricity or galvanism alone which performed all the incessant chemical actions of the living body; and, acting directly on the blood (g)—not merely stimulating the vessels to do so, which would have been a simple, instead of a compound absurdity—converted this blood into every variety of solid and fluid, organized or otherwise, and transmitted each through the coats of the blood-vessels; and animal heat being soon afterwards discovered to be a secretion, it was to be expected that galvanized blood would be converted, among other things, into caloric, which was accordingly found to be the case. In what manner, however, electricity or galvanism, which is always the

(a) Lawrence. Dr. Wilson Philip also, a chief advocate of the hypothesis next to be mentioned, admits that “life exists only in living bodies, and no task can be more hopeless than to look for it elsewhere.”—(On the Vital Functions, 1826).

(b) “A calf’s head,” says Sir Charles Bell, “is made to yawn, or a man cut down from the gallows to move like a figure of cards pulled with strings. The jaws move, and the eyes roll, and this is done by conveying the galvanic shock to the nerves: hence it is supposed that nothing less than the principle of life itself can work such wonders, and that galvanism is that principle. But in no circumstance is there a resemblance; and the whole phenomena resulting from galvanism transmitted through an animal apparently dead are fairly to be attributed to its being a high stimulus, conveyed through the moist animal body, and exciting the powers

(properties) which remain isolated in the several parts; and in exciting these powers (properties), far from renewing them, it exhausts them altogether.”—(Useful Knowledge). It is quite true,

“*Nutritur ventis, ventis extinguitur ignis,
Lenis alit Flammos, grandior aura necat;*”

but had the winds been identical with the fire, the gale with the flames, it is impossible that this could have happened.

(c) Sprengel.

(e) Brande (Phil. Trans. 1809), Sir E. Home, &c.

(f) Wollaston (Phil. Trans. 1811).

(g) It is expressly said by Wilson Philip, “The vessels only convey the fluids to be operated upon by the nervous power” (i. e. galvanism)—(On the Vital Functions, 1826).

same, acting, not upon the capillary blood-vessels—each set of which may be presumed to have its own specific character of irritability—but upon the arterial blood, which is likewise always the same, should give rise, in different parts of the body, to depositions so entirely different from each other, as are the several secreted solids and fluids, remains to be explained (a), the suggestion that these differences may depend upon the different quantities of this agent supplied to the different secreting organs (b) being a very improbable one, inasmuch as, however such differences might modify the quantity of the secreted matters, it is impossible to conceive that they could so materially influence their quality. But assuming, for a moment, that electricity or galvanism were constantly so extricated within the body—an assumption altogether gratuitous—and that it were the main stimulus to all the vital actions, sensible and molecular, it would be rather hostile, than favourable to the opinion that it is identical with the so-called nervous energy. We know of only two modifications of this energy, regarded in the light of a stimulus—that of sympathy and passion, or instinct, and that of volition—and both appear to act rather as accidental and occasional stimuli on the irritability of certain parts, than essentially and constantly on that of all; so that any stimulus supposed to be in perpetual and universal operation cannot be identical with such nervous energy. Moreover, each of these modifications of the nervous energy is quite distinct from the other, and is conducted by its own proper department of the nervous system—the former probably by the so-called respiratory, the latter certainly by the motiferous nerves—which electricity or galvanism, when artificially applied to the body, is conducted equally well by both; to say nothing, therefore, of the impossibility of its being identical with both, it cannot be identical with either. Again, nervous energy is found to be in general at once intercepted by tying the nerve by which it is naturally conducted, whereas, the conveyance of electricity or galvanism is not at all obstructed by this operation; and if a respiratory nerve, in direct contact with a motiferous nerve, be so tied, or vice versa, the stimulus of sympathy and passion is intercepted, while that of volition is unobstructed, or the reverse, whereas electricity or galvanism must be quite unsusceptible of any such isolation. But the looseness of the arguments which would establish the identity of these principles with either life or nervous energy, must be too palpable to require any further exposure; and it is only surprising that physiologists should have been so long in universally recognizing the true relation in which this powerful agent stands to both; it is a stimulus to irritability, and in so far analogous to the nervous energy in its capacity of a stimulus, and it is the most powerful means of promoting life, or living action, with which we are acquainted; but as it is *not* identical with the one, so it *cannot be* identical with the other.

The next stimulus to irritability to be spoken of is the medium, whether air or water, which immediately surrounds organized beings, and of which, in the process of respiration, they appropriate a portion to themselves. This stimulus acts principally on the irritability of the proper respiratory organ and of the surface; in the former of which it excites the capillary pulmonary vessels to those actions by which they give off and take up the requisite gaseous substances, while in the latter it is believed to excite, not only the capillary vessels of the whole dermoid tissue to those actions by which its peculiar secretions and absorptions are effected, but also, through the skin generally, in some measure the subjacent parts, and thus to promote the healthy excitement of every organ of the body. That the atmosphere or water generally is a stimulus to the respiratory organ, whether vesicles, lungs, or gills, as the alimentary matters are to the stomach, is unquestionable; and that, while its secretions are excited by these media in general, its absorption of a portion of the oxygen, contained in these media, is excited chiefly by this principle, is manifest from the comparative rapidity with which it is found to be absorbed from other internal surfaces which are sometimes accidentally exposed to its action (c). Similar to this is the action of the atmosphere or water in general, and of the oxygen in particular, on the external surface of an organized being, regarded, in some degree, as a second respiratory organ; but these agents are supposed to have another important relation to this external surface, regarded as a general envelope of the whole being, inasmuch as, by stimu-

(a) Dr. Alison (Quarterly Journ. of Science, 1819).

(b) Dr. Hunter Lane (Liverp. Med. Gazette, vol. i, p. 305).

(c) Thus in pneumothorax, abdominal tympanites, pneumatosis, and other diseases in which there are æriform depositions in various parts of the body, the gas, which is at first in general merely atmospheric air, soon loses its oxygen, and becomes pure nitrogen. This can arise only from the sti-

mulus imparted by the former having promoted its absorption; but there is, nevertheless, no good ground for the vague apprehensions sometimes entertained from the accumulation of air in "the innermost recesses of the body," with which the second Dr. Monro has the credit of having filled the minds of the vulgar, both in and out of the profession. It perhaps merely turns them for a time into a kind of respiratory surface.

lating this surface by the pressure which they exercise upon it, they act indirectly upon all the organs of the body, and maintain them in a state of healthy irritation; and it has been accordingly presumed that it is to the increased pressure of the air that we owe the alacrity and vigour which we usually experience on a dense cold day, and from its diminished pressure that result the languor and lassitude so generally experienced under opposite circumstances. It is very generally known that the pressure of the atmosphere, under ordinary circumstances, is equal to 15 lb for every square inch of surface, and that that of water, while it is only the same as this immediately below the surface, goes on increasing as it becomes deeper, till at the depth of thirty-four feet it is doubled, and so on in proportion. Upon these data, the external surface of a man of ordinary dimensions is represented as sustaining, under the ordinary barometric pressure, a weight equal to about 40,000 lb ; but, as the range of the barometer, in this country, is through about 3° , or one-tenth of the whole average height of the mercury, it follows that he must be subjected at one time to a pressure of 4000 lb more than at another. Nothing can be more fallacious, however, than the conclusions to which these premises have led respecting the average stimulus, and the greater or less degree of this at different times exercised by the atmosphere—and of course by water—on the irritability of organized beings; for we must continually remember that these beings press upon the medium which they inhabit from every point of their substance with precisely the same weight as they are pressed upon by this medium, so that any general effect of this external pressure, regarded as a stimulus, must be neutralized, and consequently, while the actual amount of such pressure must be a point of little or no moment, any change in this, gradually as such changes are under ordinary circumstances made, and taking effect, as they can do, only till the equilibrium between the external and internal pressure is established, could have little or no effect in modifying such stimulus, had it any existence. And that this must be the case will be abundantly obvious, if we estimate the amount of the actual pressure made by the atmosphere, not upon the external surface of the human body, but upon the internal surface of the lungs, which has been computed to be from thirty (a) to a hundred times (b) greater than the former, and which—taking the mean of these computations—must consequently sustain, under the ordinary barometric pressure, a weight equal to about 2,600,000 lb , and be subject to a variation of pressure equal to 260,000 lb ! We seem to have, in fact, nothing whatever to do, under ordinary circumstances, with the actual pressure at any time exercised on organized beings by the medium which they inhabit, regarded as a stimulus, nor even with any variations of this, unless such variations are made so suddenly as not to allow time for striking a balance between the pressure from without and that from within; and the greater or less energy of the functions, therefore, commonly attendant respectively on a dense or rare atmosphere, appears to be the effect, not of such density or rarity, but of the cold or heat of which they are in general the concomitants. It is a very different affair, however, if such changes are very abruptly effected, as occurs from suddenly descending to great depths below the water in a diving bell, or from suddenly rising into the atmosphere in a balloon, or even rapidly ascending a high mountain; from all which very remarkable consequences are sometimes experienced (c), although any extraordinary hilarity, in the former case, or any great depression in the latter, are not among the number. Such changes as these, however, appertain, not to the natural stimuli to the healthy functions, but to the exciting causes of disease; and, upon the whole, it seems fair to conclude that the medium which surrounds organized beings, however much it may influence their physical condition, and however essential it may be to their respiration, exercises in general, by its mere pressure, no stimulus upon their irritability. Such a being, whether almost in vacuo, or in a medium condensed to hundreds of atmospheres, would still, perhaps, after a time, maintain a balance of pressure from without and from within; so that, changed as might be its volume, and laborious or impossible as might be its fundamental function, the stimulus from mere pressure would perhaps be the same.

The stupendous condor of the Andes is known to endure an atmosphere the pressure of which is less than one-third of that which we inhabit, while fishes, on the contrary, are presumed to exist at a depth of upwards of seven hundred fathoms of water! The stimulus of the air, as instrumental to respiration, is much less essential to the life of the sluggish water-plants than of others, and to that of cold-blooded than of hot-blooded ani-

(a) Monro.

(b) Lieberkuhn.

(c) Among the chief of these are excessive difficulty of respiration, inflammations, copious hæmorrhages from the various outlets of the body, acute pain in the ears, &c., all which are very easily explained. The usually asthmatic habit and blear eyes of

pearl-divers, and the abundant hæmorrhages which whales are accustomed to suffer, upon rising again to the surface of the water, after having dived to great depths upon being harpooned, furnish good illustrations of the deleterious effects of any sudden changes in the pressure of the surrounding medium.

mals in general, being the more so, in all tribes of organized beings, the greater their activity—hence it is the most so in beasts and birds. Perhaps there are no very well authenticated instances in which an adult human being has been deprived of air for more than five or ten minutes, without being asphyxized (a), although some very wonderful stories, of divers and others, are related to the contrary, whereas the frog is capable of sustaining a want of air for thirty hours, and the leech or earth-worm will survive for days or weeks, although surrounded by oil, or kept in vacuo. New-born animals also of all kinds are less rapidly affected by want of air than adults, for reasons which need not be here explained (b). In like manner, among aquatic animals, some fishes, as the mackerel (*Scomber*, 26), the salmon-trout (*Salmo*, 29), the herring, and the shad (*Clupea*, 29), are very rapidly asphyxized by being removed from the water, as instrumental to their respiration, while others, as the eel (*Muræna*, 26), the perch (*Perca*, 28), the carp and tench (*Cyprinus*, 29), can live for hours or days without this stimulus. The cases in which living animals, both terrestrial and aquatic—oysters, worms, cray-fish, beetles, frogs, toads, serpents, lizards, even rats—have been found imbedded in solid rocks, or in the heart of trees, are familiar to everybody; and are explicable probably on the presumption that such substances are sufficiently porous to admit the small supply of air or water requisite under circumstances in which all the functions must be presumed to have been so far from active (c). We know, on the one hand, that moles receive air through the pores of the earth, and that human beings have been sometimes engulfed in snow for many days without being asphyxized; and, on the other, that all animals during their hibernation—and the animals just alluded to were in a state very analogous to this—require comparatively a very small supply of these stimuli to support their existence. With respect to the instrumentality of the air or water which surrounds organized beings to various other functions—such as to the circulation of the blood, which the former at least is presumed to promote, by the pressure which it exercises on the veins, upon a vacuum being formed about the heart, either by the natural resiliency of the lungs, or during expiration; to smell, taste, hearing, and the voice, to which they are essential, as either conveying the immediate stimuli of the odoriferous or sapid particles of other bodies, or of vibrations excited in themselves, or admitting of such vibrations; and, lastly, to locomotion, as exemplified in flight and swimming, or even in progression on land against gravity, in the manner of many molluscous animals, and insects, some lizards, and a few amphibious animals, to which they minister by admitting of what is called suction—with this we have no concern at present, since it is only as stimuli to irritability that they are at present a subject of consideration, and their action, in all these cases, is, not in exciting irritation, but in either superseding, as is supposed, such irritation by a merely physical process, in conducting the immediate stimulus which is to effect such irritation, in being themselves affected by such irritation, or in rendering such irritation available. Such, then, appears to be the relation in which air or water stands to life; that neither of them, nor any one of the principles of either of them is, or can be, identical with the latter, as has been idly supposed (d), needs not be here insisted on.

(a) Fothergill, Davy, Brodie, Edwards, Roesler, &c. It is a very different question after how long a period, from the supervention of asphyxia, life is restorable—that is to say, how long irritability or vitality may survive the abstraction of one of the principal stimuli by which it is excited.

(b) Edwards.

(c) It was found by Hérisant that many animals could live although entirely surrounded by Paris plaster, which almost instantly perished if the pores of this were obstructed by oil or any other means. The fetal chick also is well known to receive air through the pores of the shell, and to be soon suffocated if these are stopped up.

(d) In Hebrew, the words *nephesh* and *ruach*, in Sanskrit, the words *atma* and *pranah*, in Greek, the words *Ψυχη* and *Πνευμα*, and in Latin, the words *anima* and *spiritus*,

all directly inculcate the same vague idea of the identity of life, soul, spirit, ether, wind, air, and breath, and sufficiently indicate the prevalence of this idea from time immemorial; and the remnants of it are still perceptible in the common phrase of "dying for want of breath," which is intended as equivalent to saying "dying for want of life." We have seen, however, that by some certain of the ancients, life was represented, not as air, but as water. In after times air was sunk into one of the six non-naturals, as already mentioned; but it was again—or, at least its oxygen—exalted to honour in the hands of Girtanner, who, at a time when chemical explanations of all physiological facts were in vogue, once more deified it, not indeed as life itself, but as the immediate and most essential stimulus to vitality.

LECTURES
ON THE
PHYSICAL EDUCATION AND DIS-
EASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN,

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XXXIX.

*Hereditary Syphilis—Congenital Diseases of
the Skin—(concluded).*

GENTLEMEN—I occupied your attention at our two preceding meetings in adducing proofs that small pox may be communicated by the mother to the infant in her womb; and I dwell upon this point of pathology, as it determines a question of great importance, upon which physicians have for a long time entertained different opinions, whether an unborn fœtus can be affected with syphilis. In addition to the authorities already cited, I may add the names of Mauriceau, Sydenham, Watson, Sir Astley Cooper, all of whom describe cases of congenital small pox. Almost all the authors who have written on this disease, have affirmed that the mother who is affected or contaminated may transmit syphilis to the infant in her womb. I shall further prove, that an infected father may communicate the venereal disease, though he has no primary or secondary ulcers, not only to the infant, but also to its mother.

Many physicians, however, think on the contrary, that the infant is never infected in the womb of the mother, and that it cannot contract the disease unless in passing through the vagina and genital fissure, when it comes in immediate contact with open ulcers, and even then it is scarcely ever contaminated. "If we reflect," says, M. V. Andry, a staunch advocate of this side of the question, that the discharge of the waters, ought necessarily, in lubricating the diseased parts, to remove the pus on the surface of chancres; that the infant in most cases passes through the vagina rapidly; that it is covered with a caseous or tenacious matter, more or less thick; that the parts susceptible of being infected, such as the mouth, the external organs of generation, &c. must be in immediate contact with the surface of the syphilitic ulcerations of the vagina; that the fœtus possesses very little vitality or sensibility; how little aptitude has a new-born infant, especially in the first days of its life, to contract contagious diseases, even whilst plunged in the very focus of infection, &c.; we can easily conceive how difficult it is for the fœtus to be infected, even in this manner, which is the only admissible one. Numerous facts further prove, that an infant the issue of in-

fectured parents can come into the world perfectly sound, and always preserve good health; and that it is extremely difficult to distinguish the characters of syphilitic infection in new-born infants. The principal symptoms are inflammations and ulcerations of the external mucous membranes, and certain cutaneous eruptions, such as phlyctenæ, pustules, &c. Hippocrates has however observed, in his book *de Morbo Sacro*, that infants born of sound parents may have the mouth, the eyes, the ears, external genitals, &c. affected with inflammations, mucous discharges, and even ulcerations, aphthæ, &c. which disappear by the use of simple lotions. We may therefore conclude, from the preceding facts, that every species of syphilitic infection from the mother to the infant is impossible."*

This author cites a case related by M. Bosquillon, which was pronounced to be syphilis by MM. Doublet, Fabre and Louis, which got well by ordinary treatment. The preceding extract appears very conclusive, though nearly every fact stated in it is disproved by observation. It is well known that it is extremely difficult to wipe or wash off the matter of a chancre, and therefore, the sudden escape or passage of the waters (amniotic fluid), during labour could not effect it. Again, the infant does not in most cases pass through the vagina rapidly, nor is its skin always covered with tenacious matter, nor is there any valid reason to doubt that its eyes, lips, or genitals may come into immediate contact with the ulcers on the mother; nor is this the only mode of infection, as we shall see hereafter. M. Andry is correct, however, in stating that new-born infants are not susceptible of contagion, but this does not prove that the diseases of one or both parents, like their moral and physical dispositions, are not transmissible to the infant at the moment of its procreation. It is also inexact to state that infants, the issue of infected parents, may be born healthful and always preserve good health; as daily experience proves the contrary. Such infants, though rarely born in health, very speedily shew symptoms of syphilis. In fine, it is contrary to the received opinion of the moderns, that infants may be born with the usual symptoms of syphilis, though uncontaminated by that disease; and it is also well known to experienced and observant practitioners, that infants born with such symptoms are affected with them soon after birth, and are most speedily cured by mercury. These, and many other facts which I shall immediately adduce, completely disprove the accuracy of M. Andry's conclusion, that every species of syphilitic infection from the mother to

* *Memoire sur les Maladies du Fœtus et des ses Annexes. Par V. Andry, D.M.P. Journ. des Progrès des Sciences et Institutions Medicales, t. 1, 1830.*

the infant is impossible. A preponderating majority of the ablest physicians of all countries maintain the contrary opinion. The following conclusions are deducible from their observations.

1. The venereal disease, in a primary or secondary form, may be transmitted by either parent to the offspring.

2. When the parental constitution is highly contaminated with secondary syphilis, the infant will decline in strength and its movements be diminished in the womb about or after the sixth month of pregnancy, the mother will cease to feel it move between the sixth and seventh month, and it will be born dead between the seventh and eighth month, its body being in a state of incipient decomposition. This result may be observed in several pregnancies (I have known it occur in twelve) until the disease is cured in either or both parents.

3. When there is a less degree of parental infection the infant will be born alive, but thin, shrivelled, and partially affected with a copper-coloured, or other well marked venereal eruptions about the genitals or on other parts of the skin, or with ulcerations in various parts, as hereafter mentioned. Mercury administered to the mother or infant, will alone effect a cure and establish the health of the latter.

4. When the parental constitution is still less affected, the infant may be born in apparent health, but in a few weeks will present syphilitic symptoms, which will yield to mercury only.

5. If the infant soon after birth have one or more ulcers on the lip or lips (chancres), it will cause a similar affection of the nipple or nipples; these will contaminate the lips of a healthy infant or adult, and either may propagate the disease to an indefinite extent.

6. When conception is effected, the administration of mercury, sarsaparilla, &c. to the parents will not save the life of the infant, when their systems are intensely infected; but after the birth of the infant, they should live separately for six or eight weeks, or until their medical adviser thinks they have taken sufficient medicine to exterminate the taint in their constitutions. When this is accomplished, which is generally, but not always the case, a living, healthful infant will be produced, and a numerous progeny may succeed it.

According to the preceding categories, syphilis may be communicated to the embryo at the instant of conception, or during parturition, or during lactation, when the nurse has venereal sores about the nipples. A woman may be contaminated with secondary symptoms, or with primary sores, or she may be infected after conception, and in such case there may not be time for secondary symptoms to appear, as these seldom occur for months, and sometimes years after the primary ulcers. It is for this

reason that a woman who contracts the disease after conception, and during any period of pregnancy, may bring forth a living infant free from the disease, though her next may be infected, and every future infant, until the mother is cured of the secondary form of the malady. The secondary form of syphilis is said to be communicable through the breast milk; but this is not always the case, as we shall see immediately by the citation of a fact in point.

I shall now proceed to adduce unanswerable proofs of the foregoing statements, and first describe the appearances of syphilis in new-born and very young infants.

Congenital Diseases of the Skin—Syphilis.—The disease may manifest itself in the forms of the various eruptions, as pustules, pimples, scales, phlyctenæ, ulcers, chaps, excrescences, erysipelas, genital discharges, purulent ophthalmia, coryza, or hoarseness. These symptoms may appear at birth, or in a few days or weeks afterwards; the disease may attack any part of the body, but more particularly the mouth, eyes, organs of generation, and sometimes the space round the nails. When phlyctenæ or large blisters are present, they generally affect the shoulders, chest, thighs, and limbs. Ulcerations are most common about the genital organs, and in the folds of the groins and thighs. They are also less frequently observed on the lips, gums, tongue, palate, and vault of the palate. These ulcers are red and hard on their edges, which are elevated, deep or excavated in their centres, and if caused by open venereal sores on the parent, are covered with a tenacious yellow matter. Ophthalmia is the most frequent effect of gonorrhœa, and sets in on the second or third day after birth. One or both eyes become violently inflamed, the eyelids are red and enlarged, and when separated there is a copious discharge of purulent matter. Vision will be speedily destroyed unless the most active and judicious treatment be employed. The conjunctiva or membrane which covers the eyelids and eyes is intensely inflamed, and the cornea or front portion, as well as the whole globe of the eye, becomes speedily affected, and there is the greatest danger of loss of vision, unless the nature of the disease is understood and proper remedies administered. It is important to know that new-born infants are often attacked with slight inflammation of the eyelids of one or both eyes; which is caused by cold, exposure of the eyes to a strong light immediately after birth, such as that of a candle or of a fire. The disease is also caused by the carelessness of nurses, in allowing the soap lather with which they wash the infant after birth to get into the eyes. This simple ophthalmia either disappears in a day or two after the application of cold water, rose water, or the latter with a few grains of acetate of lead. The eyelids are but very slightly in-

flamed, not enlarged or tumefied, and when separated, there is not a copious purulent discharge down the cheek. The diagnosis is therefore easily drawn.

The lining membrane of the nostrils, which is a continuation of the conjunctiva, is often affected by venereal disease, the infant snuffles, it cannot suck, its voice is hoarse, there is impeded respiration, the nostrils are dry, or filled with mucosities, or ulcerated and filled with pus; the cheek may be ulcerated. Some or many of these symptoms are present; and when the infant is emaciated, feeble, delicate, fretful and peevish, having eruptions which defy ordinary remedies, we may suspect venereal contamination.

A great deal of domestic unhappiness is often unjustly excited by the venereal disease, when a woman learns that her husband's former licentiousness is the cause of her having several dead infants in succession. It ought to be known, however, that a man who contracted syphilis long before his marriage, who supposed himself cured and was told so by his medical adviser, prior to his entering into the matrimonial union, may have the relics of the disease in his constitution, though unaware of their existence, and they may cause the distressing occurrence of which his companion has reason to complain. I have been consulted in numerous cases of this kind, and considering them morally as well as medically, I entertain the conviction that an individual who received the best medical treatment, long before his marriage, did every thing in his power to eradicate the venereal disease, was assured by his medical attendant, that no symptom of it remained, that he might safely enter into a matrimonial contract, such person is not, in my opinion, to be blamed, as he did every thing in his power to free himself from the disease, and was told by his medical attendant that he was cured. Neither is the medical practitioner in the slightest degree culpable, as the records of medicine attest that every symptom of the venereal disease may be absent, and yet the constitution contaminated. Moreover, it should be recollected, that few, it is said not more than one in twenty, is free from the seeds of some disease, and that the parties contracting marriage solemnly swear to take each other for life, in "sickness and in health." There is, perhaps, not more than one man or woman in twenty perfectly healthful; and the matrimonial vow is upon the whole, equally just to one as the other. Moreover, the conduct of the husband before marriage should be forgotten; he might or might not be united to his wife, but when united, there is no just excuse for an estrangement of their affections. It is as yet an unintelligible fact, how a man who has no symptoms of venereal disease, yet infects his wife, and they procreate offspring which is born dead

and putrid. There is a mystery about generation which physicians cannot penetrate or comprehend, and perhaps will remain so to the end of time. Who knows any thing concerning the origin or termination of life?

The disease may be communicated by primary or secondary symptoms in either parent; but most commonly the latter. Parents who have no symptom of the disease at the time of marriage, but who have had it, and whose constitutions are still infected, which may be the case for several years, will beget infants with the symptoms already described. It is well known that the primary venereal symptoms may be removed in a short time, or may exist for a month or two, without the supervention of the secondary. Thus, a woman may be infected immediately before or during pregnancy, and may bring forth an infant free from the disease, and in perfect health. In such cases the constitution of the mother is not as yet contaminated; but if during pregnancy she is attacked with secondary symptoms, eruptions, sore throat, &c., then her infant will be infected in a greater or less degree, and will present secondary symptoms at, or in a few days or weeks after birth; or it may be born dead and decomposed between the seventh and eighth months. I have repeatedly prescribed mercury to the full extent for pregnant women affected with chancres or primary sores, and have known that though these disappeared, the infants were affected with the disease at birth, or in a few weeks afterwards.

There is a very valuable essay on this subject in the seventh volume of the *Medico-Chirurgical Transactions*, by Mr. Hey of Leeds, one of our ablest surgeons, entitled "Facts illustrating the Effects of the Venereal Disease on the Child in Utero." He is of opinion that the husband infected with secondary symptoms may communicate the venereal disease to the wife, and of this fact I have known some remarkable examples. It is extremely difficult to explain it, but Mr. Hey, Mr. Lawrence, and most obstetric writers admit it.

Mr. Hey makes use of another fact long known to obstetricians. It is this, that a woman infected by her husband who has secondary symptoms, may communicate the disease to several successive children. Dr. Hamilton, the eminent professor of obstetrics, in the University of Edinburgh, has long inculcated this doctrine; but the late Dr. Beatty contends it was first maintained in Dublin about the year 1792. Both advise conjugal separation for some weeks after the birth of the first infant, during which time the husband and wife should be put under the influence of mercury and sarsaparilla. This plan is generally, though not invariably successful, as every experienced practitioner is aware of the great difficulty of curing some individuals with mercury,

sarsaparilla, &c. I know a lady who contracted the disease from her husband in a few weeks after marriage, though he had not a single symptom for a year previous to his entering into the matrimonial contract, and was declared by his medical attendant to be perfectly cured. The latter informed me in consultation, that he did not believe his patient, who was a scrofulous irritable person, had had syphilis at all, but merely herpes preputialis. The lady, however, who was also a scrofulous subject, was attacked during pregnancy with sore throat, excoriations of the labia, with purulent discharge, and eruptions on the skin. She was not aware of the nature of her complaint. I advised that she and her husband should use mercury and sarsaparilla, with the view of diminishing but not curing the disease in the infant in the womb. Both parties had the mouth affected with mercury; but about the sixth month of pregnancy the lady felt the movements of the infant much weaker. These ceased at the seventh month, and she was delivered in three weeks afterwards of a dead infant, with the extremities livid, the cuticle desquamated, and putrefaction or decomposition considerably advanced. Both husband and wife were again mercurialized, and took large quantities of sarsaparilla; but the next infant was born between the seventh and eighth months, dead and putrid. The same treatment was resorted to on two succeeding occasions, and was followed by the same result. A separation from the moment of the birth of the last infant was now advised for two months, during which both husband and wife were kept under the influence of mercury and sarsaparilla. At the expiration of this period they cohabited, and in due time the lady brought forth a living healthful infant. She is now the mother of five vigorous children. It has been long known that women contaminated with syphilis have a great aptitude for conception; and when this has happened, which was the case in the four pregnancies of the lady whose history I have narrated, and who was most severely affected, the life of the infant cannot be preserved by anti-venereal remedies. Had iodine been in use when this case was treated, a cure would have been effected much sooner, as the proto-ioduret, or deuto-ioduret of mercury would, I think, have speedily accomplished it. These possess very slight, if any effect, on the ovum surrounded by its fluid and coverings, which for the first month of pregnancy are connected in the slightest degree imaginable with the uterus or womb. The history of the development of the impregnated ovum, or of the new being from the instant at which it is vivified, teaches us that neither the mind nor body of the mother, nor any kind of medicine taken by her, can affect it during the first hour, or, perhaps, months of its existence. We can therefore understand

the reason that influencing the mother with mercury after she has conceived, does not free the infant from syphilis; and that she and her husband should live separately from her next confinement, until both have fully tried the requisite medicines. A great many cases, in which dead and decomposed infants were born in succession, between the seventh and eighth months, and which were cured by the parents having taken proper remedies during the period of conjugal separation already mentioned, have fully convinced me of the correctness of this pathology: it is not known, however, to many practitioners. The late justly celebrated Mr. Abernethy inculcated in his lectures, as may be seen in the *Lancet* edition, the correctness of which he verified on oath in a Chaucery proceeding against the publisher of that periodical, that the venereal disease only affected the foetus in utero at the sixth month of pregnancy; because at this time the mother feels the motion of the infant diminish, and soon finally cease. But the scientific obstetrician inquires, how is it, that the infant could have escaped until the sixth month of its existence, both parents being contaminated at the time of its procreation?

The venereal disease may be communicated to a nurse by sores on the mouth of an adult or infant. Mr. Hey relates a remarkable case of a woman who gained her living by drawing the breasts of women after delivery, who infected several from ulcers on the angles of her lips. One woman so infected had sore throat, which was deemed venereal by Mr. Hey and another practitioner. She was treated with mercury, and during the use of this remedy, became pregnant. She was, however, prematurely delivered at the seventh month of pregnancy of a dead infant. She was confined the next year, and delivered of an infant apparently healthy at birth. When it was six weeks old, an eruption appeared on it, which Mr. Hey deemed to be venereal. He accordingly ordered calomel for the mother, and chalk with mercury for the infant. The eruption speedily disappeared, but in eight months afterwards sores were observed on the labia, which were treated by mercury. In seven months afterwards the nostrils became sore, and the infant grew hoarse. The mercurial course was continued for two months, when a perfect cure was at length effected.

The mother brought forth another infant, which was repeatedly affected with copper-coloured blotches, that yielded at length to mercury. This woman was contaminated with venereal disease by the woman who had drawn her breasts from 1771 to 1775, a period of four years, and so were her infants. There are other modes by which syphilis may be communicated.

It is possible that the venereal disease may be communicated by drinking from a vessel previously used by an individual who had

venereal sores on the lips. This is, however, of rare occurrence.

An infant with sores on its lips may infect a nurse who suckles it. Thus a poor woman was employed to suckle an infant so affected, who applied it to the left breast only, and kept the right for her own offspring. A clean sore, not similar to a chancre or venereal one, formed on the left breast, the glands under the arm enlarged, an eruption appeared on the scalp, and sores on the genitals. Both she and her foster infant were treated with mercury. Her own infant, however, remained perfectly well, though its mother laboured under secondary syphilis. The foster child was afterwards transferred to another nurse, whom it also infected. She was apparently cured by mercury, but her next infant, though born to all appearances healthy, when three months old, became covered with a syphilitic eruption, which was also cured by mercury.

The following case, the history of which you heard at the Western Dispensary, and some of you have diligently attended the subject of it at her own residence, while all have heard the particulars and results, is deeply interesting:—

A. G., aged forty-one years, was admitted under my care, December 2, 1834. She was unable to attend, and I repeatedly visited her at her own residence, accompanied by some diligent pupils of this class. She was pale and emaciated, the mother of sixteen children, four of which were born alive, and twelve between the seventh and eighth months, dead and putrid. She stated that she had been infected with syphilis by her husband when she was suckling her fourth infant. She consulted the late Mr. Ollier, of Westminster, an able surgeon, and one of my predecessors at the Western Dispensary, who informed her that she was affected with the bad disease (syphilis). He ordered her mercury. About the sixth month of her next, the fifth pregnancy, she felt the movements of the infant less than on former occasions: these gradually ceased, and she was prematurely delivered of a dead and putrid infant, between the seventh and eighth months. She has borne twelve other infants dead and putrid. Her husband died two years ago, and had been repeatedly infected with syphilis during the twelve preceding years.

At present she suffers from a copious purulent foetid discharge from the vagina, loss of appetite and strength, and great debility.

On instituting a vaginal examination, I found that the os and cervix uteri were destroyed by ulceration; and the points of the five fingers, brought closely together, could readily pass into the uterus. The vaginal discharge was so offensive, that the mother and sisters of the patient could not remain in the apartment with her. My diagnosis was destructive ulceration of the

uterus; result fatal. I ordered her a nourishing diet, wine, quinine, pil. sap., c. opio at bed, and a vaginal injection composed of solution of chloride of lime, 3ij, water, 3viij, t. opio, 3j. This last was to be used with a double syringe, which I lent her. She rapidly improved under this treatment, but in a short time the fæces escaped through the vagina. Previous to this occurrence, the fætor of the discharge was entirely removed, but on a vaginal examination, it was discovered that there was a recto-vaginal aperture or fistula. The same medicines and diet were continued, and the vagina was plugged daily with oiled lint, moistened with a solution of chloride of lime. Mr. Dawson was kind enough, not only to use the syringe, but apply and remove the plug every twenty-four hours, and repeat the operations, for which I feel much obliged. In a few days the fætor of the discharge was completely removed, and the evacuation was nearly abated. The fæces passed through the vagina whenever the plug was removed. The patient seemed to improve, but had frequent severe attacks of hæmorrhage. On the 9th of January, 1835, the hæmorrhage was excessive, the quantity of blood effused nearly filled a chamber utensil. She rapidly sunk after this occurrence; and I obtained permission to examine the body. I also succeeded in obtaining leave for some of the pupils of this class to be present—Mr. Dawson, Mr. Higginbottom, Mr. Ley, and Mr. Howard. I now shew you the morbid appearances. (*The preparation was exhibited and described*). The diagnosis and prognosis of this case were literally correct. The cause of the disease remains to be established; for this reason, that I have repeatedly observed similar cases, in which there was no venereal contamination. The case is, however, of great interest, as it proves that a woman infected with syphilis may bring forth so many as twelve children dead and putrid, between the seventh and eighth months. It corroborates the conclusions of eminent authors on the subject.

When an infant is born feeble and delicate, its skin wrinkled, scaly, or covered with copper-coloured or red eruptions of various kinds, the nostrils, lips, genitals and anus excoriated, the countenance pale, yellow, livid, the voice feeble or hoarse, the whole body thin and wasted and the inability of motion; these signs indicate great decrepitude and are the precursors of a premature death, unless proper remedies be employed. With most of these characters it is not difficult to recognise the venereal disease in new born infants; but the diagnosis will be more or less obscure when these symptoms are isolated, or only a few of them are present. It requires some experience and judgment to distinguish the various forms of the venereal infection from small-pox, crusta lactea, ulcers of the mouth,

with apthæ, coryza or stoppage of the nose, with ulceration of the nostrils, excoriations of the genital and contiguous parts, caused by the contact of the urine and fecal matters; erysipelas of the genitals, congenital discharges of female infants, purulent or leucorrhœal, and simple ophthalmia and coryza caused by catarrh or exposure to cold. The history of the general health of the parents, and their general appearance, will often enable us to arrive at an accurate conclusion as to the nature of the state of the infants.

The venereal disease in new born infants is often exceedingly obstinate and difficult to be cured, in proportion as it has been neglected or is complicated with other diseases. In some cases the new born infant has the nostrils almost impervious; it therefore cannot suck the breast or swallow any kind of food without much difficulty. It rapidly emaciates and speedily dies, unless mercury be exhibited. The danger will therefore vary according to the nature and severity of the symptoms, and according to the means employed for their removal. The only remedy for this disease is mercury, and this may be administered to the mother, nurse, or infant, however young. The exhibition of mercurial pill to the mother or nurse generally effects a cure. Some prefer calomel, and advise it in the proportion of from one twenty-fourth to a quarter of a grain. Modern practitioners have learned that calomel may be given in successive doses, to the extent of a drachm, to very young infants; Dr. Hamilton increased the quantity to the amount of three drachms, and others have given three times this quantity in croup and obstinate cutaneous diseases of very young infants. I have invariably observed that mercury administered to the mother or nurse will be conveyed through the breast milk, and effect the cure of the infant. I have seen many cases in my hospital and dispensary practice, in which the infants were the most enfeebled objects that could be imagined, but they began to improve in a few days after the mother had taken mercurial pill or calomel. A cure is in general effected in three or four weeks, but there are some obstinate cases which require the use of the medicine for two or three months and even longer. It is a common practice in foreign countries to prescribe the syrup of sarsaparilla for infants as well as mothers and nurses. They also use frictions with mercurial ointment, in the proportion of two grains daily while the infant is at the breast; and increase a grain every month after the infant is weaned. Mercury should be discontinued during dentition or teething, when the infant is griped, affected with convulsions or diarrhœa. When any of these diseases appear, it is to be treated in the manner described under its respective head.

The infected mother ought always to nurse the infant, and if she cannot, a healthy nurse ought to be selected, when circumstances permit, unless there are primary sores on the lips or tongue of the infant. It would, says Professor Capuron, be inhuman to compromise the health of a sound woman by giving her an infected infant to nurse.

It has been already stated, that an infant who has a primary venereal sore on its lips, or a chancre, will infect a healthy nurse, by causing ulceration or excoriation of the nipple or nipples. But unless the infant has sores on its lips or tongue, it will not infect the woman who suckles it. If the mother or nurse labours under ill-cured syphilis, the infant will not be restored to health, until the parent or nurse is cured. This is a valid reason why mercury should be given to the mother, and the greatest caution employed in the selection of nurses.

It is really astonishing to observe the speedy cure of infants affected with syphilis, after the employment of mercury in their cases, and also when there is reason to suspect their mothers are contaminated. The remedy cannot possibly do harm or injury either to mother, nurse or infant, when prescribed in doses appropriate to different ages and constitutions.

SELECT LECTURES,

FROM

M. BROUSSAIS'

Course of General Pathology and Therapeutics;
translated and revised

By JAMES MANBY GULLY, M.D.

LECTURE IV.

—

Furuncular Inflammation—Pustular Inflammation.

THE prognosis of furuncular affection is easy, and is founded on the intensity of the affection, its propagation and dissemination. When a boil is inclined to reproduction, it seldom stops at one, especially if the individual has changed the climate he lived in, and passed from a cold to a warm one. In that case, successive furuncular inflammations appear for several months together, so as to exhaust the powers and keep up febrile movements that induce considerable emaciation; this fact I ascertained when practising in the army in the south of Europe. When the affection we speak of has become very intense and in a phlegmonous form, or has extended into erysipelas—and this depends on the individual predisposition, and the way in which it is treated—it may bring on phlegmasiæ and other occurrences, such as those diseased states cause; the prognosis is then to be similarly modified. The most annoying symptom in boils and anthrax is the pain.

As in erysipelas, the treatment should be, at the earliest period, stimulating; but it rarely happens that the patient is aware of it at that stage. The disease most commonly goes on to the isolation and expulsion of the core; topical applications may be used that aid its formation, but it is not until it has been expelled or withdrawn that the disease stops. Cauterization may stifle the inflammation in the early period alluded to: but if twenty-four hours be allowed to elapse, it becomes too late, and it then only remains to treat it with demulcents, or to incise, by which its existence is abridged: the latter is the best, when the boil contains several cores and approaches to anthrax: the incision should be longitudinal in slight cases, in a T shape if more severe, and crucical when most intense. If the relief is not hereby sufficient, a few leeches should be applied to the edges, and these should be afterwards covered with emollient and narcotic poultices, by which large eschars and loss of substance are avoided. Furuncular inflammation requiring this extreme treatment, is most usually observed in robust old men who live too well.

The tendency to the reproduction of boils has been said always to be owing to some gastritic affection: such is not, however, invariably the case. The capillaries of the skin themselves have sufficient vitality to generate and retain the inflammatory disposition and principle of irritation which thus shews itself at different points; and I have not unfrequently seen the treatment of gastritis applied to such instances, without success, when emollient and narcotic baths dispelled them altogether.

When this gastro-intestinal complication really exists, you will succeed by the baths mentioned, by a few bleedings if necessary, by cooling drinks and vegetable diet; but you must not think it necessary to give purgative mixtures, bitters, and anti-scorbutic plants; do not believe that you ought to stimulate the digestive canal by pills that cause an incessant mucous torrent. I pass over the fevers and other affections that anthrax may be followed by, because for the present I wish to keep one organ alone before you.

Pustulo—Scabious Inflammation of the Skin.
—This is the third form of cutaneous inflammation, and, like the preceding, is caused by all kinds of irritation and individual predisposition: the latter it is impossible to explain.

The characters of pustular inflammation of the skin are heat, itching, circumscribed redness, and an elevation of the diseased surface above the skin; on this elevation is a vesicle, filled with serosity, first limpid, then reddish, as in some kinds of erysipelas, with the difference that in the latter the vesicle is on an uniform surface, whereas in pustular inflammation it is situated at a varied distance above the surface, and in relief. The vesicle empties, or is emptied by scratch-

ing; the fluid coagulates and forms a crust: it frequently also shrinks without emptying. The itching is the common character of circumscribed irritations of the skin, and was formerly, and, by some, is still attributed to acrid, saline, and acid salts, or humours; but any irritation of the skin caused by substances in which no such salts or humours exist—titillation with a feather for instance—produces the same effect.

On examining the skin, the redness is seen to be superficial, and the inflammation does not penetrate so deep as in boil: the two inflammations may, however, be complicated.

The propagation of pustular inflammation is effected by the multiplication of the pustules: they do not become severally larger, but more numerous, so as sometimes to extend over a great surface of skin, in which case, as the inflammation of each pustule approaches that next to it, and is mixed up with it, a kind of erysipelas ensues, and may itself be followed by phlegmon: this, however, is rare in pustules that do not owe their origin to a specific cause. The dissemination goes on as in the preceding cases: the irritation is repeated and propagated in the mucous surfaces and the nervous system, whereby febrile action is generated.

The pustular inflammations of the skin are known by different names; the most common is that of *dartres*, when they are independent of any specific agent. In fact, *dartres*, are pustulo-scabious inflammations *par excellence**. They do not at all suppose an internal inflammation, nor any virus nor infection of the humours, and they may be induced by all the causes of cutaneous irritation. They are favoured by the inflammatory disposition accompanied with a lymphatico-sanguineous constitution.

Dartres have received various epithets, according to the degree of redness they exhibit, the thickness of the crusts, their situation, their moisture or dryness, their obstinacy, disorganizing powers, &c. I shall, however, confine myself to the description of the fundamental characters that should afford indications for cure, and to proving to you, that though *dartres* are really pustular affections, it by no means follows that all pustular affections have a right to the name of *dartres*. For the rest, they take various modes of proceeding, either spontaneously disappearing without propagation, the inflammation ceasing, and the skin returning to its functions, though left in dry condition and in a state of lymphatic congestion, exhibiting a wandering character, pass-

* After this definition, I can conscientiously make use of the word *dartre*, which is not traducible into English. With the French every skin disease is a *dartre*; and *dartre* is every thing relating to the morbid skin. I never knew an Englishman that could say what *dartre* really means.—J. M. G.

ing from one point of the surface to another, being obstinately fixed in one part—an instance of which is *mentagra* which is a local irritation kept up by local stimulation—or terminating sometimes by gangrene, from the excess of inflammation, &c.

Regarding their propagation, they sometimes go on with surprising rapidity, and if improperly managed, may become transformed into phlegmons, cause indurations, disorganizations, incoercible ulcerations, and even take on the cancerous character. It is then that dissemination occurs: if irritation did not previously exist in the viscera it is developed there. Particularly in the digestive apparatus, and as the internal vasculo-nervous tissues are endowed with more activity than the skin, the irritation may leave the latter and concentrate itself on the viscera, and a change of disease occur. When death takes place in consequence of pustular or dartsous inflammation, it is not by the skin that it arises, but by visceral phlegmasiæ, frequently mixed up with sub-inflammations, as may be ascertained by dissection. In the skin you find different degrees of thickening, of lymphatic congestion, of disorganizations, and sometimes the sequelæ of phlegmon. When the disease is in the scalp, having the name of *tetter*, the same appearances obtain after death, and the same characters in life; it is vain to multiply individual descriptions and varieties—the phenomena are always identical.

The prognosis is plain; it rests on the intensity of the pustular phlegmasia; the more this tends to propagation and dissemination, the more are the viscera rendered liable. In general we may say that the danger bears a proportion to the external inflammation, and the part the viscera takes in it. If the cutaneous phlegmasia suddenly ceases with a stoppage of copious mucous secretion, an internal irritation in the degrees of inflammation or sub-inflammation is substituted. Danger also arises from the skin itself, from the itching and burning that prevent all sleep and obstruct nutrition; there may likewise supervene on the sub-inflammatory shade thickening and impermeability of the skin, which becomes gorged with lymphatic fluids, whence a complete suppression of the transpiration, and disorder of the secretions and excretions, arise.

In the treatment of dartsous inflammations, antiphlogistics, local bleedings, general ones, if there is necessity for them, emollients, all kinds of demulcents externally; and internally a regimen suited to ward off super-excitation. The inflammation reduced and if the disease remains, though divested of its phlogistic character, it may be well to have recourse to topical stimulants or astringents: these are numerous, but the sulphurous preparations rank the first. In short, the greater the inflam-

mation, the more necessity is there to employ local antiphlogistics and emollients, and to guard the viscera from invasion by it. If while diminishing it in the skin, the inflammation increases internally, you must proceed with all speed to recal it to the exterior, and stay the progress it is about to make or has made in the viscera. Then after it has been sufficiently combated in both its situations, the indication is counter-stimulation, that artificial stimulation opposed to morbid stimulation. Should an obstinate irritation in the skin persist, the specific treatment then becomes necessary, and consists in proportioning the modifying agents to the degree of susceptibility of the organ, and not in applying any determinate formula, flower, root, acid or oxide, to each particular form of the cutaneous affection.

Thus it will be seen that stimulation is only proper to change and destroy the old inflammation when it has been already diminished to a certain point by demulcents and local evacuations. If this be attained, the inflamed point supports a stimulation which it previously could not have done, and which is effectually curative. This fact is undeniable; if you dispute it you give your adversaries room for insidious objections and opportunity of driving you into contradictions. In general, facts should be taken as they are found, and we must not confine ourselves to the consideration of a single order of phenomena: they should afterwards be studied according to the philosophical rule, not in a speculative but a practical manner. For in medicine we have two chief methods of philosophizing: one which considers the history of the science in order to follow in it the processes of the human mind, when occupied in the investigation and verification of the notions of which medicine is composed, and this is the philosophy of the history of medicine; and another, which by gradual approximations demonstrates the analogies and identities presented to us by an infinity of facts, and this is the philosophy of practical medicine, or of the life of the human body; this is the philosophy to which we now adhere, which if we do not, we shall be lost in a fatiguing system of empiricism, which multiplies objects like grains of sand, so that no human intellect can contain them. Wherefore are these approximations objected to when it is so evident, by comparing the means employed in the treatment of the affections under consideration, that they are all referable to the leading idea that I have just laid down: namely, that the inflammation once extinguished, and the irritability or nervous condition once combated simultaneously or successively by narcotics, we must next have recourse to stimulation, if the habit of vicious secretion persist, and this stimulation being effected by astringents, metallic salts and oxides, sulphurous preparations, caustics, in short by all the sub-

stances mentioned under that head in the *Materia Medica*, and to which appropriately made compression may be added? The main thing is to know when to choose the time and the degree at which stimulants are appropriate. To this must be added the precaution of keeping the irritated part from the contact of the air by warm clothing, and also that of not irritating the internal organs, so as to avoid chronic gastritis and enteritis, and not make people valetudinarian under the pretext of cleansing them. When the inflammation has become cancerous, or a scorbutic condition exists, you must not allow yourselves to be frightened with these words: the state in question is the consequence of ill-timed stimulation of the skin, and a depraved nutrition produced by an internal phlegmasia. If we can manage to reduce the disease so that it shall only occupy the skin, it may yet be stopped: wonders may be done in the treatment of cutaneous affections when the conviction is once attained that it is necessary to destroy the inflammation at any price; but in doing so avoid all empiricism. The most successful skin-doctors always follow the therapeutical plan I have laid down, and all the special treatises on cutaneous diseases advise the same; time and experience will show you that I am right.

—o—

MEDICAL EDUCATION.

Evidence given before the Committee appointed to inquire into and consider the Laws, Regulations, and Usages regarding the Education and Practice of the Medical Profession. Part I.

[This Part relates to the Royal College of Physicians.]

The first witness examined was Dr. Hawkins (Registrar of the College), the only important part of whose evidence is, that though a statute was enacted in 1772, qualifying "any Licentiate of 36 years of age and seven years' standing," as admissible to an examination for fellowship, yet no licentiate has ever been elected under this law; Drs. Wells, Sims, Stanger, and others having been rejected on the putting of the motions.

The next witness was Sir H. Halford, from whose evidence we make the following extract and summary:—

Sir Henry—being asked the origin of the bye-laws of the College which restrict the admission into it almost exclusively to the graduates of the English Universities, although that practice is not according to the original bye-laws of the College—replied that he thought that practice had originated from the original connection between the Universities and the College. The first founder of the College, Linacre, established

lectures at Oxford. The successor of Linacre founded a College at Cambridge, Caius College, and there has been a natural connection between the University and the College of Physicians ever since.

54. Has the College any reason to doubt the legality of confining the choice of the electors to the graduates of the two English Universities, there being no mention of any such restriction in the Charter and the Act of Parliament confirmatory to it? I apprehend the College is convinced that it does not necessarily confine itself to the members of the Universities of Oxford and Cambridge; there is a certain preference of those members in the mind of the Fellows of the College, for they are people who have undergone a moral and intellectual trial in the Universities from whence they came, to which they are not subject at the foreign Universities. They are domiciliated at Oxford and Cambridge, but not at Edinburgh or Aberdeen, or any other University from whence they may come; and the reason, I apprehend, for the probation of ten years is, that those people who have not been so domiciled may have an opportunity of giving proof of their moral qualifications, as well as their intellectual ones. That is the reason of the preference of the members of the English Universities in the minds of the fellows for the election of licentiates into their body.

96. How do you account for licentiates having been admitted according to the statute on the proposal of the president, and none having been admitted under the statute on the proposal of a fellow? I know not any reason, excepting that on the proposal of a fellow the licentiate is to undergo an examination, on the proposal of the president he is not examined.

99. Did you exercise the privilege as president of recommending a licentiate for admission last year? No, I did not last year. I have done it within this last fortnight, and I will state fairly before the Committee that if I had seen a person of extraordinary eminence, who was entitled to that distinction, I would have done it last year.

101. Was not Dr. Wilson Phillip (the person you have selected for admission into the College this year) as celebrated for his discoveries in physiology last year as he is this year? I believe he was; but there was a controversy going on at the time with an eminent person with whom he was engaged—and perhaps it was better to let that be determined before he was proposed.

In answer to the question as to whether pains are taken by the College to inform itself of the course of medical education which the graduates of Oxford and Cambridge, soliciting admission into the College, have passed through; or whether they merely go through an examination into the three departments of physiology, pathology, and therapeutics—Sir Henry stated

that they were examined in two dead languages, in anatomy, physiology, pathology, and the practice of physic; but that the College did not require that they should have gone through any regular curriculum of study, nor that they should produce testimonials from professors of the course of lectures they had attended; nor to have attended any course of hospital practice; because if the candidate "is well acquainted with the theory of physic, it affords a good presumption that he will acquire practical knowledge in time." Neither is the candidate examined as to his knowledge of midwifery (though he is expected to know the diseases of women and children), nor upon the practice of surgery.

201. Have the bye-laws ever been suspended for the purpose of admitting a king's physician to be a fellow of the College? No; there was an instance, some ten years ago, of the king desiring to make a licentiate his physician, and he spoke privately to me, and said "You had better make him a fellow of the College." He was proposed by me as president, and was elected.

203. The preamble of the statute for the admission of fellows into the College by the president is this—"Quando quidem fieri potest ut inter permixtos numerentur viri quidam egregiis et de re medicâ preclarè meriti, quos statutum, nostrum de sociis in ordinem sociorum cooptari vetat." Was the principal point in which the candidate was one of the "egregii et de re medicâ preclarè meriti," that he was physician to the king? No; I beg pardon, I do not know that we have a more intelligent or able fellow of the College than this gentleman is. It might be so far a recommendation that he was a physician of the king. He was a physician of a considerable hospital at the time, and he had acquired a certain degree of eminence in the country before he came to London, and was living in the good esteem of the whole medical profession.

204. How did it happen that his qualifications had not already recommended him to attention, and occasioned his being admitted a fellow of the College by the exercise of the president's privilege? There might have been others who appeared to the president, short-sightedly perhaps, even more talented than that individual—elder men.

225. Does the statute of the College still exist that none engaged in the practice of midwifery shall be admitted as fellows of the College? Certainly.

226. Therefore none of the censors of the College, whose business it is to examine those who claim a license, can have a practical knowledge on the subject of midwifery? That does not follow; they have attended in their studies through the hospitals as well as others. It does not follow that they are ignorant of that; they have every knowledge of the *homine nato et non nato*. The

reasons the College gave, I presume, were satisfactory in the eyes of the Secretary of State, who referred it to the College.

231. Since, according to your own statement, midwifery forms one of the subjects of the examination of the College, would it not be desirable to repeal that bye-law which excludes from admission into the College any person engaged in the practice of midwifery? No, I do not think it is expedient.

232. Will you state your reasons? I think it is considered rather as a manual, and we should be very sorry to throw anything like discredit upon the men who had been educated at the Universities, who had taken time to acquire the improvement of their minds in literary and scientific acquirements, by mixing it up with this manual labour. I think it would rather disparage the highest grade of the profession to let them engage in that particular branch which is a manual operation very much. As to all the knowledge of the diseases of women and children, it is expected of us, and we hope we are thoroughly informed of them.

234. If the admission to the fellowship were restricted to those of good moral character and of good education, would it, in that case, tend to lower the character of the College? I think it would be better not; it has never been done. It has always been objected to. There is a sort of manual operation, a sort of surgical operation, with the practice of physic, which, we think, does not quite accord, and we are sure it is not necessary.

The whole evidence before the Committee agrees in the opinion that there should be an uniform standard of qualification, and a general Board for conducting the examinations of those about to enter upon the practice of the profession. The honours and the appointments should be afterwards distributed according to individual talent, merit, and experience. It may be perceived that the expense of becoming a surgeon in London is at present ample to the attainment of the highest qualifications, but from the over-reaching spirit of monopoly, neither the student nor the public receive an adequate return.

We may at some future time give an analysis of the evidence of the voluminous volume before us; but as the same questions were asked of all the witnesses, such repetitions occupy a quantity of space which Medical Journalists cannot appropriate to it. We have given a summary of the conclusions of all the evidence of the fellows and licentiates of the College of Physicians. All were reformers, but some few very moderate ones. But since the publication of the evidence, the College has repeatedly met on the subject of reform, as we have already informed our readers

[Part II. relates to the Royal College of Surgeons.]

The first witness examined was Mr. Guthrie, as President of the College; and his evidence occupies more than 80 folio pages. It is but justice to state, that he explained and defended the proceedings of the College with great ability. He produced a vast deal of documentary evidence to prove that the College acted in accordance with opinions of different chancellors, chief justices, and the most eminent barristers of the different periods to which he referred. It appears from his evidence that the College would have been much more liberal, if their charter allowed them.

The following occurs in the evidence of Sir Astley Cooper, Bart.:—

5506. What is the present expense of hospital attendance in London?—There are three classes: the first is the apprentice, who usually pays £500 or £600 to be boarded and lodged in the house of the surgeon to whom he is attached.

5507. Do you mean of the hospital-surgeon?—Yes. The second is the dresser, who pays £50 for the advantage of dressing for 12 months. The third is the pupil, who pays £26. 5s. to be considered as a perpetual pupil, but, in reality, to enter only for 12 months: because it was thought right to hold over him, if he did not conduct himself properly, the power of disposing of him at the end of the year.

5510. Would the £500 or £600 include the whole expense he would have to pay for the run of the hospitals?—No, he has to enter for lectures of different kinds besides.

5512. What is the minimum expense incurred by a surgical student studying in London?—As an apprentice, it would cost him £2,000 for the six or seven years of education, before he could embark in practice. That is about the sum which a man ought to calculate that his son would spend under such circumstances.

5513. What class of practitioners is it whose education would cost that sum?—A person designed to be a surgeon in London, a surgeon of an hospital in London, and a lecturer.

5514. Can you give the items of which that sum would be composed?—The board and lodging, if he be apprenticed, is paid for at once upon his entrance; that is £600. The going to Edinburgh would cost him a considerable sum, and the going on the Continent, according to my system of education, a further sum.

5515. Then the £2,000 includes the cost of the year at Edinburgh, and the year at Paris, &c.—Yes.

5516. Supposing him educated for a general practitioner, and in London, what would the expense then be?—I should say from £200 to £300.

5517. Including the expense of the li-

cense of the Apothecaries' Company, and of the diploma of the College of Surgeons?—No, I do not include those; but £300 would cover the whole, if he were a prudent man.

The suppression of irregular practice and empiricism would be a desideratum to the profession and the public; but as experience has shown the best educated men in society to be the greatest patrons of quackery, attempts at its suppression by legislative enactments might serve only to render it of greater importance. The charlatans of London derive great advantage from the opposition of medical men. It would, perhaps, be advisable to lay a heavy duty on secret medicines, and inflict, according to the offence, fine or imprisonment on those who practise under a false title and without due qualification; or, as Mr. Guthrie proposed, to make them take out a license for the destruction of their dupes, similar to that for shooting game. In this way, if the state should suffer in its members, it would gain in its revenue.

The regulation of fees is a subject which must be attended with extreme difficulty, as well in proportioning them to the experience and standing of the practitioner, as to the circumstances of the patient. On this account, much must be left to individual discretion; but it is essential to the respect necessarily due to men taking charge of human life, that they be paid in fees like gentlemen. The apothecary is at least as honourable a member of society as the attorney; and should, like him, be legally entitled to his fee. The present practice of charging for the quantity of drugs, for the most part needlessly forced upon the patient, is an abomination. In most cases the drugs are of mere fractional value, and though an attractive colour be given to the useless contents of the phial, on paying the bill, suspicion, disgust, and ill-will are frequently excited towards the medical attendant. Were the system of paying the practitioners an annual salary, instead of occasional fees, more generally adopted, it would tend much to harmonize the profession with the public. The following extracts, from the evidence of John Scott, Esq., deserve attention:—

6373. Ought the education of the surgeon and the education of the physician, to run *pari passu* to a considerable extent?—I think, throughout the whole extent, from beginning to end. No man ought to practise surgery that is not qualified to practise medicine.

6388. Is the distinction, undefined as it is, that is made between the two departments of practice, a useful one?—Yes, to attain eminence, in any particular branch, a man should devote a considerable share of attention to that branch.

6389. Though the education of the phy-

sician and of the surgeon should be the same, you think that science and practice will be brought to greater perfection if some professedly devote themselves to physic, and some to surgery?—Yes, after having each thoroughly studied the whole.

6390. Were surgeons and physicians to be united in one common profession, would not the public, unaided by any distinction of professional title, be able to discover who the parties were that were best able to operate, if necessary—and who to advise, as to the nature and treatment of any internal complaint?—They do so now; and I believe are equal to do so.

6391. Do you approve of the present constitution of the Council of the College of Surgeons?—No.

6392. What alterations ought to be made in its constitution; or, if you contemplate some general Board to superintend the whole of the profession, state your views upon that subject?—I think there should be an amalgamation of the three divisions under one superintendence.

6394. I consider that the science of medicine is one and indivisible, and that therefore it is proper to unite, in the way I have suggested, the Boards who examine upon it. It seems to be wrong that the physician should be examined only in physic, the surgeon only in surgery, and the licentiate apothecary only in medicine and pharmacy: They ought all to be examined on all the three subjects.

The feelings which the regulations of the College of Surgeons generate in the profession are thus plainly expressed by J. C. Carpue, Esq.

6722. To what sort of practice is a professional man required to confine himself, in order to be eligible as a Member of the Council?—I know nothing of the College; I am so disgusted with it altogether, that I have not been near it for many years.

6723. The following is the description contained in the bye-laws of the College:—“No member of the College, whose professional practice is not confined to surgery, shall be elected a member of the Council.” And again, “Any member of the Council that shall not confine his professional practice to surgery shall be liable to removal from the Council.” By reading over the list of the College, would you be able to say how many of the members actually come under this description?—There are ten thousand names to read over, and I am not acquainted with many of the members. There are 10,000 members governed by twenty-one.

6724. Would any come under this description if interpreted strictly?—I almost doubt it.

6728. But if they were to act strictly according to their own bye-laws, most of them would be found disqualified to sit on the Council?—Most of them I think.

Whatever differences of opinion may exist with regard to minor questions, there are certainly leading reforms in our medical institutions, the necessity of which the impartial reader of our report will at once admit to be of self-evident demonstration.

1. The abolition of restrictions of the College of Physicians in favour of the English Universities.

2. The demolition of the *imperium in imperio*, which the fellows have established in the mode of electing the members of their own body and their president.

3. The establishment of a Board of Examiners, whose members, chosen equally from the three departments of physic, surgery, and pharmacy, should investigate the candidates' knowledge of each, and leave to circumstances and his own discretion the choice that he would pursue in practice.

4. The equalization of the qualification of the three Metropolitan Colleges—London, Edinburgh, and Dublin; and the privilege to their several members to practise in any part of the United Kingdom.

5. The institution of annual examinations in each branch to which a student may profess to apply himself, in order to withhold his certificate when found deficient.

6. The limitation of hospital appointments to a certain number of years, so that experience might be diffused through the profession. The elections to be decided by merit, not by patronage.

7. The preliminary education to be tested by examination previously to the commencement of studies purely medical.

8. The professional attendant to be paid for his advice and skill, not for his drugs.

As the advantages which the public and the profession would derive from these changes scarcely admit of question, it is needless for the present to enter upon the discussion of their merits. We are prepared, however, for a further exposition of malpractices, and also the suggestion of remedies in detail when the important subject of medical reform will be debated in the legislature. The existing medical, like other corporations, are the strongholds of injustice and fraud—they must be reformed altogether. Institutions must conform to the times, or be overturned by the weight of that intelligence which is at present pervading and penetrating society to its depths.

—o—

DUPUYTREN'S CLINIC.

Cysts, with Osseous Walls, developed in the Bones.

M. DUPUYTREN has more than once called attention to this disease, which he was the first to describe accurately. If fibro-cellular tumours, he observes, are very frequently developed in the soft parts, and especially in the

walls of the uterus, similar tumours may also occur in the substance of the bones. A contusion—an injury of any kind, may implant the germ of these tumours; and when once their birth has taken place, we can have no difficulty in understanding their growth. They are united to the surrounding parts by a peduncle, through which they derive nourishment and life. Their growth is the consequence of the nourishment thus afforded; and the increase of size causes the layers of bone to separate. But though we readily conceive that a *solid* body interposed between the bony plates may, by its progressive increase of size, separate the layers, and distend them to an indefinite degree, it is less easy to understand the development of cavities containing only a *fluid*; and especially how this fluid can act so forcibly as to distend the substance of the bone. Such, nevertheless, is the fact. I have observed numerous examples, either in the extremities of the long bones, in the bodies of the vertebræ, or more frequently still in the bones of the face; as in the superior and inferior maxillæ.

The matter contained in these cysts, we have already observed, is either solid or fluid. The following is a very remarkable instance of the first.

CASE I.—Osseous Cyst, containing a Fibro-cellular Substance.

It is now twenty years since a young man presented himself at the Hotel Dieu, with a voluminous tumour of the right horizontal branch of the inferior maxillary bone, elevating the cheek. He had been educated with a view to the ecclesiastical profession; but on account of this deformity he was refused admission. M. Dupuytren carefully examined the tumour, and satisfied himself that it was situated in the bone itself. On pressing the tumour, which had an oval form, he perceived a slight crepitation, such as occurs when paper is crumpled between the fingers, or, better still, on crushing a piece of very dry parchment. The perfect conviction he had acquired of the existence of a cyst with bony walls; the absence of any lancinating pain, or fungous excrescence; the youth and perfect general health of the patient, and his ardent desire to be relieved of a malady which presented an invincible obstacle to his profession—all determined M. Dupuytren to operate, and convinced him that he had not an osteo-sarcoma to deal with.

The angle of the mouth, on the right side, was freely divided; and the incision was continued along the body of the inferior maxillary bone. A similar incision was also made in the inside of the mouth. The osseous cyst being penetrated, a little reddish-coloured serosity spurted out, and a fibro-cellular mass was perceived, and partly extracted by the aid of forceps. Suppuration dislodged the

rest; and by means of repeated injections, a cure was soon obtained. The sides of the cyst gradually approached each other; and there remained but a trifling deformity—a little elevation, and slight cicatrix of the skin.

We shall now relate two very curious cases of the second class of osseous cysts—those containing liquid matter.

CASE II.—Cyst with Osseous Walls, containing a Sero-sanguinolent Fluid.

About three months ago, the sister of a physician in the neighbourhood of Tours, a lady between twenty and thirty years of age, came to consult M. Dupuytren for a tumour, of the size of a hen's egg, in the right horizontal branch of the inferior maxillary bone. The patient believed herself to be affected with an incurable malady—an osteo-sarcoma. M. Dupuytren examined the tumour; and the absence of any symptom of osteo-sarcoma, such as lancinating pain, varicose, degeneration, &c. joined to the crepitation which was distinctly perceived on pressing the walls of the cyst, induced him to encourage the patient with better hopes of the issue of the disease. Delighted with the hope which the surgeon gave her of being cured, the young lady earnestly entreated the performance of the operation which he told her was necessary.

The tumour projected more into the mouth than externally; and pushed aside the tongue. It appeared to have arisen from the incomplete extraction of a carious tooth. An incision was made within the mouth, along the side of the tumour; and on the latter being opened, a great quantity of sero-sanguineous fluid was evacuated. At the bottom of the cyst, a solid mass was perceived; and on drawing it out, it was found to be perfectly analogous to adipocere. It was, in fact, adipocere, and probably arose from the transformation of particles of animal food, which had found their way into the cyst through the socket of the tooth which had been drawn. Injections, poultices to the cheek, venesection, and low diet for a few days, effected a cure. No tumour or deformity remains.

CASE III.—Osseous Cyst, containing a Sero-purulent Liquid.

The success of the case last mentioned, brought to the Hotel Dieu, shortly afterwards, another young female, affected apparently with a similar malady, and expecting, not unreasonably, a similar cure. The tumour, oval in shape, and as large as a hen's egg, was developed in the substance of the left ascending ramus of the lower jaw. Its growth had been slow, without lancinating pains, without fungous excrescences, and without change of colour of the skin. The tumour projected most internally; and its position required a difference in the mode of

operating. As in the other two cases, the existence of crepitation was at first very evident. Many persons perceived it; but repeated pressure of the tumour by a great number of hands, caused it to disappear. M. Dupuytren, sure of having perceived it, attributed its disappearance to its thin sides being forced in upon the contained parts, in consequence of the frequent contact it had sustained.

When the patient was brought into the theatre, a new examination confirmed the results of the previous ones. Even the crepitation which had been absent for a time, again became manifest; owing, no doubt, to the elasticity of its sides. An incision, about an inch in length, was made along the posterior border of the masseter muscle, commencing a few lines below its middle, in order to avoid injuring the vessels and facial nerve, and continued to near the angle of the jaw. The lips of the wound being held apart, the tumour was seen and felt, covered by a membrane which M. Dupuytren was induced to believe was of a serous description, and which to the touch was soft as velvet. No inequality or excrescence was perceived on the tumour; the surface of which was every where smooth and regular. In form and volume, as nearly as could be judged, it resembled an egg. A stroke of the knife then divided the anterior wall of the cyst, upon which a sanguinolent serous liquid flowed out in abundance. No solid substance was discovered. A tent was introduced between the lips of the wound, in order to prevent union. Repeated emollient injections into the cyst were ordered to be made; a poultice to be applied to the cheek; and bleeding from the arm to be practised—provided (which did not, however, appear probable) this simple incision of the soft parts and of the tumour, should give rise to any general or local symptoms, sufficiently violent to demand active measures. If, when suppuration had taken place, the pus should collect, and the opening already made should not be sufficient for its discharge, a counter-opening was ordered to be effected, at the most depending part; and that is the worst the patient need anticipate for obtaining relief from a malady, which she long thought incurable; and of which, probably, in one or two months, scarcely any traces will remain.

Since the operation, no unfavourable occurrence has taken place. Thanks to the introduction of the tent, the wound has continued open; and whether in consequence of the repeated injections which have been made, or of the irritating contact of the air, or of both causes combined, the interior of the cyst is suppurating abundantly. At each injection the water which first leaves the syringe, is returned thick and loaded with healthy pus; but at last the water returns clear, and the cyst is completely emptied. Slight redness and swelling have appeared in the cheek,

about the circumference of the opening. At present this redness is not alarming; not being of sufficient intensity to make us dread the supervention of erysipelas. The patient feels pain more or less severe in the cyst; and the distance of the sides appears already to have somewhat diminished. M. Dupuytren is determined not to employ any artificial means of compression to bring them together. The situation of the tumour, indeed, ought to suffice for this. Pressed on one side by the pterygoid muscles, and on the other by the masseter, it can scarcely be doubted that the forcible and sustained action of these muscles, joined to the suppurative inflammation in the interior of the cyst, will bring together its sides, and will efface all deformity, except that arising from the cicatrix of the wound, which the position of the tumour rendered it necessary, should be made externally.

The cases which we have just detailed, have given M. Dupuytren an opportunity of insisting on the diagnosis of tumours of this kind; and in particular of establishing the marked differences which exist between these tumours and osteo-sarcoma, with which a superficial examination may confound them, but from which it is nevertheless so important to distinguish them. Osteo-sarcoma, he observes, is attended from the beginning by lancinating pains, by varicose tumefaction, by fungous degeneration, and by numerous inequalities. In these tumours, on the contrary, the surrounding parts do not participate in the malady; the surface of the cyst is smooth and regular, and its growth is indolent. Osteo-sarcoma is developed quickly, the increase of these tumours is much less rapid. Osteo-sarcoma is traversed internally by splinters and fragments of bone; such fragments are never found in tumours of the other kind.

As to the crepitation we have described, which is never observed in osteo-sarcoma, and which is a symptom almost pathognomonic of the tumours in question, it greatly resembles, says M. Dupuytren, that which I have observed in those tumours of the hand which are divided into two parts, by the anterior carpal ligament; one part being anterior or inferior, and the other posterior or superior. There is this difference, however; that in the case of the latter, the crepitation is owing to the shock, which the tumours when displaced receive, on striking each other.

**EFFECTS OF THE NEW POOR LAW ON
THE MEDICAL PROFESSION.**

—
“Homo sum humani nihil a me alienum
puto.”
—

*To the Editor of the London Medical and Sur-
gical Journal.*

SIR—Well knowing the spirit of philanthropy which breathes in your every effort to advance the interests of the community, so far as it relates to the advantages which medical science is capable of conferring, as well as your equally laudable exertions to maintain, unimpaired, the rights, and to promote the interests of the medical profession, allow me, through the medium of your scientific and ably conducted Journal, to make a few observations on the provision made for the *sick poor* under the new poor law amendment bill. It is not with the legislators of this measure that I would complain, but rather on the other hand I would willingly give them credit for the best intentions in the formation of it—having done so much in the cause of reform as they have—and I rather believe that the majority of observing men will admit the principle of the bill to be good, so far as its proclivity goes to re-establish that praise-worthy independence which existed amongst the once happy peasantry of this favoured land, the partial, or utter extinction of which salutary feeling, all must deeply regret, though this state of things is referable in a very great measure to the mal-administration of the poor laws under the old system; but it is with those who are authorized to carry the various principles which this measure embodies into execution, that I would remonstrate; and more particularly as it relates to the provision that they are making and ostensibly intend making generally for the sick poor; with these intentions there is justifiable cause for complaint, notwithstanding its being admitted that those who have given the slightest attention to the administration of the poor laws, must long since have been convinced of the necessity of some change in the law, which had for its object a due provision for the poor, but bearing in mind that the abuse of the best thing is the worst; hence in effecting this desirable change, no barbarity or inhumanity of feeling should have been developed—no, not even should there have been any thing approximating to a pathetic indifference manifested in any provision it may be necessary to make for the relief of the *afflicted* poor; but this unhappily has been done; and the question I ask is, why, in the making of such a provision, should an act of the grossest injustice be done towards the suffering poor, and the stamp of degradation sealed on the medical profession. Philosophers, from the earliest to the latest periods of our history, have at-

tested that the study of medicine is the most abstruse, noble, and dignified, that can engage the mind of man; and that to be able to practise it successfully, it must be known scientifically, and to acquire this knowledge is no easy task; there must be brought to it unceasing study, unremitting application—yes, the medical man, to be a medical man, in the strictest acceptation of the term,

“Must toil by day, by night that toil repeat,
And yet, alas! what mighty fruit he gains,
A beggar's harvest glean'd by mighty pains.”

And is it not then, allow me to ask, Sir, a degradation to the medical profession, to give its members that may be called upon, or selected to attend the sick poor, a very far less salary than those who have to discharge irresponsible duties in comparison with those of the medical man; and it is alike degrading that the sick poor should be marketed out in the way as it is ostensibly the intentions of these poor law commissioners to do: for the suggestions and opinions of the persons called guardians are subservient to those of the commissioners; and the guardians, too, are selected from the immediate neighbourhood, and consequently more cognizant of the wants, and more conversant with the feelings of the poor. We find that medical tenders are advertised for, for several unions and respective districts, situated in unions of too great an extent to be attended by one medical man; but be it remembered, that the places so situated as to require the dernier resort of advertising for medical tenders, are generally those where the resident medical men have in a body indignantly refused the terms of remuneration proffered by the poor law commissioners, justly concurring as they do in the supposition that it would be most unprincipled conduct on their parts, and such as would engrave indelible disgrace on their characters as medical men, to accept of an altogether inadequate remuneration, for the length of time they would be called upon to sacrifice, the supply of medicines, &c. which an attendance on the poor would necessarily require of him. But what has been the consequence of this justifiable indignation on the part of medical men, in some places? Why, a mere adventurer has been introduced by these poor law commissioners, and perhaps without even a very *strict* inquiry as to his eligibility to discharge the duty of medical attendant to the poor; and what were the conditions or terms offered by these sub-administrators of the law to the resident medical men in many places? Why! ye gods, will ye believe it! Two shillings per head; and the best terms that could be made with them were two shillings and sixpence, not for the pauper poor as a body—for then, by putting the healthy in the balance against the sick, the thing would have been somewhat equalized;—but no, for the sick poor only

and these not to exceed a certain number in each parish—to use a paradoxical phrase now prophetically short-sighted—to decree the number that are to be sick. I presume it must be thought that we have no such things as epidemics, or that we are to be henceforth entirely free from them. So that if the sick in each parish exceed the stipulated number, those over and above such number the medical man must attend gratuitously, if it may be so called in contradistinction to the stipulated number that would, with *such terms* of remuneration, receive an attendance scarcely a remove from the gratuitous. And why should the medical man be expected to labour gratuitously? Would it not be as rational to expect a clergyman to attend to the spiritual wants of his parishioners without an adequate compensation? There would be quite as much justice in the one as the other. But is it, I would inquire, possible for any man duly to attend poor creatures resident five or six miles from him, requiring daily attendance, perhaps for weeks; and by way of illustration, we will say labouring under enteritis, gastritis, cerebrites, pulmonic affections, &c. or any of the other formidable ills human nature is daily liable to? And I would hope that there is not a human breast that would have the hardihood to deny the beneficent, the assuaging, the truly charitable protection which medical science so extensively affords to society against some of the severest of human calamities. But how can this protection be rendered available to the poor; for it is utterly impossible for any medical man to do justice to the poor so distantly situated, for the despicable remuneration of two shillings and sixpence for twelve months' attendance, should the patient require it. Hence the deduction that the poor wretches must in many instances be necessarily consigned to fate; and in the majority of cases a painful fatality would attend the consignment. And could we bring before our view Hamilcar offering a solemn sacrifice to the sanguinary divinity of Carthage, he could not have enjoyed a higher degree of exultation over his human victims, than the providers of such means for the alleviation of the sufferings of the afflicted poor may boast of. Let the poor but honest man be asked, what description of parochial assistance he most appreciates, and he will tell you unhesitatingly, the "medical;" and it is not inhuman nature to suppose that he will tolerate the deprivation of that which he prizes so highly, "sub silentio;" and the daily accounts we have through the medium of the press, afford incontestible evidence of this fact, as well as the great difficulty there will be of carrying the principles of the new poor law amendment bill into full operation. And why do these sub-administrators of the law thus exert themselves to create a rebellious and disaffected feeling in the minds of

the poorer classes? It is said that a noble peasantry is a country's pride; but as it relates to England, I fear the saying will not be strictly applicable, ere long, if the ruling powers exhibit an indifference to their necessities—for the old adage is "*insita hominibus natura violentiæ resistere.*" Let us no more boast of our national philanthropy in voting away twenty millions of our money for the abolition of slavery in our colonies, when too it was matter of conjecture with many of its warmest advocates, as to whether those to whom the boon was given, were sufficiently advanced in a state of civilization to be enabled fully to appreciate the blessings of freedom—let us, I say, not boast, if we have effected this good at the expense of putting our own poor in a worse state of bondage; for freedom is next to being useless, if the free poor are deprived of the means of existence. Life is valuable, but health is still more so, and more particularly so to the poor. But what shall be said of the feelings of the poor; words are inadequate to express them when their health is invaded by disease, and they are without claim to that aid which has for its grand object its removal or alleviation. Let them not be deprived then of that friend, who is the friend of the destitute, who by his unwearied attentions smooths the pillow of the dying, inspires the desolate with hope, and whom the hollow eye turns to behold as, and the haggard lip to pronounce as, the dispenser of good. But it may be said that they cannot suffer from such a deprivation, while hospitals, infirmaries, dispensaries, &c. are so numerous; but let it be remembered that these are not in every place; and it is much to be regretted that they are not more abundant. Would it not, allow me to suggest, have been advisable, in the absence of a better provision, and leaving the medical man without a *fixed and a fairly remunerating* salary, to have introduced a clause in this new poor law amendment bill, enforcing the formation of a self-supporting dispensary in every place having a certain number of inhabitants, to which the poor should contribute according to their means; and if they had not a mite to contribute, let them not on that account be deprived of its advantages? To such institutions there always are many honorary subscribers; and let each parish be obliged to contribute a sum annually towards its support, in a proportionate ratio with the amount of its pauper population; let the medical men resident in the place attend on fixed days in turn, if they pleased, and receive an equal and fair remuneration out of funds so raised, for their time and labour. But I will not pursue the subject farther, but consign it to abler hands, having already trespassed at too great a length on your valuable pages; but the importance of the subject must be my excuse. We will hope better things; and trust that there is

not a government so callous or insensible to the ordinary impressions of humanity, or that could so brutify and drown feeling, as to weaken the gigantic strength of a nation like Britain, by a cruel perpetuation of disease amongst its poor.

I am, Sir, yours respectfully,

A constant reader,

June 3rd, 1835.

MEDICUS.

—o—
Reviews.

The Cyclopædia of Anatomy and Physiology.

Edited by Robert B. Todd, M.B., Lecturer on Anatomy and Physiology at the Westminster School of Medicine, &c. &c. Part I. Royal 8vo. pp. 112. Illustrated by numerous engravings.

This work is intended to comprise the sciences of anatomy and physiology in the largest sense, as regards the animal kingdom. It will contain human and comparative anatomy and physiology, with animal chemistry. It will also include surgical and morbid anatomy.

It is the first work of this description that aspires to embrace in the most comprehensive sense the anatomy and physiology of the animal kingdom, with the general surgical and morbid anatomy of man. That great merit is due to those who conceived the plan of this work, no one will deny, and that still greater praise will redound to the editors and contributors, we entertain not the slightest doubt. Dr. Todd's *Cyclopædia of Anatomy and Physiology*, from the splendid array of literary and scientific talent engaged in it, comprising many of the most distinguished names in this country and in France, cannot fail to become a work of reference and authority.

The manner in which it is got up is very creditable to the publishers, whose high respectability ensures a similar continuation throughout the work.

It is however to be regretted that vegetable physiology is not included. Had this department of science been embraced, the work would be much more perfect than in its present form. Again, it excludes medicine, surgery, obstetrics, or legal medicine.

Dr. Todd's article on the Abdomen, which is graphically done in an anatomical point of view, occupies nineteen pages and a half.

The same article in the *American Cyclopædia of Medicine and Surgery* extends to thirty-eight pages; the physiological considerations relative to the abdomen a page and a half, the symptomatology nearly three pages, the pathology nearly forty-three pages. The one article fills twenty, and the other eighty-six pages. It may be said, in reply to this comment, the works are different, and therefore it is not fair to institute a comparison between them. We rejoin it is fair; because the description of the anatomy and physiology, without the pathology and therapeutics, renders the arrangement of the one much more complete than that of the other. As anatomy and physiology are the basis on which the superstructure of sound and judicious medical practice is based, the latter ought to have followed the former.

In recording these sentiments, nothing is more foreign to our intention, than to depreciate the merits of the work before us, as we really think that this part is most ably executed; and if the future numbers be as good, the work will be a most valuable one on the subjects of which it treats. We use the subjunctive mood here, as it may happen, as it did with another work of a similar kind, that some of the articles may be miserably executed. We do not however think, looking at the list of contributors, that this is likely to occur; because every one of them possesses sterling talent.

The first part was published on the 1st instant, and another will appear every other month until completed. The work is very well printed on superfine paper, double columns, and will be completed in about twenty parts. The writers in this part are Dr. Todd, Dr. Bostock, Mr. W. T. Brande, Mr. Owen, Dr. Cragie, Mr. B. Phillips, Dr. Coldstream, Dr. Symonds, Mr. T. Bell, and Dr. Grant.

Time does not allow us to analyse the articles in this part at present, nor are such the most interesting to the majority of our practical readers; but we shall, when our space allows, give extracts from this valuable work. It promises to be the most comprehensive system of human and comparative anatomy and physiology in our language. The descriptive anatomy is exceedingly minute, and the physiology

brought down to the present day.—The work well deserves a place in every medical library.

—o—

The London Medical

AND

Surgical Journal.

Saturday, June 13th, 1835.

TO OUR SUBSCRIBERS AND PROFESSIONAL BRETHREN IN GENERAL.

WE are now enabled to offer our grateful acknowledgments to our professional readers, for the warm support they have given us, and for the consequent extensive circulation of this Journal. They have as we expected, with one or two insignificant exceptions, advocated the course we pursued in refusing to fill the pages of a medical periodical with puffs about humbugs who assume the titles of our faculty. Fearless of the St. John Longs, the Ramadges *et hoc genus omne*, and regardless of the sordid meanness of men with whom it was our misfortune to be associated, we advocated and upheld the respectability of our profession, and never would prostitute our pages by lauding unprincipled and ignorant pretenders to, and unblushing dabblers in medicine. Our brethren could not fail to support us in this refusal.

It has ever been our main object to uphold the dignity, respectability, usefulness, and rights of the qualified classes of the cultivators of the healing art, convinced as we are that no other class in society contributes so much to human happiness. Actuated by this conviction, we have exposed the knavery of rash unprincipled quacks, who would impose upon the credulity of the world by pretending and professing to cure incurable diseases, and the degrading folly of their abettors. We directed the finger of scorn towards those who proclaimed, "Cancers, consumptions, and other incurable diseases, cured here." We too annihilated

cholera hunters, and their horrible quarantine, the offspring of dark ages and the fell destroyer of all the tender ties of humanity—we stood alone as non-contagionists from the first appearance of the cholera in 1831, when the Metropolitan Board of Health, not one member of which had seen a single case of the disease, were fighting the isle from its propriety; when the Medical Societies of the metropolis proclaimed contagion; when in consequence of this gross ignorance, fathers were to be separated from their children, and every tie of nature broken asunder in all this storm of ill-founded prejudice—we stood alone as non-contagionists. The disease appeared in Paris, and those affected with it were admitted into the hospitals—an advantage universally denied in London, with the exception of the Free Hospital in Greville Street. The physicians and surgeons of Paris, after the most ample and painful investigation, unanimously declared the disease to be non-contagious—Here was a triumph for us! We exclusively published the conclusions of the Parisian faculty, when lo! our Board of Health, Medical Societies, and cholera hunters, high and low were confounded. The public press universally promulgated this result, the contagionists became non-contagionists, and in 1832, when the cholera re-appeared, the public was freed from the egregious bug-bear of inexperienced Boards of Health, and the inhuman law of quarantine—"Here we did the state some service, and well they know it." Those we exposed became our enemies. One unjustly titled medical practitioner declared he would give five pounds for a rope to hang us; another fought hard to have us summoned before the College of Physicians for our delinquencies; a third proposed to erase our name from the roll of their College of Surgeons; a fourth thought to influence the Privy Council and persuade them that we had libelled the

government, and that his Majesty's Attorney General should proceed against us. All these sage counsels were however found impracticable; it was felt "that truth was great and will prevail." We defied and escaped all the myrmidons of power and stupidity.

We did not however escape the advocates of quackery. They brought us into a court of law, and through the instrumentality of a juror (who was expelled the court as an attorney for wilful and corrupt perjury), succeeded in amercing us in heavy damages. The profession, however sympathised with us; the independant part of it, assisted us in liquidating a demand incurred in their defence, and the result was a vast increase of support in subscribers to this Journal, and a great addition to our practice. Steady in the pursuit of the even tenour of our way, we refused to prostitute our pages to lauding quacks and impostors on the public. We were so incessantly urged by those whom we had the misfortune to be associated with, that we were compelled in defence of our own respectability, and the dignity of the profession, to dis sever our connexion with them. We then started unshackled, secured a host of talent for this journal, and by the generous intervention of those who held our former pathway to be the true one, we arrived at our present position.

To improve this as well as to improve the value of the periodical, to those who have up to this time supported it, we propose to enter upon a series of coloured plates, which while it will adorn the Journal, will also save our subscribers the expense of other and more costly though less finished productions in separate publications.

We are now enabled to state without doubt, or the possibility of failure, that we shall enrich this periodical with a series of highly executed coloured engravings on medical botany, diseases of the skin, and morbid anatomy.

The drawings on medical botany

have been made by a celebrated botanical draughtsman at the Chelsea Garden, and represent the plants mentioned in the British Pharmacopœias.

Those on diseases of the skin we have had executed from the splendid plates of Baron Albert, M. Rayer, Dr. Willan, Dr. Bateman, and others.

The series on the extensive field of morbid anatomy have been collected from various sources, and we now invite contributions from our contemporaries throughout the kingdom.

It has often been a source of great regret to us, that we were not allowed on former occasions to make this offer, and this arose from the opposition of our late partners.

We shall give a plate every fortnight without any additional expense, to our readers. We commence with medical botany, and shall, so soon as we have executed a sufficient number of plates on diseases of the skin and morbid anatomy, give these also in alternation. Thus we shall give twenty-six highly coloured and executed plates every year with this journal, for one pound six shillings, though the plates alone would cost double the sum. We expect that the addition of plates, to the variety and excellence of our matter, will obtain a patronage and circulation for this work never possessed by any medical publication in this country. We enlarge the sphere of usefulness to every member of our profession, by enabling him to contribute drawings and morbid appearances to the records of medicine. We shall commence the publication of the plates almost immediately, and continue them every fortnight, without the possibility of failure.

—o—

It appears that the French minister of public instruction has reserved to himself the choice of those who are to fill all the medical chairs that shall hereafter be formed by the government, thus throwing overboard altogether the election by concours. Though no friends to the concours as it is practised in France, we are still less inclined to

stand by the choice of French ministers, who are notoriously the most inveterately and unblushingly jobbing of their species in Europe.

—o—

LITERARY MERITS OF OUR HOSPITAL SURGEONS.

WE promised in our last to continue the critique of M. Baumes on the state of surgical science, as demonstrated in the hospitals of our metropolis. In accordance with that promise we proceed to quote his remarks on the questions, "What are the leading works on surgery that have been published by the London Hospital surgeons since the period of M. Roux's account?" and "In what degree have they aided the progress of science?"

"At that period Sir A. Cooper had already published the best and most original of his works, that on Hernia. This work is well known, and has been properly appreciated for a long time. His other researches, published about the same time, or since, and whose subjects are Luxations and Fractures, the Diseases of the Breast, of the Testicle, and a few others, though highly interesting on the score of pathological anatomy, are by no means equal to his first work, in really novel matter. The surgical talent of Sir A. Cooper is far above all the surgeons, old and young, that the London Hospitals contain, and he has justly taken a place among those who since the commencement of the passing century, have assisted in the progress of surgical knowledge.

"Mr. Lawrence had also written, at the date of M. Roux's journey, his Treatise on Hernia, and the latter gentleman has justly eulogised it as a work of method and erudition. And indeed this is its principal merit; and it was no small merit at that time, when positive data on the subject of hernia were as yet nowhere collected together so as to exhibit a co-ordinate system for the guidance of the student, and the instruction of the practitioner.

"Since then, Mr. Lawrence has written a Treatise *ex professo* on the Syphilitic Diseases of the Eye; and in 1833 a voluminous work on all the Diseases of that organ. It would be difficult to prove that these works have really been any gain to science. In fact we have been so supersaturated, before and since the

writings of Beer, with infinite divisions and subdivisions of the diseases of every part of the eye-ball, that authors would do well to drop the subject, unless they have something really useful and directly applicable to practice to communicate.

"Mr. Travers, of St. Thomas', has written nothing particular (*n'a pas écrit grand' chose*) in surgery since his *Researches on Wounds of the Intestines*, and the separative process of nature in them. The spirit of surgical observation he then shewed has since remained in an almost absolute state of sterility.

"Mr. Guthrie is known by his works on the Pathology and Surgical Therapeia of the Eye, and particularly by his interesting observations on Gun-shot Wounds, and the lesions that require amputation. But in his work on the Diseases of the Urethra, and Neck of the Bladder (1833), he has not shewn himself equal to the progress which this subject has made in other countries. Does it not shew him, for instance, to be behind-hand, when in speaking of cauterizing strictures, he brings against that method objections that are purely applicable to Home's process? The latter ignorant and dangerous proceeding is far different from that proposed by Ducamp, and from all the improvements since wrought in the operation. This part, therefore, of his Treatise, in which however he seems to regret the universal proscription of the cauterizing plan in London, is utterly incomplete, and scarcely one objection is advanced which is not either founded on false data, or which might not easily be overruled. All that he states, too, on puncturing the bladder by the rectum, and of the operation of puncturing the perineum in retentions of urine from contractions of the urethra, seems to have been written previous to the progress that surgery has made in latter years. M. Roux made some very just observations on the frequency of this operation in the London Hospitals, and since that time things have undergone no change.

"Sir Benjamin Brodie, whose name was among those that promised a brilliant career in the science and literature of surgery, has not equalled his promises as a surgeon and original writer; but as a fully occupied practitioner, he holds the surgical sceptre in the rich and aristocratic classes. A long time

age he published some Remarks on White Swellings of the Joints, which M. Roux considered very ingenious. At a later period he published a volume on the Diseases of the Urinary Passages, a fourth edition of which has recently appeared. Unfortunately he may be reproached—and such is the opinion of English surgeons that are capable of judging—with not keeping progress with the march of knowledge regarding the diseases of those important organs concerning which the last fifteen years have thrown so much light. His book is a kind of familiar conversation between a teacher and his pupils, wherein the former explains to the latter his own mode of practice, without bothering himself or them with what others think. He does not say a word on the history, the advantages and modes of proceeding in cauterizing; scarcely a word on lithotomy: very little more on the internal or medical treatment of affections of the bladder: nothing at all on the different kinds of lithotomy, except that which he himself employs. But, *en revanche*, he dwells at great length on the importance of not making too large an incision in the prostate, and particularly of not involving what he calls the cellular capsule that surrounds it, because it is an obstacle to urinary infiltration; and on the consequent advantage of gently dilating this moderate incision with the gorget on the fingers, &c. &c. This is his own plan of operation, and his professional brethren assert that he has less success in the operation than is obtained in the other metropolitan hospitals.

“ Mr. Mayo, except some Observations on the Diseases of the Rectum, has been mostly engaged in anatomical and physiological researches. But his last works, though not devoid of merit, sink before those of Sir Charles Bell.

“ Sir. C. Bell has not been so happy or so rich in his surgical productions as in his physiological discoveries. His works on the great operations of surgery, on the lesions of some parts of the osseous system, on the diseases of the urinary organs, though they exhibit the observing spirit and profound anatomical science for which he is distinguished, yet present nothing that is new, nothing that bears the stamp of originality possessed by his other writings. Being a talented and tasteful draughtsman he has abused his pow-

ers, and accompanied all his works with plates that are frequently more expensive than useful. For the rest, this abuse of plates is common to many of his confreres, with the difference that their engravings are sometimes worth more than the text. Bell is a man of simple tastes and far from wealthy: he is a man of genius, and it may be added, is neither understood nor appreciated by the majority of his hospital confreres.

“ There have also appeared some Memoirs by Mr. Key, on the modifications of the prostatic incision in lithotomy: of Mr. Arnott, on the Diseases of the Urethra, on a mode of dilating it with air, &c.: of Mr. Scott on the Application of Compression to Congestions of the Joints, an idea that is not novel, &c. &c.; but without refusing all merit to these surgeons, we must say that no original idea, no fundamental thought, on which inferences of any consequence could be founded, or which could assist in advancing the science, are developed in their works.

“ It may therefore be laid down as a fact, that no publication really out of the common order has issued from the London hospitals during the last few years. And this is also the opinion of those that are engaged in collecting all the discoveries of the art in England, and particularly of Samuel Cooper. This at once erudite and modest man told me, that meeting one day at an hospital with a surgeon who has since risen into great practice, the question was broached, whether any young surgeon could be found actually in office in the hospitals, on whom any justly brilliant hope could be grounded? and that after much consideration they could produce no name that answered to such a hope.

“ The rebuke that may be most generally addressed to the London hospital surgeons is, that they are ignorant of, and careless about what is passing in other countries; that they do not adopt what is really worthy of adoption, out of their own country; or that they make such frivolous trials of it, as to be induced early to abandon it and pursue their old track; and that they testify, in short, an unwillingness to acknowledge any utility in methods the advantages of which are everywhere else acknowledged.”

DR. GOLIS'S TREATMENT ON THE DISEASES OF CHILDREN.

We are indebted for the following long but valuable article, to the *Gazette Médicale*, of the 25th October 1834, and the 31st January 1835. It is an account of the practice of that distinguished physician, Dr. Gölis of Vienna, in the diseases of children, and was drawn up by Dr. Brosius, his pupil. We copy it from our contemporary, the *Medical Quarterly Review*.

Inflammatory Diseases.—According to Dr. Gölis, two thirds of the diseases of childhood are inflammatory; stimulants must therefore be administered but sparingly, and we must often confine ourselves, especially when the case is doubtful, to mild and gentle treatment. Febrile diseases observe a regular type, and the exacerbations recur at fixed hours; it is only occasionally that they are hastened or retarded a little. Inflammatory fevers are marked by a peculiar brilliancy of the eyes. If fevers of this kind are complicated with worms, they are sure to be attended by anomalous symptoms.

Pneumonia.—The pneumonia of children is recognized chiefly by the pain produced by respiration and coughing. The following is Dr. Gölis's usual prescription in this and other inflammatory diseases. *Rx.* Inf. Glycyrrhizæ rad; Decoct. Sem. Lin. āā ʒij; Potassæ Nitratis ʒj; Oxymel Simpl. ʒiss; M. summat coch. j. min. omni horâ. (For a child about two years old).

This mixture of an infusion of liquorice root and a decoction of linseed is the vehicle for the majority of potions prescribed at the children's hospital at Vienna. In private practice Dr. Gölis uses in its stead a decoction of the root of mallow or saloop. When resolution has taken place, the acetate of ammonia is substituted for the nitrate of potash, a drachm being added to the above mixture.

In the pneumonia of rachitic children, Dr. Gölis has a great predilection for the acetate of ammonia, because it stimulates a little; for in cases of this kind there is relaxation of the bronchi and accumulation of mucus. What Schöffer, in his treatise on the diseases of children, calls *pulmonary paralysis*, is, according to Dr. Gölis, a real bronchitis, and should not be treated with musk, but with leeches and blisters.

Angina Gutturalis.—(Cynanche tonsillaris). Dr. Gölis shows great dexterity in opening children's mouths, to look at the throat; he introduces his little finger into the mouth, and presses it on the base of the tongue. This causes an attempt at vomiting, opening the throat, and enabling him to satisfy himself as to the existence of an angina gutturalis. This disease is often accompanied by retching: when it is situated in the œsophagus, children keep their neck stiff.

We must never omit to look at the cavity of the throat, when cattarrh prevails epidemically, or we shall run the risk of overlooking many an angina. If this angina is accompanied by fever, nitre is to be given as in pneumonia. If there is no fever, the acetate of ammonia is to be given. Besides these internal remedies, the neck is to be warmly wrapped up, and covered with bags of medicinal herbs.

Angina Serosa.—This disease consists in swelling without redness, and is treated with the acetate of ammonia.

Angina Membranosa, or Croup.—When the appearance of croup exactly coincides with that of the eruption of measles, it is not to be feared; but it is dangerous if it appears while measles is running its course, or afterwards. When a child is affected with croup, he must not be suffered to sleep for more than half an hour at a time; he must be kept awake by continually giving him luke-warm drink. When calomel produces liquid stools, its use must be suspended for a short time; for if persisted in, it might easily cause an enteritis. The angina would disappear, but the child would inevitably be lost. We are not to use calomel with too much diligence, if the child is of a scrofulous habit, for this medicine might easily change a simple attack into a decided scrofulous affection. We must also beware of administering musk too soon against the remains of spasmodic cough, because if the slightest inflammation should still be present, this drug might cause a relapse. It is better to persist in the use of antiphlogistic remedies. The means employed by Dr. Gölis in croup are those adopted by all good practitioners: leeches, calomel, which is sometimes administered in the dose of a grain every hour, with sugar, besides frictions with a mixture of mercurial and mallow ointment on the neck and upper part of the chest; nitre in the intervals; emetics when the breathing is stertorous; and lastly blisters, which when employed in time, are, according to Dr. Gölis, the most powerful method of preventing membranous exudation.

The emetic which Dr. Gölis generally prefers for children, consists of Antim. Tart. with a few grains Ammon. Mur. dissolved in distilled water. He considers the sulphuret of potash as inefficacious and as difficult to administer, from the disgust which it excites, and therefore one with which we ought not to waste precious time.

Inflammation of the Cavity of the Mouth, or Stomatitis.—In this affection the acetate of ammonia is given internally. If there are small ulcers, they are to be touched with the following mixture: *Rx.* Mellis Rosæ ʒiss; Mucil. cydon. ʒj; M. Borax is too stimulating.

Difficult Dentition.—This affection is easily recognized by the rose colour of the gums,

which enlarge at the spot where the tooth is to come through. If dentition is very painful, it is often accompanied by an eruption, and in plethoric children, who have porriginous crusts upon their head, the porrigo sometimes increases suddenly.

Inflammation of the Spinal Marrow or Myelitis.—When a child presents the following symptoms, we may be sure it labours under myelitis. The body is quite straight from head to foot; the arms are strongly fixed against the chest; the fore-arms move but feebly in the elbow joint, but rather more in pronation and supination; the hand can sometimes be carried up to the chest, but rarely as far as the mouth. The lower extremities are firmly applied to one another in their whole length, and if we endeavour to separate them, the child cries. It also cries out loudly if the position of its body is changed, as, for example, if any one takes hold of it by the shoulder. The disease is also characterized by a great tendency to diarrhoea. Such are the symptoms of myelitis, before the inflammation attacks the brain, but when that is implicated, convulsions appear, and the diarrhoea ceases.

The treatment is antiphlogistic.

Acute Hydrocephalus.—If a child cries constantly from the day of its birth, if it eats a great deal, and the stools are greenish, if it lies quite straight in bed, and throws its head back, burying the occiput in the pillow, we may be sure that hydrocephalus will occur. When Dr. Gölis is apprehensive of this disease, he inquires if the children are cross, if they have become indifferent to what they most liked before, if they sigh frequently, and sometimes vomit, and if they often stare in a fixed and dreamy manner. A nasal utterance is also to be reckoned among the pathognomonic signs, and also the fact of the child's attempting to catch hold of things on one side. In a word, the look, the physiognomy, the gestures of a child threatened with hydrocephalus, are all full of meaning to the experienced practitioner.

A symptom never wanting in acute hydrocephalus, is a speedy diminution of the size of the abdomen. In children thus affected, the belly, however large, becomes flat during the inflammatory stage; and during the period of coma, this is the most certain diagnostic mark between acute hydrocephalus and typhus, in which the belly is most frequently tympanitic. However large the belly may have been before the disease, the bowels are so much retracted towards the vertebral column, that one might imagine that they had entirely disappeared. The most frequent causes are contusion of the head, concussion of the brain through falls blows, &c.

When the disease is merely suspected, calomel and tartar emetic ointment may be employed by way of precaution. Calo-

mel is generally the chief remedy in this disease; it is given in the dose of half a grain every hour or every two hours, or a grain every three hours, according to circumstances, such as the existence of constipation.

The application of cold lotion to the head, and the use of nitre in the inflammatory stage, may be continued without inconvenience when affusion has taken place; because (says Dr. Gölis), when this period has once arrived, nothing can do much harm. He says that cold affusions and the application of sulphuric ether to the head, which have been recommended by Formey in the stage of effusion, are of no use.

When acute hydrocephalus is accompanied by a watery diarrhoea, effusion does not easily take place. A favourable issue may also be anticipated if the child recovers the power of moving his head, and can turn it in every direction. It is well also to find the pulse losing its usual slowness, and becoming again regular and febrile: this is a sign of the commencement of absorption.

DISEASES OF THE CHEST.—*Simple Cough.*—When there is merely a simple cough, Dr. Gölis gives the infusion of liquorice root with the emollient decoction already mentioned, adding a few drops of Sydenham's laudanum and simple oxymel. If the cough becomes thick, instead of simple oxymel, he uses oxymel of squills. Thus, for a child two years old he prescribes \mathcal{R} . Inf. glycyrrhizæ rad; Decoct. lini. sem. (vel althææ) āā, ʒj; Laudani sydenhami, gtt. ij; Oxymellis simpl. vel scillæ, ʒiij; M. sit dosis coch. j. min.

When the cough is obstinate, or there is a neglected catarrh, Dr. Gölis strongly recommends dulcamara in the following form.

Inf. glycyrr. et decoct. emoll., ʒiij; Extr. dulcamaræ, gr. x; Laudani sydenhami, gtt. ij; Oxym. simpl, ʒij; M. The dose is to be a teaspoonful for a child two years old.

In the case of a child of four or five, who had an obstinate cough with fetid expectoration, Dr. Gölis gave a powder composed of equal parts of liquorice and vegetable charcoal, in the dose of a teaspoonful several times a day, and prescribed in addition a ptisan of lichen.

Convulsive Cough.—*Whooping Cough.* Dr. Gölis always treats whooping cough according to the prevailing character of the disease, and he teaches that we cannot be successful in the treatment, unless we know if the epidemic is of an inflammatory, catarrhal, or purely nervous kind. When there is no fever, and the disease is nervous, he prescribes \mathcal{R} . Moschi, gr. iij.; Extr. Opii. aquosi gr. ss.; Acac. gumm. pulv. ʒj.; Sacchari albi, ʒij. M. and divide in pulv. vj.; sumat j. tertiis horis.

Dr. Gölis also extols belladonna in whooping cough; but this remedy requires for its employment, that the disease should be

purely spasmodic, and not inflammatory, or catarrhal. When belladonna is indicated, he prefers the root in the following form: *Rx.* Bellad. rad. gr. j.; Extr. Opii. aquosi, gr. ss.; Sacchari albi, gr. lxxx. *M. ft. pulv. viij.*

One of these powders is to be taken morning and evening, or every three hours, according to circumstances, until the face becomes more animated.

At the same time he prescribes the following embrocation to be rubbed upon the epigastrium: *Rx.* Tr. Aromat. ʒss.; Laudani Syden. ʒss.; or the following mixture, which is spread upon soft leather, and applied to the region of the stomach: *Rx.* Electuar. Anodyn. Bellad. rad. pulv.; Laud. Syden. ʒʒ; Gum. Arab. ʒj.

A ptisan is to be employed, made of dulcamara, and the roots of liquorice and mallow.

In an epidemic hooping cough which occurred at Vienna in 1816. Dover's powder combined with emollients produced the most fortunate results, when administered as follows: *Rx.* Inf. glycyrr. rad.; Decoct. emoll., ʒʒ ʒiss; Potassæ nitr., gr. x; Pulv. Doveri, gr. j vel. ij; Laud. syden., gtt. ij; Syr. simpl., j. A teaspoonful of this mixture was given every hour to a child two years old.

Frictions with tartar emetic ointment torment children, and, for the most part, uselessly; and even when they lessen the hooping cough, the convalescence of the little patients is always protracted, principally because frictions of this kind destroy the appetite for a long time.

If there is no fever during the second stage of the disease, children bear cold drinks very well; otherwise, all their drink must be lukewarm.

Improvement begins as soon as the intervals between the fits of hooping increase. The disease is often succeeded by an obstinate cough, during which the children throw up sputa, as if they were phthisical. They should then take a decoction of sa-loop, fourteen ounces being made from fifteen grains, and an ounce of syrup of poppies added; and an infusion made of one ounce of mallow, and half an ounce of dulcamara and liquorice root.

Periodic Asthma of Children.—In this affection Dr. Gülis prescribes: *Rx.* Moschi, gr. ij; Mucil. acac., ʒij; Aq. tilie flor., ʒij; Ammon. succin., gtt. ij; Syrupi anthem., ʒss; *M.* A teaspoonful is to be given every hour to a child of a year old.

At the same time he orders warm baths, to which pearl-ash and an infusion of chamomile are added. The child remains a quarter or half an hour in the water, and is then immediately wrapped in warm linen and put to bed; the whole being done to promote diaphoresis. The potion is also given: *Rx.* Valerianæ rad., ʒss; Fiat inf., ʒij; tum adde; Ammon. succin., gtt. viij

ad x; Syr. Anthem., ʒss. At a later stage, blisters are applied to the chest.

Periodic Suffocation.—Fits of suffocation are sometimes observed in children; they become quite blue, and out of breath. These fits return, but not at regular intervals. According to the experience of Dr. Gülis, they may be caused by an effusion of water in the brain; or they may indicate the first stage of chronic hydrocephalus. If the disease is accompanied by fever, this must be combated first of all; and it will then be well to administer small doses of calomel alternately with the following powder: *Rx.* Valerianæ pulv., gr. v; Calcis carb; Sacchari albi, ʒʒ ʒss; *M. ut ft. pulv. t. d. sumendus.* Baths, impregnated with chamomile and pearl-ash, are also to be ordered, as in the case of periodic asthma.

Palpitation of the Heart.—Dr. Gülis treats this as a separate disease, and orders a few drops of the following mixture to be taken three times a day: *Rx.* Tr. digit., ʒiss; Ammon. succin., ʒss; Laudan. syden., ʒj; *M.*

Hemoptysis.—In this disease Dr. Gülis extols an emulsion of gum combined with decoction of digitalis, particularly when de-traction of blood in any shape is contra-indicated by a state of cachexia. This cures the hemoptysis without leaving any induration behind as astringents do, in consequence of which a little hard cough usually remains.

(To be continued).

Hospital Reports.

—

NORTH LONDON HOSPITAL

—

Cases of Chorea, cured by Carbonate of Iron, in Large Doses.

MARY ANN WILSON, aged 15, was admitted December the 16th, 1834, under the care of Dr. Elliotson. About two months before she caught cold. Shortly after she was seized with a pain in the head, but did not discontinue her duties as servant, until about a fortnight ago, when she says her master beat her on the back of the head with a walking stick. He had gone out and ordered her to sit up for him, and threatened if he found her asleep, he would kill her. He came home about three in the morning, and finding her asleep, beat her. She was much frightened at the time, and has not since been able to control the action of the muscles of the upper and lower extremity and those of the neck. The muscles of the face are not much affected, when she is agitated or told to put out her tongue. She finds walking, sitting, and the recumbent posture difficult. The motions are much increased when any question is put

to her, and she cannot utter a single syllable, except when she is perfectly still, and the movements quite ceased, which is very seldom. Has had no pain in the head for a fortnight, but complains of tightness in her breathing, which has existed three days; there is no cough. Tongue slightly furred; pulse 90. Bowels regular; has not menstruated for two months; began to do so at fourteen. The involuntary motions first appeared in the anus, then in the face, beginning to affect the lower extremities only two or three days since.

Rx. Carb. terri 3ij, bis die.

Full diet.

18th.—No better; took medicine every six hours.

Jan. 5th.—Much better; the convulsive motions of muscles less violent, but the eye-balls still in continual motion; the recumbent position is not now painful, and she sleeps well at night.

12th.—Motion of eye-balls almost ceased; general health improving; was seized with giddiness this morning, which lasted several hours.

29th.—Less giddiness; pain at back of the head; much nausea during the last two days; can now keep herself perfectly quiet.

Feb. 20th.—Discharged; having been free from the chorea some time.

Thomas Martin, aged 12, was admitted April the 25th. Is an errand boy, and has been ill ten days; was first much frightened by a chaise starting off near him, but not to touch him. The day following, he began to have irregular involuntary motions in the hands, extending shortly afterwards to the other parts of the body.

Rx. Ferri carbon 3ij singulas horas, the bowels to be kept open by medicine if required.

28th.—The medicine increased to-day to 3ss doses.

29th.—Does not appear so well; he frequently screams out; says he does so, because his arms are painful; they look red from friction against the bed-post; complains of sore throat; it appears slightly red. 3ss carb. ferri, 4 ta. quaque hora.

May 7th.—Considerably better; the motions being much less violent.

June 9th.—Since last report has been gradually getting better; the medicine has been continued in the last-named doses. It is remarkable that it has not produced headache, costiveness, or a single unpleasant symptom. Since about the middle of May, there has been little or no involuntary motion, and he is so far recovered as to be able to leave the hospital.

Use of Strychnine in Defective Vision.

At page 380 of the present volume, we reported the case of Samuel Nagle, who had suffered from inflammatory dropsy. He gradually improved to the 28th of April; seemed then perfectly well; all at once, however, he complained of a defect in his sight, that he could not clearly see; there were no marks of inflammation in the eye, and Dr. Elliotson ordered strychnine in doses of 1-9th of a grain to be given him, in order to stimulate the nerve; in about a week he was completely relieved. The same plan of treatment was adopted with a girl, who was admitted a short time since with hysteria and psoriasis. She had been bled for tenderness in the epigastrium, when she was suddenly taken with pain in the eye, and inability to distinguish objects clearly. 1-12th of strychnine was given her twice a day; in three days the affection was removed.

CLINICAL LECTURES.

WE have always advocated the usefulness of clinical lectures, and the necessity for their delivery by hospital physicians and surgeons; Dr. Elliotson, in order that no case of interest should be lost to the students, has commenced lecturing three days a week at the North London Hospital. We consider such a proceeding worthy of being put on record as a precedent desirable to be followed;—shewing as it does the interest of the professor in the instruction of his pupils, and the commencement of an era of more usefulness in these public institutions.

—o—

Case of seven Soldiers wounded by one Bullet.

The 3rd of July 1830, towards six o'clock in the morning, twelve soldiers were quietly retiring from a trench whither they had brought food for their comrades. They marched in two ranks, and in each rank they were kept at some distance from each other in consequence of the sticks by which they carried the cooking pots. At the time these men were passing our position, a ball from the fort of the emperor wounded seven of them in the following manner. The soldiers that were first, with regard to the ball, but last with regard to the direction of the march, received the ball on the right shoulder and in the breast. The arm was taken off, and the chest laid open, and the lungs considerably contused; he died on the spot. The second had the fore-arm and the lower third of the arm carried away, and the parietes of the chest slightly contused. Amputation of the arm in this case was com-

pletely successful. In the third the ball struck the right loin, carried away the integuments and muscles to a great extent, and laid bare the external surface of the liver, part of which was taken off; he died immediately. The fourth had the muscles of the buttocks almost entirely carried off, the coxo-femoral articulation opened, the extensor muscle of the aponeurosis of the thigh and the sartorius torn, and the anterior and superior spine of the ilium fractured. Had the mischief been less extensive we might have ventured to disarticulate the femur: but the extent of the local and general disorder having made us consider death as certain, M. Devaux, after cleansing and giving a new surface to the entire wound, thought it better to attempt healing by first intention, without however any hope of success. With stitches and adhesive plasters the hanging portions of tissue were brought together, and the whole appropriately maintained and covered. He died on the way to the temporary hospital. The fifth had his thigh carried off above the condyles of the femur: immediate amputation higher up saved him. In the sixth the ball struck the middle part of the leg: amputation saved this one also. The seventh, who was not exactly in line, had only the integuments of the lower and external portion of the leg slightly contused: no accident supervened in this instance.

Thus of the seven wounded—or rather six, for the last could scarcely be said to be so—three died directly, and the three others required amputation, which succeeded in all of them.—(From a paper by M. Bonnafont, assistant-surgeon in the army of Algiers, inserted in the *Journal Hebdomadaire*, May 30.)

Doings in the North.

We have received reports of several cases, which speak little in favour of the change of surgeons made in the Royal Infirmary. Were we inclined to publish *unfortunate* cases, we have full means of doing so in those before us. Our plain motto has hitherto been impartiality—we hope never to lose sight of it. We cannot, however, help thinking that the splendid talents of the last surgeon to the institution in question, must be greatly missed.

The London University has been presented with £1,000 from an unknown friend, signing himself "A Patriot."

Cats in Printing Offices.

It is a remarkable fact that cats cannot be reared in printing offices without considerable difficulty. M. Huzard Courcier thinks this is in consequence of the very finely powdered metallic particles that abound in those places, which irritate the animals to mad-

ness by the itching they produce, until the workmen destroy them. When they eat mice that they have caught in the printing shop, they are seized with vomiting, and are sick for several days. There are some examples of cats that have lived altogether in the localities mentioned, but they are rare.—*Annales d'Hygiene Publique*, April.

RADIX RHEI V. THE RHABARBARIANS.

SIR—I am in the habit of hearing much of your valuable Journal, which is distinguished by classical acumen combined with sound practical knowledge, obviously the result of much reading and reflection. These virtues are duly appreciated; which induces the belief, that you will correct the extraordinary course you have for some time adopted, in the use of a name respected throughout the world—indeed sir, it is an abuse to be at once deplored and reprobated, in one of your high attainments. I have now to appeal to you on the subject of the Hall, the members of which certainly may be regarded as the night-men of the profession. These sir, you sometimes designate Solons, by which I suppose you mean the lineal descendants of the ancient law-giver; this assuredly cannot be condemned. What I complain of is, your bringing my revered name into contact with these vile huxters and dry-salters. You call them rhabarbarians, toujours rhabarbarians—call them barbarians if you please, but the assimilation of my well-known and benign virtues with these bags of soot and glauber salt, can no longer be endured. Your inadvertence has given great offence to my magnanimous allies, from whom I have received numerous communications and assurances of support, should due reparation not be made—but a word to the wise.—I beg therefore to be no longer confounded with these assafoetida cormorants, examinera, and mandrakes—these walking buccabungo, cabbage elephants, and potatoe heads, more horrible to contemplate in their noxious recesses and dens, than anything, however concentrated or compounded, in the way of abomination, heretofore the produce of the slime of the Nile or the Cloaca,

I have the honour to be, Sir,

RADIX RHEI SALUTEM FERENS GENTIBUS
UBIQUE TERRARUM.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXI.

Food and the Fluids, as direct Stimuli to Irritability—Indirect Stimuli.

ANALOGOUS to the last mentioned stimulus is that of aliment, taken at intervals by most animals—for plants have no corresponding organ—into the stomach. Its action appears to be partly chemical and partly mechanical, and to be exerted, at once on the irritability of the capillary vessels of the stomach, so as to promote its proper secretions and absorptions, and on its muscular fibres, so as to excite its contractions, the irritation thus produced in the stomach being extended, by sympathy, to almost every organ of the body, and in particular to the muscles of voluntary motion, the greater degree of healthy contractions thus produced in them giving rise to the renewed energy and alacrity so generally experienced from taking aliment into the stomach. Hence the necessity of food and drink being not only nourishing, but stimulating, and the impropriety of inculcating a long continued use of the same substance, or very great simplicity in diet in general; and as, generally speaking, the most concentrated aliment is the least stimulating, and therefore the least digestible, it is perfectly possible, however paradoxical it may appear, to starve an animal by giving it too nutritious food (a). All animals have accordingly a range, in this respect, more or less extensive; and even the young of mammals, which feed so long upon the milk of the mother, furnish no exception to this remark, for not only is the quality of this milk very different at different periods after parturition, but it is, at all times, a very compound fluid. The Brahmin thrives on rice, the African gum-gatherer on gum, and the West Indian negro on sugar, but it is only for a time, or with a due admixture of other substances; and it was the experience of this necessity of such additional stimulus which taught the Esquimaux, the Kamskatdales, the Ottomacs, and others, who could get nothing better, to mix saw-dust, or even clay, with their train-oil or other food, and has led mankind in general to the almost universal use of salt and other condiments. The chyme, into which the aliment is gradually converted in the stomach, acts, in like manner, as a stimulus on the irritability of the capillary vessels and muscular fibres

(a) The fatal effect already alluded to, of the attempts made by Dr. Stark to live on one kind of diet alone, however nutritious, and those of similar experiments made by Magendie on dogs and other animals, sufficiently illustrate this important fact, and abundantly prove that it is not from their food being azotized or non-azotized, salt or fresh, that sailors on long voyages, or persons in besieged towns and other similar situations, take the scurvy, but from their getting little or no food at all, or—what amounts nearly to the same thing—food uniformly of the same character. They

likewise display the impropriety of giving to convalescents, and others whose digestive powers are impaired, arrow-root, sago, tapioca, jellies, eggs, and so forth, consisting, as they do, of comparatively simple and highly concentrated matters. Many would recover on hung-beef, grated on bread and butter, or on the flesh of “a tough old cock boiled to rags”—a favourite prescription of the late Dr. Willan—who perish on veal and chicken-broth, and other slip-slop appurtenances of a sick-room, and for an obvious reason.

of the long intestinal canal, during its slow progress downwards; and thus the stimulus indirectly imparted to an animal by the aliment, although taken perhaps at long intervals, is hardly less continuous than that communicated by the air or water which constantly surrounds it, and with which its reciprocal action is uninterrupted. It is a common error to regard the stimulus of the aliment as only an occasional one. It is undoubtedly in more active operation immediately after taking a meal than at other times; but it is perhaps never entirely withdrawn even from the stomach, during the longest natural intervals of abstinence, and it is certainly in constant operation indirectly on the intestines. Generally speaking, the necessity for a frequent supply of aliment is greater the higher is the rank of the animal, but the quantity taken at each meal is proportionally less; and this power of sustaining long abstinence, together with extreme voracity at intervals, is in general more remarkable in cold-blooded than in hot-blooded animals. That man is capable sometimes of enduring very long abstinence is sufficiently established by many very remarkable cases, both of individuals (a), and of many persons together who have suffered shipwreck, or been exposed to any other common calamity, but that he does not, at least in a civilized state, habitually subject himself to this is certain; and again, that he can occasionally devour an immense quantity of food at once is sufficiently well known, but it is equally certain that such is not, at least in a state of civilization, his usual practice (b). On the other hand, many insects, and in particular the Lepidoptera, habitually subsist for weeks or months without food, and the scorpion (*Scorpio*, 17) has been known to endure an abstinence of three months, the spider (*Aranea*, 17) of a twelvemonth, and the beetle (*Scarabæus*, 21) of three years, without inconvenience. Among the vertebrated tribes, also, some fishes, as the perch (*Perca*, 28), are said naturally to take food only about once a fortnight. So, among reptiles, the crocodile (*Crocodylus*, 35) has been known to sustain a want of food for two months, the chameleon (*Lacerta*, 35) for eight months, the toad (*Rana*, 32) for fourteen months, the land-tortoise (*Testudo*, 53) for eighteen months, and the serpent (*Coluber*, 34) for no less than five years. And even the hot-blooded vertebrated animals bear abstinence longer than is commonly supposed; the eagle (*Falco*, 40), for example, has been proved capable of doing without food for twenty-eight days, and, among mammals, the civet (*Viverra*, 49), for ten days, the antelope (*Cervus*, 45), and the wild cat (*Felis*, 50), for twenty days, the badger (*Canis*, 50) for a month, the dog (*Canis*, 50) for thirty-six days, and, it is said, the bear (*Ursus*, 50) for six months. The quantity, however, which the lower tribes of animals sometimes take, when they can get it, is enormous; the voracity of some fish, for example the conger eel (*Muraena*, 26), the mackerel (*Scomber*, 28), the perch (*Perca*, 28), the pike (*Esox*, 29), the dog-fish and the shark (*Squalus*, 31), being proverbial, and that of many reptiles, as the boa and crocodile, birds, as the vulture, and quadrupeds, as the wolf and hyæna, being almost equal to it. The young of all animals, again, unlike what occurs with respect to want of air, bear want of food less easily than adults, and take it both more frequently and more copiously. The larvæ of insects are known sometimes to take two hundred times their own weight of aliment in the course of a day, and the rapidity therefore with which they are enabled to dispatch the carcass of a large animal, which has been elsewhere alluded to, is not wonderful. The quantity of food also consumed by a growing child is in general almost inversely as its age, and accordingly its weight is commonly tripled by the expiration of the first year after birth, while it takes six years more to double its weight at the first year, and seven years more again to double its weight at the seventh. It is unnecessary again particularly to allude to the cases in which living animals have been found imbedded in situations in which, if respiration were difficult, the reception of aliment must be supposed to have been almost impossible. It has been imagined that, in these cases, they subsist upon their own exuviae of one kind or another (c); and perhaps these may be quite sufficient for the purpose, under circumstances of such diminished energy of all their functions. They must be conceived to be in a state analogous to what is called hibernation; and we know that marmots, bats, and other quadrupeds,

(a) Pouteau, Mem. de Paris. 1769; Mackenzie, Phil. Trans., 1775; Willan, Phil. Trans. 1793; Currie, Med. Rep., 1804; Royston, Med. and Phys. Journ., 1809, &c.

(b) Some savage and semi-savage tribes, as the Norwegians and other inhabitants of the north, are characterized by their ravenous and indiscriminate appetites. A Yakout or Tongousi will eat forty pounds of meat a-day, and three of them easily make an example of a rein-deer at a meal. One Yakouti, attached to the suite of Admiral Saritcheff, is said to have been accustomed to consume daily, the hind quarter of an ox,

twenty pounds of fat, and a proportionate quantity of melted butter for drink! Our civic aldermen, with their six quarts of turtle soup per man, are after all mere triflers as to quantity; and, with respect to quality, even the notorious French soldier Tarrare, who used to eat every kind of offal, and even putrid limbs taken from charnel-houses and dissecting-rooms, or poultices and plasters, collected in hospitals, and reeking with blood and matter, hardly surpassed some of these tribes in the indiscriminate nature of the materials of their repasts,

(c) Grignon, &c.

during this state, as well as insects during their metamorphoses, neither take nor require any aliment whatever. The aliment has never been explicitly identified with life, although the hypotheses of some of the advocates of the vital principle doctrine tend directly to the inference that it contains this principle (a), it is superfluous to say how unreasonably and absurdly.

The only remaining head of direct stimuli to the irritability of organized beings includes the various fluids, whether crude, mature, or secreted, which constitute a part of themselves. Of the sap, cambium, and other fluids of plants, in this capacity, it is unnecessary to speak particularly, since what is said of the corresponding fluids of animals may be easily applied to them; and of the arterial blood, venous blood, lymph and chyle, in their character of stimuli to irritability, some notice was taken during the discussion of the question, whether they were entitled to be considered as possessed of this property. And how constant and important a stimulus, partly chemical perhaps and partly mechanical, these must constitute to the heart and capillary system—the latter of which is universally diffused throughout all the organized tissues—will be sufficiently apparent when we reflect that not less perhaps than fifteen thousand pounds of arterial blood, or a quantity equal to more than a hundred times the average weight of a human being, is sent out from the left heart, and of course traverses the parenchyma of the body, to reach the right heart by the veins and lymphiferous and chyliferous vessels, while of course the same quantity of venous blood, lymph and chyle is expelled from the right heart, and necessarily passes through the parenchyma of the lungs, to return to the left heart by the pulmonary veins, in the course of twenty-four hours; so that each side of the heart, estimating the whole organ to weigh ten ounces, receives a daily supply of about forty-eight thousand times its own weight of these fluids into its cavity, and every point of every organ of the body—heart included—through its parenchyma, a daily supply upon an average of not less than a hundred times its own weight! The stimulus communicated then by these fluids to the body collectively, supposing it to bear any proportion to the frequency of their renewal in each organ, must be enormous; but we must take care to keep constantly in mind that these fluids have two almost directly opposite relations to the heart and capillary system, and that as they are, on the one hand, a chief stimulus by which the motions of these organs are excited, so they are, on the other, the load to dispose of which alone these motions are in requisition. In the normal state of the body their operation as a stimulus is precisely such as to excite the motions required, either to urge them forward, or to dispose of a portion of them in the processes of nutrition and secretion, as a load; but, under various circumstances of disease, at one time their action as a stimulus is so great as to excite more violent motions than their resistance as a load requires, while at another their resistance as a load is too great to be overcome by the motions which their action as a stimulus is competent to excite. Of the former of these abnormal conditions, we have an example, with respect to the heart, in the second stage of fever, when the pulse is found to *fall* upon bleeding, and, with respect to the capillary vessels, in the stage of inflammation preparatory to that in which the blood becomes accumulated, when the parts are constricted and blanched; of the latter we have an example, with respect to the heart, in the first stage of fever, when the pulse is found to *rise* upon bleeding; and, with respect to the capillary vessels, in the stage of inflammation consisting in the accumulation of blood, when the parts are turgid and red (b). This is not, however, the place for insisting particularly on these antagonizing relations in which the fluids in question stand to the heart and parenchyma, since it is in their character of stimuli only that they fall at present to be considered. And a similar excuse may be offered for declining in this place any agitation of the question whether these fluids are, under all circumstances, equally efficient as stimuli, or whether their quality is liable

(a) Such is the case with that of Dr. Pring, who represents life as continually formed "by the assimilation of its identity from the blood," the said blood being capable of being formed of course only by the assimilation of its identity from the food; so that, if life be a simple substance, the food must to all intents and purposes contain it. In general, however, the vital principle school of physiologists, as, under the ancient regime, they represented aliment, not as life, but as the staff of life, so, under the more modern, they were satisfied with enumerating it as one of their six non-naturals.

(b) There is no principle in semiology or

therapeutics more important, or of more frequent application, than that which impresses this two-fold, and, as it were, adverse relation of the blood to the reservoirs and vessels in which it is contained; and it was from the fatal oversight of regarding this fluid always in the light of a stimulus, and neglecting to observe that it sometimes oppressed more by its bulk than it stimulated by its surface, that all poor Brown's practical errors resulted—errors which are still held in remembrance only to be execrated, while his merits are unknown or unregarded. So true is it that "the evil that men do lives after them; the good is oft interred with their bones."

to such changes as to render them more or less powerful, in this capacity, at one time than at another. That they undergo in many diseases very remarkable alterations, and such as may most materially modify their action in this way is certain; but our business at present is strictly physiological, and it would be quite out of place, therefore, to enter here at any length into a question, at once one of the most obscure, and one of the most extensive in all pathology, particularly as the presumption of any primary loss of balance in the principles of these fluids, such as a superabundance of sugar, of sodo-albumen, of fibrin, of acid, or of alkali, of oxygen, hydrogen, carbon or nitrogen, ever occurring as a cause of diseases appears to be quite unfounded, whatever alterations they undergo in such diseases being, in all probability, the result generally of a vitiation of the secreted fluids and solids, which are subsequently received into the circulating fluids by absorption. In the same manner as the arterial blood, venous blood, lymph, and chyle, act as stimuli on their respective systems of vessels, so, among the perspired secretions, act the carbonic acid and halitus from the lungs upon the bronchial tubes, producing, by their momentary accumulation, an irritation which at once excites these vessels to contract, and, as extended by sympathy to distant organs, constitutes the chief primary stimulus to expiration. In like manner act the other perspired secretions—the gastric fluid, the menstrual fluid, and the rest—among the follicular secretions, the cystic bile, the thick portion of the semen, the stools, &c.; and among the glandular secretions, the hepatic bile, the pancreatic fluid, the urine, the thin portion of the semen, the tears, and the saliva, first each upon its own proper secreting surfaces, follicles or ducts, and next upon the other organs to which many of them are subsequently conducted, the irritation so excited being often, like that of the rectum by the stools, and urinary bladder by the urine, extended by sympathy to those voluntary muscles which co-operate in evacuating them, and constituting thus the chief primary stimulus to their action in this way. The greater number of these secreted fluids are more or less proper to certain parts of certain animals, and they cannot therefore be essential otherwise than as local stimuli in any case, while their action even in this way is often unnecessary; nor, indeed, are the arterial blood, venous blood, lymph, and chyle, the distribution of which is so general, and some modifications of which are almost universally met with, any more than a great quantity of caloric, or a frequent supply of air or aliment, equally indispensable as stimuli to the irritability of all tribes of animals. In general those animals which are the least dependent on the three last-mentioned stimuli, are the least so likewise on the fluids in question; and, accordingly, cold-blooded animals commonly manifest this independence more remarkably than those with hot blood. In man, as is sufficiently well known, the abstraction of even eight or ten ounces of blood—probably not more than one-eightieth part of the whole amount of his circulating fluids—frequently produces a very striking diminution of general irritation or vital action; whereas the frog or newt continues sometimes to live for days, and to exercise most of its accustomed functions without apparent impediment, although the greater part of its whole mass of blood has been withdrawn. The young, likewise, of all tribes of animals appear less easily to sustain a diminution of this stimulus than adults; and there are not wanting instances in which the quantity abstracted by the bite of a single leech has proved fatal to infants. With respect to the uses to which the blood, lymph, and chyle are subservient, otherwise than as immediate stimuli to the irritability of the heart and capillary system—such as that of producing, by their momentary accumulation, an irritation of contiguous organs—like that excited in the lungs by the momentary retention of venous blood in the pulmonary arteries, which, extended by sympathy to distant organs, becomes the principal primary stimulus to inspiration—or that of serving by their retention for a time in the erectile organs, such as the papillæ of the dermoid and mucous membranes, the corpus spongiosum urethræ, the corpora cavernosa clitoridis, the fimbriated extremities of the fallopian tubes, the nipple of the mammæ, the corpora cavernosa penis, &c., to distend these organs, and thus to adapt them to their respective functions, or, lastly—the most important office of all—that of furnishing the materials out of which the various solids and fluids of the body may be secreted by the action of the capillary vessels; with these we have nothing to do at present, since it is of these fluids in the first of these capacities alone that we are now speaking; and the same thing may be said of the several secreted fluids above-mentioned, many of which, besides acting as mere stimuli to the irritability of the organs with which they come immediately into contact, perform numerous important offices. Such, then, appears to be the true relation in which all these fluids stand to life; the motion of the blood or any other of them being the immediate domicile of this, as a substance, being too obviously incorrect to require any animadversion, and that of any such fluid being possessed, though not of life, still of vitality, having been already, it is hoped, sufficiently refuted (a).

(a) The patrons of the doctrine of the inherent vitality of the blood have merely mistaken one condition of life for the other.

It is in general the most essential stimulus to vitality, and therefore as necessary to life as vitality itself. — It cannot be both en-

We come next to the indirect or secondary stimuli to irritability, beginning with sympathy and passion, or instinct, the latter of which is merely one department, as it were, of the former, while both again, regarded as stimuli to irritability, are merely varieties, as before observed, of sympathy, inasmuch as by sympathy, in the strictly physiological sense of the word—in which alone it is here employed—is to be understood the translation of a direct or primary irritation of any organ, except the brain, to any other organ; and by the term passion, or instinct, in the same sense, the translation to any other organ of such a direct or primary irritation of the brain. It will be in future shown, indeed, that an irritation of the brain is, strictly speaking, never absolutely direct or primary, since it must be always preceded by sensation, as the only stimulus to every modification of thought, as this again must be by irritation, as its only stimulus: nevertheless, in as far as regards passion or instinct, considered as a stimulus to irritability, it originates indirectly or secondarily in an irritation of the brain, which, therefore, in relation to this stimulus, is direct or primary, by whatever conditions it may itself have been preceded. Hence sympathy, on the one hand, and passion or instinct, on the other, are all resolvable into one species, as it were, of indirect or secondary stimulus to irritability, the former variety being sometimes called, by way of distinction, *organic*, and the latter *animal sympathy*. And that such a stimulus to irritability as sympathy and passion, or instinct—vaguely and indefinitely as these terms are frequently employed in physiology—actually exists, the employment of such terms not being merely the substitution of words for ideas, as is sometimes supposed, is obvious from the familiar facts of sneezing—already instanced—which is effected principally by the action of the abdominal muscles, being excited by snuff or any similar substance applied to the schneiderian membrane, and of starting, which is effected chiefly by the muscles of the spine being excited by surprise or sudden apprehension of danger. The snuff cannot have produced a direct irritation of any part, except of the surface to which it was applied, nor the surprise or dread of danger a direct irritation of any organ, except of that which is the immediate seat of passion or instinct; but the abdominal muscles, on the one hand, and those of the spine, on the other, must have been acted upon by a stimulus, or they could not have been contracted—it is this translation, by whatever means it may be effected, of a direct or primary irritation of one organ to organs at a distance, which is called respectively sympathy and passion, or instinct, when we speak of these as powers acting on irritability.

dowed with a power to act on this property, and possessed of the property of being acted on by this power. It is obviously the former,

ergo—but the hypothesis has been already weighed in the balance and found wanting. *Quiescat in pace.*

M. BROUSSAIS'

Course of General Pathology and Therapeutics;
translated and revised

BY JAMES MANBY GULLY, M.D.

LECTURE V.

Phlegmon—Gout.

PHLEGMON is that inflammation of the cellular tissue that has served as a type of all inflammations among ancient authors, because they were best acquainted with it. Our chief classical writers scarcely allow the term inflammation to erysipelas; and those of the Galenical sect assumed that erysipelas was the effect of the bile, while phlegmon originated in the blood. With them phlegmon was the principal disease, the inflammation par excellence. It will also serve us in our researches, and you must ever keep it before you.

Phlegmon presents the four leading characters of inflammation, pain, swelling, heat, and redness. All the senses are witnesses of its presence when subcutaneous: it raises the skin: to the hand it gives a feel-

ing of smoothness, accompanied with heat: there is pain, at first burning, then pulsative and increased by pressure: the redness is less intense than in erysipelas.

The causes of inflammation of the cellular tissue are those of all inflammations, and at the head of them are traumatic lesions; it is the prominent phenomenon of surgical disease. In a part wounded, there is first a flow of blood, then of serosity, then tumefaction, and then sanguineous injection with heat, and this becomes an actual phlegmasia. The cellular tissue of the irritated part swells, fills with serum and blood, and inflammatory irritation is developed; this irritation thus becomes a very important phenomenon. Whenever inflammation is developed, the cellular tissue participates in it, and plays a more or less prominent part; it furnishes the creamy matter that is observed on the surface of the skin after blistering with suppuration; it is in it that the inflammation which takes place when muscles are cut, or when they are only congested, exists. In short, the more cellular tissue an organ contains, the more does its inflammation bear the character of phlegmon: so that there is some reason for erecting the latter into the type of inflammation.

It is not in it alone, however, that that phenomenon occurs: inflammation and sub-inflammation are possible in a variety of other tissues.

Next to the first cause, vulneration or division, we find laceration, pressure, contusion, fractures, and other violent causes. At other times, phlegmon is the consequence of propagation: inflammation occurring in some membranes of relation, as the skin and mucous membranes, it extends to the subjacent cellular tissue, as may be remarked in phlegmons that follow upon erysipelas and anthrax. In some instances it appears to be critical, being developed after some internal inflammation. In this character it is seen in the cellular tissue of the parotid glands and lymphatic ganglions, where it forms buboes: around the anus; around the joints, where it was often remarked by Hippocrates, unless, indeed, he confounded it with arthritis: and in the vicinity of organs that have some secretion, a fact that might lead us to regard it as the extension of a sort of depurative excretion. But we must not give the epithet of critical to the inflammations of the skin and cellular tissue that are the result of pressure in prolonged acute disorders, inasmuch as the causes are different.

In many instances, no account can be given of the appearance of phlegmons, and we are forced to ascribe it to a general inflammatory disposition. We see them renewed in all parts of the body, as if there really existed a phlegmonous diathesis: this is chiefly remarked after the eruptive phlegmasiæ.

Phlegmon is characterized by pains, smarting, throbbing, as if there were a pulse in the part—and in fact there is one, the swollen arteries producing a sensation that is not illusory—vessels that at first do not appear sanguineous, but afterwards become so, multiply, the tumefaction goes on increasing, accompanied with heat, unyielding to pressure in the centre of the inflammation, and with œdematous gorging to a certain distance around, when the phlegmon is subcutaneous. This gorging does not yield to pressure so easily as that which proceeds from another cause: in the more distant parts of it, however, it may be depressed and retain the impress of the finger, because it gradually descends from the degree of inflammation to that of dropsy, and the further from the centre of the inflammation we go, the more serous is the engorgement. Regard must also be had to constitutions: some subjects are robust and have firm and unyielding tissues, while in others the tissues are lax and flaccid, either by nature, or in consequence of previous phlegmasiæ that have enfeebled them; phlegmons, though essentially the same in both, do not exhibit equally decided characters.

This is what we see when the phlegmon is situated beneath the skin; but if it occurs

between muscular masses enveloped in aponeurosis, it is not so easy to seize its characters. Here you must for the first time use deduction; it is well to exercise yourselves in it. When, for instance, you remark pain in the thigh, with smarting, tension, weight, swelling, and heat, you suspect a deep-seated phlegmon; but to confirm your suspicion, you must have recourse to the sympathetic phenomena or dissemination, an idea of which you should in the first instance draw from visible phlegmon. And what do we observe where this has made some progress? We observe the patient to suffer from shiverings, lassitude of the limbs, more or less headache, decrease, or appetite replaced by thirst: we observe the pulse to be accelerated, and that being small and frequent it soon becomes fuller and larger, retaining its frequency, that the skin, at first cool, grows hot, and becomes halitous over the whole body. To produce these symptoms, the phlegmon must be of some extent; for if it be limited, as in a light whitlow, no febrile symptoms, none of the phenomena of dissemination are developed. I dwell on this idea, and shall return to it; further on, you will see why I am anxious that you should understand it*.

Return we to hidden phlegmon. Here is a thigh swollen, unyielding, hot, and painful: you suspect there is a phlegmon forming in it, and you wish to be certified thereanent: how will you proceed to satisfy yourself? You observe whether sympathetic symptoms are superadded to the local signs; if the patient has felt malaise or gastric disorder, if he has had fever, the phlegmonous pulse, the halitous skin, &c., you pronounce the existence of phlegmon, you then feel the limb more attentively, and ascertain a turgescence. If you are unable to stay the disorder, or if you see it for the first time when it is considerably advanced, you remark a swelling that occupies the cellular tissue, and you continue by the touch and the above mentioned signs to detect a sub-aponeurotic focus of inflammation. These data suffice to assert its existence, and even to determine you in practising an incision that shall be deep enough to reach it. If you ask the most experienced surgeons how they proceed in similar cases, they will tell

* The same must be my excuse for "selecting" what many readers may consider trivial lectures on boils and whitlows, and erysipelas. It requires either oneself to possess or to have studied and appreciated Broussais' mode of connecting facts, to say beforehand how he intends to apply the well-known phenomena hitherto announced, to the explanation of the phenomena that are observed in more obscure diseases. This present instance of hidden phlegmon is a simple example of that mode; "further on" the reader will see more of it.—J. M. G.

you that there was fever with a heat peculiar to phlegmon, that at the period of the formation of pus the fever ceased and was replaced by shiverings or became intermittent, that these phenomena were in corroboration of their own presumption that there was a collection of pus in the part, and that they consequently determined on the operation.

But let us examine with more precision the progress of phlegmon. It may end naturally, and by a rapid resolution, or be so diminished by art that the same effect shall ensue; it may go on to fluctuation and be then resolved, and there are numerous instances of phlegmons that were on the point of being opened which have been altogether absorbed; in which case we generally distinguish the spot that the pus occupied, by a softness on pressure. But it more usually happens that by a law which we can only observe and not explain, the inflammation concentrates in the skin corresponding to the centre of the tumour, the cellular plates become gradually decomposed and an opening is effected in the point, or if it does not take place there, if an aponeurosis presents an obstacle to it, the inflammation takes another direction, is propagated through the interposed cellular layers, causes them to suppurate, and a large sub-divided abscess is formed, constituting a serious and complex disease. When the phlegmon exists in a part where the cellular tissue is not very lax, the pus concretes around the collection and forms a kind of sac or cyst confined by a false membrane; this, however, is rare in visible phlegmons, and is more common in the viscera.

The phlegmon having thus formed a collection of pus, if this is laid open the suppuration gradually diminishes, the centre shrinks, and the pus finally becomes a plastic matter which aids cicatrization. If the point is not opened and the pus is obliged to pass through the layers of cellular tissue, it becomes absorbed, and the patient infects himself, a foul matter is incessantly re-entering the system, and is a continual stimulation, while a febrile state is generated by the irritation of the viscera thus acted upon by the matter. The whole system is thus threatened with a consecutive inflammatory state, the parts that are more particularly liable being the great visceral centres, the organs of digestion first, and then those of respiration. The inflammation also tends to repetition in the serous tissues, in consequence of their analogy with the general cellular tissue. The lymphatics and veins in the neighbourhood of the phlegmon exhibit a remarkable appearance: the inflammation inclines particularly to pass to the veins. The ultimate term of all these phlegmasiæ is a series of consecutive phlegmons which lead to consumption, diarrhœa, emaciation, and death.

The fluids also present remarkable ap-

pearances. If you observe the blood at the onset of a phlegmon you will see an inflammatory coat, which is, according to some experimenters, a kind of alteration of the fibrin from which the cruor separates; and from them it would appear that there was more fibrin than cruor. It should also be considered that generally in the first stage of inflammation, before it has undermined the powers, there is an increased activity of hematosi; of this state the examples are numerous in which the patients are able to bear enormous losses of blood, and such instances are more frequently met with in certain shades of phlegmon of the viscera than of the cellular tissue.

When the period of resolution and suppuration arrives, the urine and sweat contain a mucous matter or a kind of detritus of the fibrin of the blood, resembling pus, for during that period and the absorption of the pus, this matter is found in almost all the excretions. At a later period, when the unopened phlegmon has caused the formation of an internal abscess which infects the blood, the composition of the latter is changed and becomes impregnated with virulent principles which our powers of investigation have not yet been able to isolate, but whose operation is that of remarkable irritation. In all such cases, whether the modifying agents of the blood render it more cohesive and fibrinous, or the fibrin is tainted with intangible putrid matters, we possess no specifics to oppose them; all we can do is to combat the inflammation.

With regard to the prognosis, you ought to be now able to state it as well as myself. If the phlegmon is small and limited it is a purely local phenomenon which only induces a slight degree of pain, by the dissemination of the nervous irritation, without any danger of being communicated to the interior; but if it be sufficiently extensive to produce fever, a thousand chances are possible. The disposition to visceral phlegmasiæ that always exists more or less when a considerable irritation obtains in any point, may cause the inflammation to become concentrated in one of them. It is this that frequently mars surgeons when about to perform some great operation, and they therefore take care to examine whether the patient has been properly prepared for it. This point has been attended to by all our leading surgeons since the time of Ambrose Paré; they have always prepared patients for operations, that is, they have diminished the inflammatory tendency in them. Thus when the latter exists and a phlegmon appears, the dissemination of the irritation and the fever may give occasion for the development of some internal phlegmon of greater or smaller consequence; and this consideration should always form one of the features of the prognosis. Moreover it should be grounded on the extent of the inflammatory focus, on its profundity

and its vicinity to the principal organs. Inflammation of the parotids is always a serious matter on account of its proximity to and multiplied nervous communications with the brain; indeed all the phlegmasiæ of parts near the brain require to be strictly watched. The same applies to the phlegmon that exists in the cellular tissue around glandular organ. Another elementary feature of the prognosis is the situation of phlegmon; if it be subaponeurotic it may have serious consequence, and every effort should therefore be made to arrest it at the onset; those situated on the margin of the anus are also to be feared on account of the fistulæ they may leave behind. When the phlegmon has not been opened and has passed into several centres or fistulæ filled with ill-conditioned pus, the danger is very great, especially if internal irritation already exists, for without this last condition there is never a fatal termination; and again I say, no one dies of external but of internal disorder.

What is the treatment of phlegmon, and to what are the indications to be followed in it reducible? You must first of all endeavour to annihilate it in its commencement—a thing not generally understood, for many have an idea that a species of fever is necessary in order to hasten the maturity of the phlegmon, which however is not at all essential. You may reduce a phlegmon to a purely local phenomenon, and regard the fever and visceral phenomena that accompany it, as altogether superfluous and without any utility to its progress. On the contrary, you should endeavour to do away with all these additions, and you will accordingly bleed generally, if there is plethora or congestion in the viscera, or too rapid pulse: you will apply leeches, and this easily, since the disease comes directly within the ken of your senses. Even when the phlegmon is critical you should still attack it in this manner—a precept, I am aware, opposed to that of old surgeons, who thought a critical phlegmon should be respected; but this is folly. In fact, where is the wisdom of allowing a disorganization of the parotid glands, for instance, to go on endangering the brain: or a phlegmon that may perhaps destroy the testicles or lay bare the rectum? No, you must combat inflammation wherever it predominates, and prevent it from ravaging all around it. Last year I made a notable application of this principle in the instance of a young lady who had been seized with measles, which was treated with general and subsequently with copious local bleedings. She appeared to be convalescent, when all at once she felt pain of the left eustachian tube and ear; inflammation of the parotids supervened and increased rapidly, the patient becoming a few minutes as pale as the sheets of her bed; the respiration was laborious, and all the signs of fatal cerebral con-

gestion were imminent. Notwithstanding the paleness and the smallness of the pulse, I had thirty leeches applied to the gorged part; the following morning the lady was cheerful and the parotids less painful. I applied revulsives to the extremities; but the next day the same phenomena as before re-appeared. I again ordered twenty leeches, and was even obliged, regardless of the fears of the relatives and those about her, to make a third application of the same number; they, however, relied on me, and allowed me to do as I pleased. At last the cerebral symptoms ceased, the parotid suppurated and the patient was saved. Had I been anxious to spare her powers and preserve her blood under the pretext that she was of a lymphatic temperament, she would have infallibly sunk under the cerebral congestion. But I was too well persuaded that the phlegmon need not be complicated with sympathetic phenomena and a general effort to bring the pus to maturity, and on this idea was founded the resolution with which I persisted in the same line of treatment. I might even have been successful enough to cut the disease short, as I have done before; but it is sufficient good fortune to be able to withdraw such fearful additions to the phlegmon as those above mentioned. In this manner it is that you should act whenever the phlegmon is threatening the viscera; and when it has attained them, address your remedies directly to them. You should proceed in like manner when, not having yet ascertained the existence of the phlegmon, you are only contending with an internal inflammation. Into the details of remedies I shall not go, my place only being to lay down the fundamental indications. When the phlegmon has given rise to an abscess, you have recourse to a surgical operation. It sometimes happens that mercurial frictions or electric sparks have succeeded in dispersing the abscess in instances where patients have been unwilling to undergo the necessary pain of opening; pressure has also been effectual to the same end, when the phlegmon is situated over a firm tissue, on a joint, for example.

To one point more I must draw your attention—to chronic and latent phlegmon. Nature sometimes produces inflammation of the cellular tissue without any fever, and in so latent a manner as scarcely to cause it to be announced by some trivial pains, and even fluctuation may advance before the patient discovers the disease. This is more particularly seen when the pus comes from some distant point, as in inflammations involving the bones of the vertebral canal and pelvis; it is also observed without any affection of the bones and in a successive manner in various parts of the body. The suppuration consequent on this phlegmon produces abscesses which have received the epithet of “cold”, for which a distinct theory has been erected. Nevertheless these ab-

abscesses should be treated just as the others are: if we succeed in detecting them in good time, we should attack them, as we do more acute inflammations, with local bleedings, by which the inflammatory movement is readily suppressed and the collection of pus prevented; this I can assert on my own experience. But I am bound to confess that more frequently I have been less fortunate, and have been surprised by the fluctuation before any indication, any pain in the lumbar or dorsal regions led me to suspect a phlegmon. This, however, did not deter me from treating it with large applications of leeches and afterwards with compression and numerous drains, but chiefly with moxas around the bony phlegmasia: from all which a cure is generally the result. These kinds of deposits are therefore not so formidable as they have been hitherto considered: if, as I said, the inflammatory movement be suppressed by antiphlogistics and compression used after opening them (if that be necessary), we have nothing to fear from absorption, unless the patients have an unfavourable predisposition, such as the scorbutic, or are labouring under some chronic affection of the viscera—for *that* is always the main point to be determined. Error is sure to follow if we consider the abscess alone; this is an unvarying rule—never judge of the serious nature of a disease or of its curability unless you have considered it with reference to the great organs of the system.

I now proceed to depict to you inflammation as it is seen in the articular tissues, where it falls immediately under our external senses. This forms part of the plan with which we started, namely, to investigate and study inflammation as we see it externally, before proceeding to treat of it when in the hidden parts of the economy. It is only in this manner that we can acquire a rational and well founded conviction as to the effects it develops in the general system, observing first what it produces in the exterior of the body, and then tracing what it produces in the interior.

Articular Inflammations—Arthritis and Gout.
—Inflammation of the articular tissues is exhibited in a variety of shades and a series of degrees, decreasing as it were from acute to latent phlegmon, from the most intense serous phlegmasia to obscure sub-inflammation. It is one of the most instructive inflammations we can study. It may affect the entire joint from the cellular tissue underneath the skin to the articular capsules or the bone itself. The cartilages do not undergo an actual inflammation, but a kind of detritus. You may imagine that in tissues so various in texture and so diversified in vitality, inflammation presents extreme differences, and you need not be astonished that so many specialties and pathological entities should have been erected on these differences,

Of all the causes of these inflammations one only is fundamental—cold; the others are merely preparatory or determining causes—preparatory to certain forms of phlegmasia; determining, when on the application of cold the disease breaks out.

Articular inflammations are divisible into two series: the first, which are the most acute, and may also become chronic, is known under the name of arthritis; the second, less acute and more limited, is denominated gout. Arthritis is the more common of the two. It ordinarily attacks young people, and requires no further predisposition than a general inflammatory tendency. It manifests itself in several articulations at once, and is always accompanied with some varied intensity of fever. The other form, or the gout, is most commonly observed in persons advanced in age. It commences in a single articulation, and that generally a small one, and is frequently preceded by a phlegmasia of the digestive canal propagated into the liver. Do not, however, believe that this circumstance constitutes a disease apart. In my opinion arthritis is to gout what acute gastro-enteritis is to chronic gastro-enteritis. When in the course of life, one, two, or three acute gastro-enterites have been predominant, none but chronic ones afterwards prevail. So it is in arthritis: after two or three attacks of the disease in its acute form, it no longer exists, but gout is the disorder.

The predisposition that I assign to gout, and which consists in a chronic phlegmasia of the stomach, and particularly of the duodenum, reacting on the liver and disturbing the biliary secretion, is not the only cause of it; for it does not produce it in hot climates, or if gout does exist there, it is because cold has accidentally prevailed. In fact, in almost all hot latitudes there are breaks in the land, mountains and valleys that expose the inhabitants to alternations of heat and cold: but if no such alternations occur, the chronic gastro-duodenitis may go on for ever without producing gout.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS,

FROM BIRTH TO PUBERTY.

By DR. RYAN,

Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;

Session 1834-35.

LECTURE XL.

—
Congenital Diseases of Internal Parts—Malformations and Diseases of the Digestive Apparatus.

GENTLEMEN—In the preceding lectures I described the vices of conformation and congenital diseases of the brain, of the dif-

ferent outlets of the body, of the skin, the deformities of the hard and soft parts of the trunk and extremities; and I have now to treat of those of internal organs. I shall commence with those of the digestive system.

On a former occasion I enumerated the vices of conformation of the mouth, lips, soft and hard palate; including hare-lip, cleft-palate, of the tongue, and malformation of the frænum, and I shall now consider the congenital diseases of these parts and of the rest of the digestive organs. Hippocrates announced this wise axiom which has long been received and is now universal in this country—"As the earth is to vegetables, so is the stomach to animals." And this is forcibly exemplified in infants, whose digestive system predominates in the first period of life. When this is severely disordered or diseased, the health and life of the infant are very much endangered. We hold then the above axiom—"Ut terra est arboribus, ita sit ventriculus animalibus;" and we therefore consider the disorders of the digestive system with great attention.

Diseases of the Mouth.—Congestion of blood in the buccal mucous membrane including the whole surfaces of the cheeks, tongue and fauces (throat), has been observed by M. Billard in new born infants. This able author gives the following description of the diseases of the mouth, which is so accurate that I shall transcribe it; as it is the best account of this portion of pathology. Among the inflammations of the alimentary canal he places those of the mouth in the following order:—

Stomatitis—Stomatitis—Inflammation of the Mouth.—It is impossible to give a general description of stomatitis, because each of the tissues which enter into the conformation of the parietes or walls of the mouth may become the special seat of inflammation. Disease in each tissue presents peculiar symptoms, so that the symptomatology is different. I shall therefore successively describe the following varieties of stomatitis:—

- Stomatitis erythematous,
- with alteration of secretion, (*muguet*),
- follicular, (*aphthæ*),
- ulcerous,
- gangrenous, (*gangrene of the mouth*).

I. Erythematous Stomatitis.—The congested state of the lining membrane of the mouth in new born infants disposes it to become the seat of erythematous stomatitis, which is generally characterised by redness, heat, and sometimes dryness of the mouth and tongue. It often co-exists with inflammation of the stomach and bowels, and is rarely accompanied by fever in very young infants, though this symptom is common to infants from the seventh to the ninth month. This inflammation is sometimes confined to

a part, or extends to the whole mouth, and even to the lips, which swell, excoriate, and sometimes become the seat of *herpes labialis*. When the disease persists for a long time, it often causes profuse salivation, especially in infants under the seventh month. In such cases the flow of saliva is often very abundant.

Simple erythematous stomatitis readily yields to emollient gargles and a milk diet; and when it is complicated with inflammation of the stomach and bowels (gastro-enteritis), it disappears by the remedies which remove such inflammation.

It is always to be recollected that the mouth is the commencement of the digestive organs, and that inflammation in any part of the tissues that compose it may extend along the œsophagus, into the stomach and bowels.

2.—Stomatitis, with alteration of Secretion—Muguet—Millet.—This species is often confounded with another, aphthæ, or thrush, though very easily distinguished from it. Muguet presents three different aspects; 1, in the form of very small white points spread over the tongue and inside of the mouth; 2, in the form of larger or smaller patches; 3, in the form of a membrane, which covers the entire tongue and inside of the mouth. Sometimes the points or patches are yellow or reddish, which colour is caused by the contact of bile or a sanguineous exhalation from the mucous membrane affected.

The pointed, creamy, and membraniform excretion is generally preceded by erythematous inflammation of the surface of the tongue or the lining of the mouth. When this inflammation continues one, two, or three days, we observe on the sides of the tongue and lips small white points or papillæ, which cover those of the membrane, to which they adhere. M. Billard has most carefully examined such excretions, and never found them under the epithelium, the surface of which is always their seat. They surmount the membrane, they cover it like mucus, and muguet is really a morbid secretion.

This is the first form of the disease, and is always preceded by inflammation of the mouth. If the inflammation stops, if the secretion which accompanies it is suspended, the little white spots disappear, and the disease is considered distinct or benign. But the inflammation very often advances, the white spots unite and form a large patch either on the surface of the tongue, lips, or cheeks, or covers the whole lining of the mouth. These patches become thick, exfoliate, or detach themselves, leaving the surface inflamed, which secretes materials of a new concretion, or the inflammation ceases. When the whole of the mouth and palate is covered with membrane the muguet is termed *confluent* or *malign*. The papillary muguet usually occupies the tip and sides

of the tongue, the muguet with patches is seen on the internal surface of the lips and cheeks, and the membraniform muguet is situated on the base of the tongue and palate. We can explain the causes of these different forms or aspects of the disease. The papillary muguet is situated at the tip of the tongue, or rather on its numerous papillæ, which secrete drops of mucosity, and speedily concrete or harden. As the papillæ and villosities of the buccal mucous membrane are larger on the palate, base of the tongue, and on the cheeks, the mucus is secreted in a sheet or layer, concretes in the same manner, and assumes the membraniform appearance above mentioned.

We shall now inquire into the nature, causes, symptoms, complications, and treatment of muguet, or stomatitis with alteration of secretion.

The disease is most common to infants; it may extend along the whole alimentary canal from the mouth to the anus, and also into the lungs and along all mucous membranes. The mucus is more tenacious or adhesive than usual, similar to what we observe in chronic bronchitis or winter cough of aged persons. The disease is sometimes seen in adults. Infants at the breast are more subject to it than those of a more advanced age. Perhaps there is something in the constitution of very young infants which predisposes them to this modification of inflammation. It is most common to delicate infants who are crowded in the same place, and to those who are improperly fed with artificial food or deteriorated breast milk. The disease is more frequent in France than in England, and it equally prevails at all seasons. M. Billard, who investigated the disease better than any of his predecessors, informs us, that it always prevailed with an equal degree of intensity at the Foundling Hospital of Paris (Hospice des Enfants Trouvés). Thus, during the quarter ending in January 1826, he observed out of 290 patients, 34 cases of muguet; in the April quarter, out of 235—35; in the July quarter, out of 213—101; and in the October quarter, out of 159—48.

The disease does not appear to be contagious, as MM. Baron and Billard have frequently observed healthy infants drinking from the same cup as the diseased, without contracting the disease. From all that has been stated, we may conclude, that the causes of muguet are: early infancy, bad alimentation, the congregation of a great number of infants in the same place, debility, inflammation of the buccal mucous membrane, and finally, the disposition which mucous membranes of infants present when inflamed to become covered with creamy and membraniform concretions.

When the disease is mild or partial, there is scarcely any fever; but in the severe forms, the skin is hot and dry, thirst is urgent, and the pulse frequent; that is to say, fever is present. This is particularly the case when

the disease extends to the stomach and bowels; or along the mucous membrane of the wind-pipe to the lungs. The voice and cry of the infant are affected when the palate, tonsils, larynx, and trachea are implicated. The voice is hoarse, and the cry dull in some cases.

It appears by the statements of M. Billard, that muguet of the mouth is often complicated with other inflammations. He found, out of 50 cases of muguet of the mouth in infants who died of the disease, two were affected with inflammation of the cerebro-spinal apparatus, four with inflammation of the skin, twelve with inflammation of the respiratory and circulatory system, and in thirty-two, the digestive apparatus was inflamed. It follows from these facts that inflammation of the digestive apparatus is the most frequent complication of muguet, whilst the other inflammations are merely accidental. This conclusion is also confirmed by the fact of the strong sympathy between the mouth and other parts of the digestive organs. Among the thirty-two cases in which the digestive organs were inflamed, there were ten in which the stomach was free from disease; in six the large intestines, and in four the small, were more or less inflamed. As to the other twenty-two, they presented inflammation of the œsophagus or gullet, of the stomach, and of some portion of the small or large intestines.

Treatment.—When muguet is simple, distinct or benign, the mouth should be washed frequently in the day with a piece of charpie or lint wetted with gum water. The bowels should be regulated. M. Guersent employs a mucilaginous decoction with a fourth part of Labarraque's solution of the chloride of lime to wash the mouth of the infant; and he prefers this to solutions of borax and sulphate of zinc. He thinks it equally preferable in lavement to lime water, which often irritates the intestines.—(Dict. de Méd. in 21 vols., art. *Muguet*.) If this plan fails, we may use gargles with alum. All gargles should be sweetened.

When the disease is confluent or complicated (black thrush), with inflammation of the digestive tube, or any other important organ, it should be combatted with the proper means for such concomitant malady. This also applies to buccal and gingival inflammations, or those of the cheeks and gums. These form more or less abundant concretions, which cover the whitish or yellowish pellicles, the gums, and internal surface of the cheeks. Many authors have described this inflammation under the name of aphthæ, others have termed it pelliculous, creamous, stomacacous inflammation, &c. All these varieties ought to be referred to stomatitis, with alteration of secretion, and should be treated by the same therapeutic means. The pathology of aphthæ will prove the difference between the diseases.

3. *Stomatitis folliculosa—Aphthæ—Thrush.*—Pathologists have long disputed about the nature of this disease. It would occupy

too much time to enumerate the different conclusions in the works on this subject; and it is sufficient in my opinion to describe the modern.

Bichat, whose genius has revealed all the advantages that can be derived from the study of the anatomical characters of diseases to establish exactly their differences and their analogies, has asked the following questions in terminating his chapter on the mucous chorion. "Are aphthæ an affection of the mucous chorion? Do they belong to the papillæ? Are they seated in the glands? Are they an isolated inflammation of the glands, whilst catarrhs are characterized by a general inflammation of so considerable an extent as the mucous system? All these questions deserve to be examined; M. Pinel has felt the void of pathological anatomy on this point." (*Anat. Gen.*, t. iv.)

M. Billard has answered all these questions, and has demonstrated that aphthæ consist in an inflammation of the muciparous follicles of the mouth.

"The muciparous follicles," says that lamented pathologist, "of the buccal mucous membrane, invisible in an ordinary state, remain hidden in the substance of the membrane, and supply by their infinity of number the smallness of their size; but when they are inflamed, engorged, and tumefied, they appear upon the internal surface of the lips and cheeks, on the pillars and vault of the palate, or on the inferior and lateral parts of the base of the tongue, in the form of small white specks or points, offering sometimes a coloured spot in the centre, slightly prominent, and often surrounded by a very slight inflammatory circle. These follicles are either isolated and less numerous, or multiplied and spread on all parts of the mouth. They can sometimes be felt with the finger before they can be distinctly seen. They are often not confined to the mouth, but extend into the œsophagus, stomach, and intestinal tube." (*Traité des Maladies des Enfants*, 1833.) The inflammation of the follicles may be very slight, and continue for some time without inducing any serious disease, or they may undergo the following alterations:—

The follicular spots may enlarge and preserve the primitive round form, they may soften in the centre, and give out a white or puriform matter. This is the second stage or ulcerated period of aphthæ. The elevated points are not tubercles, vesicles or pustles, as authors have alleged; but according to M. Billard, they are evidently the muciparous follicles, as their seat, constant form, and central orifice demonstrate. They are perfectly analogous to those which we see in the stomach, small intestines, the cæcum and colon. "If this be the case, says Billard, 'why doubt that the ulceration of these follicles is not the result of their inflammation? What reason is opposed to consider aphthæ as an inflammation of the mu-

ciparous follicles of the buccal cavity, since nobody doubts at present that the round ulcers of the small and large intestines are consecutive of inflammation in the glands of those parts, and which have the greatest analogy with those of the mouth?'"

When an inflamed follicle bursts, it is no longer prominent; it is a superficial round ulcer, with its edges tumefied, and almost always surrounded by an inflammatory circle. It often happens that the centre and edges of this slight ulceration secrete a pul-taceous, whitish, matter, adherent like a crust, which is sooner or later detached, and falls into the saliva of the infant.

Isolated aphthæ are generally situated on the internal surface of the lower lip, the fræ-num, or bridle of the tongue, the internal surface of the cheeks, and upper parts of the gums, when the teeth have not pierced them.

If aphthæ are numerous and contiguous, their edges approximate, the creamy matter they excrete extends from one to the other, and forms a layer, more or less extensive, and more or less thick. It is in this case that aphthæ may be confounded with muguet, but we can always distinguish them, in recollecting the history of the development of the inflamed follicles, and that a solution of continuity or breach of surface does not exist in muguet; besides, the excretion which accompanies aphthæ is always consecutive to ulceration, and is always observed on the internal surface of the lips and cheeks; whilst the white specks in muguet appear upon the lateral parts and towards the tip of the inflamed tongue, and extend to the surrounding parts.

It sometimes happens that aphthæ become covered with a brown crust, which is produced by the escape of blood from the ulcerated surface beneath it; and this has been mistaken for angina maligna, and gangrene. This error would lead to dangerous practice, the use of stimulants, such as ammonia, wine, quinine, &c., instead of leeching, purgation, and antiphlogistic remedies. The result would be that simple ulcerations might be speedily converted into gangrene, which would very much endanger life. There is good reason to suppose that Van Swieten, Rosen, Underwood, and many others, have made this mistake.

When the aphthous inflammation is slight, and when it readily yields to remedies, the ulcerations rapidly heal without leaving any trace behind them.

It appears, then, from the preceding statements, that aphthæ of the mouth and other mucous surfaces present two periods in their inflammatory development—they consist in small white tumours, or these tumours ulcerate, or become gangrenous.

Aphthæ have been compared to miliary eruptions on the skin, by Boerhaave, Van Swieten, Sauvages, Arneman, Willan, Bateman, and others; but if they depend on inflammation of the muciparous follicles, of which I think there is not the smallest

doubt, they cannot be compared to the vesicles of miliary eruption, from which they totally differ.

As we now possess a correct view of the pathology of aphthæ, we may inquire into their causes, general symptoms, complications, and treatment.

Aphthæ are not peculiar, though most common to infants: adults are also liable to them. This led Bateman to propose the division, *aphtha lactantium*, *aphtha adultorum*. He was right: the disease may attack infants at the breast, and adults also. The disease appears in the latter, when the last stage of phthisis arrives, and also in many other chronic diseases. The disease is most common to feeble, lymphatic, or scrofulous infants. When the lymphatic system predominates, it is readily excited by a bad alimentation, by vitiated air in ill-ventilated situations, or where a large number of infants are crowded together. Such is the result of the researches and considerations of Raulin, Lapeyronie, Baudelocque, Auvity, Sanponts, and many others. It therefore follows, that the follicular apparatus of the whole alimentary canal acquires an increase of vital energy at the same time as the lymphatic system; hence this disposition of infants to inflammation of the follicles, and to the alterations which succeed it in different portions of the digestive tube.

M. Billard has observed, at the Foundling Hospital, that whilst muguet prevailed to the greatest extent among the new-born infants, aphthæ were rare before the first dentition. M. Denis is also of this opinion, but experience warrants me to draw a different conclusion as regards the appearance of the disease in this country. Aphthæ are exceedingly common to new-born infants, more especially when spoon fed, or when applied too often to the breast. It occurs as early as the third day, is common during the first month, and less frequent towards the period of the first dentition. M. Billard accounts for his conclusion by stating, that if we follow the anatomical development of the lymphatic glands and follicular apparatus of the digestive tube in the new-born infant, we shall see that these glands are scarcely designed in the new-born infant, but rapidly increase during the first four or five months of life, so that the development of the lymphatic system attracts with it, if I may use the term, all its dependencies, impresses on the constitution of the infant a particular idiosyncrasy, from which results its predisposition to inflammation of the follicles and muciparous glands. Thus anatomical and pathological observation are found to accord. Notwithstanding this statement, we see aphthæ in very young infants, but certainly not so severe as at the fourth or fifth month, or during the first year. It has been remarked by Underwood, Billard, and others, that there is no fever accompanying aphthæ, though the mouth may

be so hot and parched as to irritate the nipple, and oblige the infant to take it with repugnance or precaution. The absence of fever is explicable by modern pathology. Pinel has shewn that it is only after an alteration of the mucous membrane of the digestive apparatus, or what he terms adeno-meningée, appears. He drew this conclusion after his numerous observations of the dead bodies of those who fell victims in the different epidemics of mucous fevers. The state of the mouth, œsophagus, stomach, and intestines, were, according to him, well worthy of remark as to the affection of the mucous membrane of these parts. Nothing was more common than to find aphthæ in the throat, that is to say, the detachment of shreds similar to the epiderm which covers the mucous membrane. (Nosograph. Philos. t. 1). The more recent observations of other pathologists have amply attested the truth of this conclusion. It is also a certain fact, that there exists at the same time a similar alteration in the follicular apparatus of the intestines, and in cases of infantile remittent fever, this is invariably observed.

When aphthæ are distinct, there is little inconvenience during the first period of their development; but it is not so when they are confluent. We then observe that the infant becomes pale, emaciates rapidly, has an abundant secretion, and vomits every thing it takes. This results from the extension of the disease to the œsophagus, stomach, and intestines, complications the most frequent and fatal. We also occasionally observe regurgitations and eructations which give out an acid odour, which is often to be ascribed to the milk the infant sucks or drinks, which the diseased stomach cannot digest, and it is vomited when it begins to undergo decomposition. This acid odour is exactly similar to that of milk turned by heat, or by vinegar. The stomach of the infant is very often disposed to secrete an acid gastric fluid, and various acids, according to some modern pathologists, and this will much more satisfactorily account for the acid odour of the matters vomited or discharged by the lower bowels, than by referring it to the acidity or alkalinity of the humours of the infant. It is not the acidity of the humours that causes the acid odour of the food vomited by persons who dine on indigestible diet, or when digestion is interrupted by a vivid mental emotion, the motion of a vehicle or of a ship.

When aphthæ extend to the intestinal tube, there will be irritation, griping, and diarrhœa, and the discharges from the bowels are so acrid as to irritate the parts about the anus, which become erythematous, red and covered with white specks, similar to the primary disease in the mouth. There is no difficulty in explaining the presence of aphthæ along the whole tract of the mucous membrane of the digestive tube, from the mouth to the anus, or on the vagina or

other portions of the mucous membrane, nor on the derm or skin when irritated, as this tissue is, according to many of our ablest general anatomists, analogous to, or continuous with, the internal lining or mucous membrane of all the passages of the body.

Aphthæ of the mouth are accompanied by pain, as we may suppose by the cries of the infant, its insomnia or want of sleep, its peevishness and disinclination to irritate the mouth by taking food. When the disease extends to the throat, and causes swelling of the tonsils, inflammation of the lining membrane of the windpipe, which is continuous with the mouth and whole digestive tube, the cries of the infant are remarkably altered, and it is this that has led M. Gardien to say, that infants manifest their pains more by hoarseness and wheezing than by real cries.—(*Traité Complet d'Accouchemens, &c.*)

Having now described the pathology of this disease, it remains for me to enumerate the symptoms.

Symptoms.—These consist of an eruption of small white specks, single or confluent, that is, running into each other, which are not vesicles or pustules, which appear on the tongue, lips, cheeks, gums, uvula, palate, and tonsils. They usually soften in the centre, and discharge a glutinous mucus, which forms a thick whitish crust, adhering at first most tenaciously, and falling off without inducing an eschar on the parts beneath. In some cases, the lining membrane of the mouth and throat and the surface of the tongue become covered with patches of a loose ragged membrane, hanging from these parts, and of a dull white, greyish, or reddish colour. There is difficulty of mastication, deglutition, and respiration, in some cases; and the disease may extend to the œsophagus, stomach, and throughout the whole alimentary canal, forming gastro-enteritis, when mucus is evacuated in large quantities by vomiting and stool; at other times, to the trachea and bronchiæ, and mucus is expelled by coughing. Aphthæ often fall off in the space of ten or twelve hours, but they remain attached for several days, and frequently a separation and reproduction take place several times before the termination of the disease. In severe cases the ulcers assume a livid colour, and become gangrenous; in others the surface of the tongue between the ulcers is of a bright red colour. The disease is most common to children in early infancy, though it may appear at any subsequent period of life. It was formerly considered endermic and sometimes contagious; but this pathology is, I believe, exploded at present.

At the commencement of the disease the infant experiences a disinclination to the breast, and is fretful whenever it is applied. Its appetite is bad, and its motions are depraved, though in some cases there is scarcely any indisposition. In others there is much

feverishness and irritability, the mouth becomes hot and tender, the nipples of the nurse become painful and sometimes excoriated or chapped, from the contact of the infant's mouth. The disease is slight when confined to the mouth; but when it extends to the œsophagus, stomach, and bowels, there will be frequent vomiting and diarrhœa, and the last disease irritates and excoriates the lower bowel called the rectum, and the fundament, which become covered with spots like those in the mouth. It does not follow however, that in this last case the internal surface of the mucous membrane throughout the whole digestive tube is affected, as dissection has shewn the contrary, and the sympathy between the mouth and lower bowel would account for the affection of the latter, though the intervening portion of the tube might be free from the disease, just as we observe picking of the nose and lips excited by worms in the rectum.

The predisposing causes of aphthæ are debility, exposure to impure air, use of improper food, a lymphatic temperament and debility.

The exciting causes are irritation of the mouth, by allowing the infant to take the breast, or suck a prepared teat or shield too often, and very frequently derangement of the bowels.

Treatment.—Indications. 1. To moderate or remove the inflammation. 2. To produce a separation of the aphthæ and to heal the superficial ulcers.

The first indication will be accomplished by frequently washing the mouth with lint or soft sponge firmly tied to a small piece of wood, or whalebone, and warm water alone, milk and water, decoction of marsh mallows linseed, barley or any other mild mucilaginous substance; and also to apply the vapour of such decoctions or of warm water to the interior of the mouth. The bowels are to be opened with appropriate medicines. It will also be necessary not to lose sight of the state of the general health of the infant, which may result from impure air or improper alimentation. Infants badly nursed or deprived of sufficient food become rapidly feeble; and we should therefore remove all causes of debility which affect the glandular and follicular systems, always attending to the state of the digestive organs, and taking care not to irritate them by stimulants or the injudicious employment of tonics. These means are sufficient for the cure of the benign form of the disease.

When the aphthæ remain stationary, and are surrounded by inflammatory circles, a leech or two applied to each cheek, with a warm bath, will be necessary, in addition to the above mentioned remedies, to combat the inflammation. The warm bath will determine the blood to the trunk and extremities, lessen it in the different parts of the mouth, and thereby diminish the inflamma-

tion which causes aphthæ. As soon as the inflammation is subdued, and that the aphthæ remain adherent after the employment of emollient lotions, we should use stimulant gargles to detach them. We thus fulfil the second indication of treatment. Borax and honey, or *mel boracis* is an old remedy, but one much too stimulating, more especially as it is in general applied too rudely with the finger covered with a piece of muslin. A better application is composed of one drachm of borax, one ounce of honey, and half-a-pint of water, and this should be gently and frequently employed in the manner already mentioned. Others prefer equal parts of honey of roses and barley water, with a few drops of dilute sulphuric acid. It is often beneficial to touch the ulcerated surface with a piece of sulphate of alumin, with a view of exciting a new action in the ulcerated parts, and to dispose the inflamed surfaces to cicatrise. Alum is an old remedy, and was first employed by Aretæus in the treatment of chronic inflammations of the mouth and pharynx. This medicine was lately recommended by Mr. Mackenzie, of Glasgow, and M. Bretonneau, of Tours, to detach the effusion of the lymph on the soft palate and pharynx in the first stage of croup. It is always necessary to employ it with caution in aphthæ, and to alternate it with emollient gargles, so as not to exceed the degree of irritation which we wish to obtain with this medicine. If used with reserve and proper caution it accomplishes the same result as borax and sulphate of zinc, which are much more excitant. We should also employ a proper solution of chloride of lime or soda in a mucilaginous fluid, as recommended in muguet: a drachm of the solution of either chloride may be mixed with a pint of barley water and properly sweetened. When the infant is irritable, and deprived of sleep, it should have an anodyne, as syrup of poppies, sedative solution of opium, the preparations of morphia, henbane, &c., in appropriate doses. Great caution is necessary in exhibiting emetics and purgatives, lest there be gastro-enteritis.

If there be no reason to suspect this complication, the bowels may be opened with castor oil, almond oil, manna, magnesia, or calomel; and when the disease is solely confined to the mouth, and continues for several days, it will be necessary to give a course of alterative medicines, such as three or four grains of the *hydrargyrum cum creta* (chalk with mercury) at night, and a teaspoonful of castor oil every second or third morning. The alterative powders advised for constipation are also efficacious. The diet of the nurse should be mild and nourishing, and all stimulating articles avoided. All these remedies will sometimes fail, and in such cases change of air is the last alternative. The country or sea air usually acts very favourably in all cases of chronic

disease in children. A nourishing diet, as mentioned when describing artificial food of infants, and for scrofulous children, is also necessary.

When the stomach and intestines are implicated, the treatment for gastro-enteritis is requisite, which will be described under this head. If the aphthæ terminate by gangrene, they are to be treated by the means which will be mentioned in the article *Gangrenous Stomatitis, or Aphthæ*. If they are complicated with or replace a cutaneous disease, by warm baths, frictions on the skin, and the means already advised. When diarrhoea is present, it is to be treated as stated when describing that disease.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 604.)

Organization of the Urethra.—The urethra is lined by a mucous membrane of a light rosaceous colour, connected with the surrounding spongy body by a dense cellular tissue. It is continuous with the mucous membrane which covers the glans penis and prepuce, anteriorly, and with that of the bladder and excretory ducts posteriorly.

The urethra is of a pale white colour, except at its orifice, where it is of a vivid red. It is furnished with numerous lacunæ which are formed by the mucous membrane, constituting small sacs or folds, for the purpose of secreting mucus, to prevent the irritation of the urine in its passage from the bladder. These lacunæ are directed from behind forwards, presenting their apertures towards the orifice of the urethra; one of these is very large in the glans penis, and is called the *lacuna magna*. A projecting column extends from each of these, from before backwards, and these columns converge towards the median line, where they form a kind of raphe or groove, which is particularly apparent in a line passing from the *lacuna magna* along the upper surface of the canal. The urethral lacunæ or folds, are estimated at about seventy in number.

The external surface of the urethral mucous membrane is connected with various tissues in different parts of its course. In its first or prostatic position, it is separated from the gland from which it derives its name, by a layer of cellular tissue. In its second or membranous part the fibrous layer is continued from the first portion, and the canal is strengthened by muscular fibres and the triangular ligament as above described. It has been already stated, that this portion of the urethra is not so thin or feeble as is generally imagined; nor is it so commonly the seat of false passages as some surgeons have asserted. It appears by recent statements that the bulbous portion is much more liable to such injuries, because the

stricture is usually situated at its commencement, and consequently the pressure of an instrument will be anterior to it, and may injure the membranous portion.

When the enlargement is at the commencement of the spongy part, then that position will be more liable to be the seat of false passages than the bulbous. It is also to be remembered, that there is sometimes a semicircular band in the bulbous portion, formed by the fibrous sheath at the commencement of the groove of the bulb, and is particularly marked, when the spongy tissue is void of blood. This band is formed, according to Amussat, by the fibrous neck of the bulb, and not by the perinæal aponeurosis, as stated by Bell and others. When the mucous membrane which surrounds the spongy and membranous parts, is raised with ease, we observe that the membrane is very thin and adherent, especially about the prostate gland, and that under it, there is another membranous layer immediately over the spongy tissue. This layer is the fibrous membrane of the spongy tissue, is continuous with the external one, and forms a fold around the opening of the spongy tissue; and it is this fold that produces the band of the bulb already alluded to, and explains the reason why the extremity of a sound is arrested, and why false passages are much more common than in the membranous portion. It is important to state that the membranous portion presents no obstacle in its normal condition; but when the prostate is diseased, there is a demarcation between this body and the commencement of the membranous portion. If we pass the finger on the part near the prostate, the crest is depressed, and the finger is arrested by a transverse band which prevents its entering the bladder. When we raise the mucous membrane which covers these parts, we find in the crest the two ejaculatory canals which run between this membrane and the prostate, which raise the mucous membrane and cause the form of the crest, on the side of which the membrane adheres, firmly to the prostate on account of the excretory ducts of this gland; we find in this band a muscular ring, which is the sphincter of the bladder; this is much more distinct below than in the rest of the urethral circumference of the bladder, leaving anteriorly, under its surface, a large semilunar depression, the concavity of which is directed forwards, and is divided into two equal portions by the ejaculatory ducts; immediately under the sphincter we find the transverse portion of the prostate, the sphincter of the bladder, and the mucous membrane. The demarcation between the bladder and the urethra is not well marked unless inferiorly, that is to say, where we find the transverse band superior to the ejaculatory canals, and much more posteriorly to their openings into the urethra, which disposition of parts has led M. Amus-

sat to give a satisfactory explanation of the manner in which the semen is evacuated while the urine is retained, and vice versa. He considers that the sphincter of the bladder being superior to the prostate, closes the opening of the bladder, while the ejaculatory canals remain free in the interior of this gland, the firm tissue of which prevents all compression. It also appears to him that these, in erecting themselves, push behind and above them the fleshy fibres which cover them, and form a fleshy bundle more marked here than elsewhere, for the sphincter is not distinct but in this place, and the organization about the urethral opening of the bladder is not the same in the infant and woman as in man, unless at the superior part only, that is to say, that this circumference is much thicker than the bladder, forms a flattened sphincter, but not the muscular ring similar to that which surrounds the inferior part of the vesicle orifice of the urethra in man. In fine, M. Amussat has well remarked that the arrangement of the sphincter of the bladder and of the prostate inferiorly very well explains the reason why the beak of an instrument is arrested and misled at this point, without having occasion to refer to the verumontanum, or to the very large supposed mucous lacunæ, which do not exist in the healthy state of the canal. With respect to the superior surface of the urethra it is of the same colour as the inferior, and has along its median line a series of mucous lacunæ, the openings of which are directed forwards, and are in general more marked than those of the inferior wall of the canal. The surface differs particularly from the inferior, in having no depression and being almost uniform in its whole course: the finger readily glides along it, until it arrives at the part corresponding to the triangular ligament of the symphysis, and easily passes over this. The absence of an obstacle is caused by the insensible union of the spongy with the membranous portion.

The demarcation between the bladder and the urethra is so slightly marked that the finger very readily passes over it. Much dispute exists between anatomists as to the exact point at which the urethra terminates, and the neck of the bladder commences. Some consider that the neck of the bladder is surrounded by the prostate, while Mr. Guthrie contends that it commences at the very opening into the urethra, and is a ring a little broader or thicker than the bladder itself. "It is that portion," says he, "at which the uvula is situated, the urethra being before, the bladder behind it, and the abruptness with which the opening commences, when viewed from within, appears to me to warrant the acceptance of the term, whilst the diseases which affect this part render it worthy of an accurate description. When this part loses the natural elasticity with which it is endowed, and which

it does from internal charges, the consequence of disease, it becomes firm and contracted, constituting a stricture resembling in many respects those which take place in any part of the urethra.* Mr. Guthrie also alleges that disease of this part is extremely frequent, and has been hitherto generally mistaken, and attributed erroneously to enlargement of the third lobe of the prostate gland. This he considers a very great mistake, as in his opinion the gland is by no means so often affected as has been supposed; and he says, "that no greater error has been committed in surgery, than that which supposes the third lobe, as it is called, of the prostate, to be the common cause of those difficulties of making water which occur so frequently in elderly people, and sometimes in young persons. I do not deny that a portion of the prostate may enlarge and project into the bladder, preventing the flow of urine from it; but I mean to infer that this evil takes place more frequently, and is more effectually caused by disease of the neck of the bladder, totally unconnected with the prostate, than by disease of that part, a fact I consider extremely important, because it leads to improvement in this branch of surgery, and to the introduction of more effective means of cure. A knowledge of this fact enables us also to explain how other diseases of the bladder takes place, and how other symptoms not hitherto explained, have arisen. He cited several cases in proof of this fact, and concluded, 1st, that the elastic structure at the neck of the bladder may become diseased without any connection with the prostate gland."

2nd. That the prostate may be diseased without any connection with it. His description of disease in the neck of the bladder is not only original, but highly important in a practical point of view, and I shall notice it fully hereafter.

It is considered by many anatomists, that the urethra possesses a muscular power, as muscular fibres sometimes pass in a longitudinal direction, between the mucous membrane and the corpus spongiosum, being most abundant towards the glans. These are supposed to contract on the passage of an instrument, and cause impediments to catheterism, as is well known to surgeons. Others are of opinion that this contractile power resides in the urethral mucous membrane itself, and that it is augmented by the contraction of the fibrous tissue, which is connected with the urethra; the urethra possesses a contractile power. There is no doubt but in front of the membranous portion, when we inject a fluid into the urethra and compress the glans, we observe on removing the pressure, the liquid is expelled to a distance nearly equal to that to which

the urine is ejected; and that this power is absent in those whose penis has been amputated.

It now remains for me to describe the vessels, nerves, and absorbents of the urethra. The arteries are supplied from the internal pudic, and are four in number; one proceeds to each corpus cavernosum, and two are sent to the bulb to ramify on the corpus spongiosum. It is generally supposed that the arteries pour their blood into the cells of the corpora cavernosa, and that from these the veins arise; while in the corpus spongiosum and glans, the arteries terminate in the veins, forming a plexus of convoluted vessels, frequently anastomosing, and producing a retardation of the flow of blood. The blood is returned from the penis by large dorsal veins, which unite at the root and form one large vein, called the vena magna ipsius penis, which finally empties itself into the internal iliac vein. In consequence of this peculiar course of circulation the blood being supplied by four arteries and returned by one vein, the arteries, when excited to inordinate action, pour in their contents more rapidly, than the vein can remove them, and distension of the organ must necessarily take place. It is also supposed that during coition, the distension of the penis, and the pressure of the arch of the pubis on the vena magna impede its functions and contribute in some degree to interrupt the venous circulation in the virile organ. It follows from the preceding description of the circulation in the penis and urethra, that there is great danger of hemorrhage when the urethra is wounded or cauterized, and that this should be borne in mind when we have recourse to catheterism, the employment of mechanical force to overcome obstacles in the urinary passage, and the use of caustic bougies.

The nerves of the penis are derived from the lumbo-sacral plexus, are portions of the great sympathetic; and hence the diseases of the urethra may disorder the functions of all organs more directly connected by nerves with this part; and from the universal nervous connexion between all parts of the body, may derange the whole. In this way we can explain the sympathetic derangements of all parts of the genito-urinary system, the prostate, bladder, ureters, and kidneys, the digestive pulmonary, circulatory, and central systems, induced by disease in the urethra; and also that idiopathic disorder or disease in any of these systems may derange the genito-urinary apparatus. Lastly, the absorbents of the penis are superficial and deep-seated; the former terminating in the inguinal and the latter in the hypogastric glands.

Such is the organization of the urethra in man. In woman, the structure of the urethra is similar to that of the membranous portion in man. The canal is about an inch and a half in length, and much larger

* Lectures on diseases of the urinary organs, London Med. and Surg. Jour. 1833, vol. iii, p. 267.

- than in the other sex. Its orifice is situated under the arch of the pubis, immediately before the entrance of the vagina, between two small lips. It is easily found about half an inch below the clitoris. The urethra is slightly curved in its course, it corresponds behind to the anterior wall of the vagina, before to the symphysis pubis, and on its sides to the roots of the corpora cavernosa of the clitoris. Its meatus or orifice resembles a dimple about the size of a split pea. This canal admits of much greater distention, from its greater amplitude, than the urethra of the male; and its calibre is so great, that it is very seldom obstructed by stricture or other disorganizations.

Having now concluded the anatomy of the urethra, it remains for me to notice the development of the prostate gland; as diseases of this organ will come in the course of the following inquiries, under serious consideration in a subsequent section.

Development of the Prostate Gland.—The prostate gland is not observable in the human embryo, until the termination of the second month of its existence. At this period it consists of four lobes, which are called prostates; between the fourth and fifth month the two internal and posterior lobes unite, and the gland is then composed of three portions, which between the sixth and eighth month become one substance; but if the perfect union of these three portions should not occur, the gland will consist of three parts, the centre of which is called the middle lobe; but this, according to Mr. Guthrie and other late writers, is of extremely rare occurrence. It has, however, been described by Morgagni, Epist. 41, by Mr. Hunter, 'according to Mr. Guthrie (Lectures on the Anatomy and Diseases of the Bladder and Urethra, Lon. Med. and Surg. Journ. 1833, vol. iii, page 423), and lastly by Sir E. Home. Mr. Guthrie states, that the preparation from which a drawing was made by Sir E. Home, was not anatomically examined, either by Mr. Hunter or Sir Everard, and that the third lobe was merely assumed.

"The fact of an enlargement of a third lobe can now only be ascertained by dividing the bladder and urethra in their longitudinal direction; and I shall propose to the Board of Curators to do so, for it is rather unaccountable that such men as Mr. Hunter and Sir E. Home should have had drawings and engravings made to show disease in a part which was not examined in the only way, by which the proof could be given, that it was actually diseased.

"There is an other thing no less remarkable; and it is, that it is quite clear, from the remains of Mr. Hunter's papers preserved in the colleges, that he had anticipated Sir E. Home in every point connected with this subject." (Op. Cit.). I have already observed, that this experienced surgeon has arrived at the important conclusion, that

disease of the third lobe is of extremely rare occurrence, and was erroneously supposed to exist when the neck of the bladder was in fault.

The prostate gland in the adult, resembles the form and size of a chestnut, it is about an inch in length and half an inch in thickness; it is white, hard, and solid, and is enveloped by a strong fibrous membrane. It has been already stated, that about the middle of the inferior surface of this gland, we observe an oblong rounded eminence, which terminates anteriorly in a straight elongated point, called verumontanum. This gland is very often enlarged, may become inflamed or scirrhus, and is sometimes the seat of abscess or calculi.

Pathology of the Urethra.—The urethra, in common with all muco-fibrous tissues, is liable to irritation and inflammation. The latter and its consequences are the causes of almost all the diseases of the urethra.

Gonorrhœa is the most acute and severe inflammation of the urethra, and is the most common cause of contractions of this canal. This inflammation, after having existed in the acute form for a longer or shorter period, passes into the chronic state, confines itself to a particular part of the canal, and causes thickening, induration, contraction, accidental tissues, and adhesions, which, more or less, obstruct the canal. It need scarcely be observed that inflammation changes the nature of parts, increases their sensibility, and their volume, causing the disorganizations already mentioned, as well as ulceration, adventitious bands, and caruncles.

Urethritis—Blenorrhœa.—This term is applied to inflammation of the mucous membrane of the urethra, in preference to the denominations gonorrhœa, blennorrhœa, blennorrhagia, and urethral catarrh, which signify a symptom, and express false ideas. The causes of urethritis are those which act on the urethra directly, and those that act sympathetically through remote organs. The most common or direct causes are, coition with a person affected with inflammation or ulceration of the genital organs, frequent manipulations of the sexual parts, masturbation, excessive venery with a healthy person, especially when there is inattention to cleanliness, or a great disproportion between the organs of the sexes, and when leucorrhœa, the menses or lochies are present, a contusion or compression of the perinæum, the frequent introduction of a bougie or catheter into the urethra, the injection of irritating fluids into this canal, and lastly, the presence of a stricture or foreign body in this part.

Among the internal causes, are irritations of the different parts of the alimentary canal; the appearance of a tooth has occasionally caused a discharge from the urethra, which was long since noticed by

Hunter and many others, and is sometimes observed at the period of the second dentition; ascarides in the rectum have sometimes produced a similar effect, certain aliments and medicines, such as new beer, asparagus, spices, turpentine, and cantharides may excite urethral discharge; hæmorrhoides has produced the same effects. Those subject to gastric derangement, with or without constipation, may have the genito-urinary mucous membrane in a state of high irritation or inflammation. Irritation of the air-passages also provokes urethritis; asthma, coryza, cynanche, pneumonia, &c. have terminated by urethral discharge. Urethritis is sometimes accompanied by violent cough and difficult breathing, and is arrested when the expectoration acquires a certain consistence, the cough becoming less troublesome. This coincidence frequently explains the causes of pretended pulmonary consumptions formerly attributed to venereal origin, and the epidemic gonorrhœas which was said to have occurred after the sudden change of the weather from hot to cold, which greatly increased the inflammations of the chest. It has been long known that the impression of cold air and moisture on the surface of the body, or on the parts near the genital organs, as immersion of the entire body or the inferior extremities in cold water, may induce urethritis, and increase or diminish urethral discharges.

Chronic inflammation of the bladder, calculus in that organ, or in the ureter, or in the kidneys, may excite urethral discharge: and it is also induced in certain patients by irritations in the fibrous and muscular tissues, such as those caused by rheumatism and gout. Hippocrates stated that stranguary, and many other symptoms, frequently accompanied arthritic pains. Murry, Barthes, and others, described arthritic gonorrhœa. Deplaigne and Titley have observed that gout was suddenly succeeded by a discharge from the urethra, which alternated with the original disease. Bell has observed many patients successively attacked with urethral discharge, and pains in the larger articulations. Cullerier has attested the same fact. The former writer has stated, that the discharge is frequently seen in labourers who work in water. Martin has related the case of a man who suffered from rheumatism in the shoulder, whose pains suddenly ceased on the appearance of a mucous discharge from the urethra. Disease of the lymphatic system will also produce it. It is frequently observed in scrofulous persons from the age of infancy upwards, as attested by numerous obstetric writers. The discharge in such cases may be totally independent of violence offered to the genitals, and has been often erroneously considered contagious, a mistake which has frequently led to the conviction of innocent persons accused of having committed female violation. Such occurrences are graphically described

by Sir Astley Cooper in his Lectures on Surgery. When female children of seven or ten years of age are subjected to violence by libertines, the contusion or distension of the external genitals may cause purulent discharge, though the author of such injury be exempt from blennorrhagia. This fact should be recollected by medical practitioners when giving evidence in courts of justice. A case lately occurred in London, in which the medical men swore that a person accused of having violated a scrofulous child of ten years of age, had infected her with gonorrhœa, though the accused was found perfectly free from any urethral discharge. But it is a vulgar notion that sexual intercourse with a healthy individual relieves or diminishes that disease, and hence the frequency of attempts to violate children of a tender age, or girls about the age of puberty. In all accusations of this kind the male should be examined, and the presence or absence of urethral discharge established. It is also proved beyond the possibility of doubt that venereal excesses between two persons whose genital organs are healthy, may be followed in one or both by urethritis. Cullerier has met with several cases of this description; he relates one, in which the woman enjoyed perfect health, and she communicated blennorrhagia to all who had commerce with her. He also mentions the case of a young girl who was never affected with any genital disease, whom he found perfectly healthy, who very recently had communicated to a young man, gonorrhœa of the most inflammatory description; and he states that he could multiply many such cases. He remarks, that masturbation practised with violence, will produce this affection, he has seen it in children of both sexes; but most frequently in girls, as the irritation is directly made on the mucous membrane. Among the mechanical causes of urethritis, are contusions on the perinæum, equitation, stone in the bladder or urethra, strictures of this canal, the introduction of instruments, and in fact every thing which may mechanically irritate the urethra, or the parts with which it is connected directly or sympathetically. Urethritis arising from such causes, is seldom very acute, is of much more frequent occurrence than is generally imagined, and usually ceases when the exciting cause is removed.

The application of chemical irritants, such as the various substances used in injections, frequently causes urethritis and inflammation of the genito-urinary apparatus. Among this class of causes, we may include natural secretions, which, if accidentally become irritating, under circumstances which at all times it is not easy to appreciate, but among which the decomposition of certain products, in persons who neglect proper cleanliness, induce inflammations of the membranes that furnish them. It is in this way that we can explain the urethral discharge, which sometimes follows sexual

commerce with women during menstruation, the lochial discharge or leucorrhœa. The commonest cause of blenorrhagia or gonorrhœa is the application of a morbid secretion from venereal ulcers, or mucous membranes inflamed by this cause. A question has long been discussed, whether the matter of a chancre could produce gonorrhœa, and vice versa. A vast number of the most experienced authors have written upon this question; the majority of whom are of opinion, that these diseases are totally different. I have never seen a case of gonorrhœa produce syphilis or the reverse. I therefore fully agree with those who deny the identity of these diseases. M. Ricord's *Essays*, published in this journal, establish the fact. Finally, certain diseases of the skin may produce blenorrhagia, such as lepra, tinea, &c.

(To be continued).

Reviews.

Traité complet de l'Art des Accouchemens ou Tocologie Theorique et Pratique avec un abrégé des Maladies qui compliquent la Grossesse, le Travail et les Couches, et de Celles qui affectent les Enfans nouveau-nés avec Atlas. Par Alf. Velpeau Professeur de Clinique Chirurgicale, &c. *A complete Treatise on the Art of Midwifery, or Theoretical and Practical Zoology, with a compendium of those Diseases which complicate Pregnancy, Labour, and the Puerperal condition; and of those which affect new born Infants—with an Atlas.* By Alfred Velpeau, Professor of Clinical Surgery to the Faculty of Medicine at Paris, &c. Third Edition, revised and enlarged. Brussels and London. 1835. Royal 8vo. pp. 547. Sixteen Plates.

We give the title of this learned and standard work in full, for the purpose of enabling our readers to form a correct opinion of its extent, and in justification of our lengthened notice of it.

This work is one of the most stupendous productions of human industry. It contains the best history of gynæcology we have ever seen. The indefatigable author gives a complete catalogue of the works of the best ancient and modern writers on the subject. It is an accurate, well digested, well written history, evincing deliberation, research, judgment, and fidelity. The work is one of the most able, impartial, and comprehensive, which modern times have produced. Every page of it is written with a spirit of candour, impartiality, and philosophy. It is an undertaking of the best kind, and creditable alike to the learning, research, and great

experience of the author. It is a most valuable compilation to those who may not have the opportunity, nor the pecuniary means, to possess the pile of obstetric literature of different ages and nations.

The work before us has been rewritten and remodelled; indeed it is an original production, and not a new edition. M. Velpeau states, in his preface, that he has strenuously determined to avoid injustice to any person. He has spoken of all without hatred or restraint, but also without enthusiasm, and with perfect independence. "The sciences form a republic in which every man ought to be at liberty to search, examine, to have his opinions, and to say what he thinks. Truth is the avowed object of all who cultivate them, but as truth may be arrived at in various ways, I could never understand why a reasonable man could be offended because his ideas do not form the law for others." M. Velpeau has evinced this spirit throughout his work.

Our author claims the merit of having proposed the term *obstetricie* in 1823, that it has since been adopted by Dr. Blundell, and also in Italy. M. Velpeau is in error so far as the adoption of the term *obstetricy* in England, as the editor of this journal was the first to adopt it, previous to the publication of Dr. Blundell's work in 1834, and Dr. Castle, the editor of the work, acknowledged having adopted the term from Dr. Ryan, who used it in 1831. M. Velpeau proposed the term *tocology*, which was also adopted by Dr. R.; but he was not the first who employed the word *eutocia*—a term used by Merriman, Blake, and others. He is entitled to the introduction of the term *occytocic*, expressive of the means of hastening labour. He complains that some of his countrymen have accused him of neologism, an accusation urged very fiercely in this country, against those who venture to introduce terms more conformable to scientific phraseology, (see Preface to *Manual of Midwifery; or Compendium of Gynæcology*. Third Edition. 1831), and to the rules of grammar. He defines the science of midwifery (*accouchemens*), the whole of human knowledge relative to the reproduction of the species. We cannot help observing that the terms first proposed by us—*gynæcology* and *pædonosology*—are more correct and comprehensive

than midwifery, for all that relates to the reproduction of the species. We also regret that the author has not employed our term obstetrician, instead of accoucheur. We trust he will excuse these suggestions, and duly consider them before the appearance of his next edition.

He informs us that he has put under contribution not only the works of his countrymen, both ancient and modern, but also those of foreigners which he was able to procure. His experience is derived from the careful observation of 1,200 parturitions. He further enumerates the various additions he has made to the former editions of the work, which was originally intended as the heads of his lectures. He has appended copious notes at the foot of every page, and cited all authors whose opinions and facts (cases) were important, not to make a parade of vain erudition, but to appropriate to each his position in the vast field of science. He affirms that he has not written a single sentence he has not read, and he ventures to hope that those who know his taste for labour will not question his statement. He has prefixed a history of obstetrics, and illustrated the subject by beautifully executed plates. Such are the chief points touched on in the preface.

The next portion of the work is the introduction, which is divided into four articles. 1. Value of the science of obstetrics. 2. Who ought to practise obstetrics. 3. Historical notice of obstetrics. 4. Division of obstetrics by various authors, and various tables shewing the results of all reports on the subject.

The introduction occupies forty-two closely printed pages, royal octavo, and contains materials sufficient for a large volume, and such as were not collected without the labour of years. This part of the work is so interesting and instructive, that to do it justice we should give a literal translation of it. Our limits will not allow us, "our poverty but not our will consents." We can only notice it superficially.

1. *The value of the science of obstetrics.* In this article the justly celebrated author details and refutes all the miserable drivellers who have attempted to appreciate this branch of science. We strongly advise our Colleges of Physicians and Surgeons, "to

read, learn, and inwardly digest," our author's remarks, as also those knights-errant medical Quixotes, who have figured in the "Times" and in "circulars to the ladies." Let our anile corporations peruse this article, and they must be confounded at their own delinquencies in excluding obstetrics from the pale of medicine. Let them reflect, if they can reflect, on the fact that so late as the year 1750, according to one of themselves, 1 woman died out of every 42; in the British Lying in Hospital in London, in 1780, 1 in 60; in 1798, 1 in 288; and at present, not 1 in 1000, if attended by scientific obstetricians. The mortality of infants was proportionate. In 1758, 1 in 15 perished; in 1780, 1 in 44; in 1798, 1 in 77; at present, not 1 in 100.

The insanity of the colleges is restrained by the good sense of the public. The voice of the public has put the inhuman members of these societies in strait waistcoats. The race of intellect is too fast for them.

The public will have medical attendants at the dangerous hour of human birth, and nothing can prevent it.

But why, in the names of science and of reason, should the generative function in its normal and abnormal states, be excluded from the rest of the human economy?—we never could comprehend.

2. *Who ought to practise obstetrics?* In this article Professor Velpeau urges all the arguments in favour and against midwives and medical practitioners. In this article, the author gives clear evidence that he has consulted the works of Hippocrates, and his eminent successors to the middle ages, when barbarism had obscured, or nearly annihilated all the sciences. He has found in the works of the fathers of physic, that almost every one of the modern obstetric operations were described and recommended. He also cites those of Galen, Celsus, Aëtius, &c.; but has not referred to the work of our illustrious countryman Harvey, in which he would have found, that the discoverer of the circulation of the blood was the first physician after the revival of literature in the fifteenth century, who performed obstetric operations*.

* Exercitationes de Generatione Animalium. Quibus accudent de Partu, de Membris ac humoribus uteri, et de conceptione. 1603.

In his work will be found numerous obstetric cases which he attended, and for which he performed the necessary operations. His work, from which we quote, was published about sixty years before the time at which Jules Clement, a French physician, attended the mistress of Louis XI; and to whom is erroneously given the merit of having been the first male obstetrician. Dates are stubborn things; and those who make random assertions will do well to refer to them.

Our author gives a catalogue of all the eminent writers on obstetrics, to the present period, in strict chronological order. He criticises the respective works, and finds much fault with two of our most celebrated obstetricians. We agree with him in opinion that Burns' work is one of our best, and is better executed than others that have succeeded it. The charge made against many of our writers and lecturers, of not keeping pace with the progress of science in other countries, is perfectly just; for they often seem to be ignorant of the actual state of medicine beyond their own country. The last part of the introduction is devoted to the divisions of labours, and statistical records of the mortality of lying-in women in different public institutions. These records will be perused with great interest by every practical obstetrician. The author now commences his treatise, and divides it into six parts—1. The anatomical part. 2. The physiological. 3. Gestation. 4. The ovum. 5. On parturition. 6. On puerperality, or the puerperal state.

M. Velpeau occupies forty-eight pages in describing gynecotomy, or the anatomy of woman. His descriptions are minute and most accurate. He first describes the bones of the pelvis, articulations, straits, dimensions, differences relative to age, sex, and species, uses of the pelvis, vices of conformation, including all deformities, their causes, and the methods of detecting them; he then describes the sexual organs: such are the contents of the first book. This is the grammar of obstetrics, the book of nature which every obstetrician must study with the deepest attention. No one can practise obstetrics with safety to his patient, or credit to himself, who is not intimately acquainted with gynecotomy, which informs him of the measurements of the pelvis, by which he

learns the largest through which the infant has to pass. We have deemed it necessary to describe the dimensions of the infant's head, and the mechanism of natural labour, after those of the bones of the pelvis, with a view to teach the student the adaptation of the head to the pelvis, during the function of parturition. This is a digression, but one of importance to the obstetric student. It shows him the importance of committing to memory both the measurements of the pelvis and head, and their relations during parturition. This exposition must be given after the osteology of the pelvis, or in the article parturition.

After a careful perusal of M. Velpeau's first book, we pronounce it most ably executed, with the exception of one typographical error, which is calculated to mislead the student.

This occurs in page 87; in the description of the axes of the superior strait or aperture of the pelvis, the word inferior is printed instead of superior.

In speaking of deformities of the pelvis, M. Velpeau does not appear to us to have treated the subject so fully as it merits. He does not state that the pelvis is not necessarily deformed in cases of curvature of the spine, a fact about which we are often consulted by the parents of deformed young women who are about to be married. It should be known that, according to the latest British writers on deformities, when spinal curvature begins after the age of twelve, the pelvis seldom suffers unless there be rickets of other bones. In fact there may be the greatest spinal excuvation, the bones ankylosed almost at right angles, and the women bear children without any operation. We have a pelvis of such a woman in our collection, and many may be seen in our different museums. But it is also a fact, that pelvic and spinal deformity coexist, and that great caution and care are necessary in ascertaining the dimensions, and deciding the question whether it is safe or prudent for a deformed woman to marry. The first obstetric consultation to which we were called after receiving our academic testimonial, was a case in point; and since that period we have been consulted in a dozen such cases. In one of these, the pelvis was so deformed, that the Cæsarean operation only could effect a lady to get

married, that we could only dissuade her from it, by shewing her a pelvis deformed like her own, the impossibility of an infant passing through it if, even embryotomized, and that gastro-hysterotomy alone could enable our practitioner to extract it, or that she should lose her life. Such cases are however of rare occurrence.

Here we must pause at present, and shall continue our review of this splendid work, until we place its merits before our readers.

—o—

ADDITIONAL OBSERVATIONS ON PHLEBOLITES. BY JOHN REID, M. D.

SINCE writing the few remarks on phlebolites which appeared in the last number of the *Edinburgh Medical and Surgical Journal*, I found, during the last summer, several of these bodies in the vesical and uterine veins, which presented some unusual appearances. The largest was at least of the size of a garden-pea; the others were considerably smaller. The largest and several of the smaller consisted of two distinct portions. The smaller portion occupied one of the extremities, was smooth externally, of a bluish colour, and was nearly of the consistence of cartilage; the larger portion was of a bony hardness throughout. When dried, this smaller portion shrank considerably, and resembled in appearance a piece of dried cartilage.

I find, upon more extensive inquiry, as I had previously expected, that many of those much engaged in dissection have observed these bodies more than once. I have found them in five out of the last sixty subjects in the dissection of which I have been concerned. My friend, Mr. Fergusson, informs me that he once found them in great quantity in the mesenteric veins.

Tiedemann gives the following analysis of them by Gmelin:

Animal matter	27.5
Phosphate of lime . .	53.5
Carbonate of lime . .	15.5
Magnesia and less . .	3.5
<hr/>	
	100.0*

It is stated by Dr. Lee that Dr. Prout has also analyzed them, and has obtained similar results.† Though the different changes through which these bodies pass in their formation have now been pretty accurately ascertained, yet the nature of the causes which produce these changes is exceedingly obscure. Tiedemann, Otto‡, Lobstein§,

* Tiedemann's *Zeitschrift für Physiologie*, Viarter Band Erstes Heft, 1831.

† *Cyclopædia of Practical Medicine*, article Veins.

‡ Otto's *Pathological Anatomy*, translated by South.

§ Lobstein's *Anatomie Pathologique*.

Cloquet, and Dr. Carsewell*, all agree that they are formed in the interior of the veins; that they at first consist of a coagulum of blood; in the interior of this clot the fibrin becomes pale and concrete, then assumes an osseous appearance, and this goes on little by little, and layer after layer towards the circumference. We could easily class their formation with the occasional deposition of calcareous matter among the other tissues, if Hodgson's opinion was correct, that they were first formed external to the veins, and afterwards made their way by absorption into the interior; or if, according to Andral†, they were in general first developed in the middle coat of the veins, and then passed into their interior in the same manner as the false cartilages are formed, and pass into the cavity of the joints. Hodgson stands alone in his opinion; and we even find Mr. Langstaff‡, upon whose authority he describes these bodies, inclined to believe that they are formed in the interior of the veins. The adhesions of these bodies to the inner coat of the veins by a fine membrane, as observed by Tiedemann and Cruveilhier§, would afford some countenance to Andral's opinion, were it not at variance with accurate observation; and we may suppose that this appearance was produced by the presence of the foreign body causing irritation and effusion of coagulable lymph.

Tiedemann||, and, following him, Lobstein, suppose them to be formed by a mechanical deposition of the calcareous matter contained in the blood, intermixing itself with the albumen of the blood. It appears to me that this opinion is unable to explain the manner of their formation in many cases, and consequently, can scarcely be regarded as the probable cause of their formation in those cases which seem to agree with this supposition. Mechanical deposition of the matters contained in the blood cannot, I think, explain their formation in those¶ cases, where we find an osseous-looking deposit taking place in the centre of a coagulum, around which the fibrin arranges itself in concentric laminae, increasing in density as we proceed to the centre, and where apparently those nearest the centre gradually assume this osseous appearance, which extends itself towards the circumference.

* *Cyclopædia of Practical Medicine*, article Veins.

† Andral's *Anatomie Pathologique*, vol. ii, p. 421.

‡ *London Medico-Chirurgical Transactions*, vol. viii.

§ Cruveilhier's *Anatomie Pathologique*, vol. ii, p. 71.

|| *Journal Complémentaire du Diction. des Sciences Médic.* vol. iii.

¶ Cloquet's *Pathologie Chirurgicale*, and Observations of Dr. Carsewell in article Veins, *Cyclopædia of Practical Medicine*.

If these bodies resulted from mechanical deposition, could the earthy salts pass through the several dense laminæ of fibrin, and deposit themselves, apparently in certain proportions, in the innermost laminæ? If the presence of the earthy salts was the result of a deposition, would they not rather be found upon the outer surface of the most external lamina, instead of penetrating through it to reach the innermost? We cannot, at least in the present state of our knowledge on the subject, refer their formation to any chemical agency. Their formation is probably akin to the occasional hardening of tubercles into bony concretions, which is a process independent of any vascular organization of the tubercles themselves. It is also illustrated by the formation of the vegetations on the valves of the heart, as observed by Laennec and Dr. Alison—also to the tubercular purulent, or encephaloid deposits, sometimes found in the fibrinous clots within the heart and great vessels.

I can scarcely venture to hazard an opinion on this subject; but I must confess I feel inclined to believe (however fanciful the opinion may appear to some physiologists) that the great resemblance of those bodies in their chemical analysis to the osseous texture, the manner of their formation, and their possessing in some cases physical properties similar to cartilage, can only be explained by supposing that they are the result of a process resembling the formation of the osseous tissue in the other parts of the body.

It is possible, that when our knowledge of the spontaneous motions observed in the circulating fluids of vegetables and animals becomes more extended, we may be furnished with a more satisfactory explanation of their origin.

Tiedemann and Lobstein are of opinion that these bodies are more frequently found in arthritic patients; and they believe that this may be accounted for, by supposing that the blood in those individuals may contain a greater quantity of earthy salts. The concretions, however, found in the joints of arthritic patients consist of urate of soda, a salt not discovered in the phlebolites. In all the subjects in which I found them, there was no reason to suspect any arthritic affection; but having had very few opportunities of dissecting subjects who have suffered from gout, I cannot speak of their relative frequency. They are generally described as being deposited in the dilated veins; but we so often see the dilations corresponding to the varied sizes of these bodies, that it appears probable that they are very frequently the consequence of their presence.

Since the preceding observations were written, I have found several phlebolites, in the spermatic or rather the ovarian veins of the two last subjects I have dissected. In one of these subjects, we found them in all the different stages of their formation.

The London Medical

AND

Surgical Journal.

IMPORTANCE OF THE STUDY OF LEGAL MEDICINE.

MEDICINE, interesting though it be as the most extensive and varied of the sciences, and valuable as an art preserving and restoring the greatest temporal blessing which man enjoys, never assumes a finer position than when it appears as the ally of public justice, and the guide of the laws. The almost unerring certainty with which an enlightened physician may illustrate many cases whose intricacies could never be unravelled without his aid, the efficient protection he may afford to suspected innocence, and the searching light with which he may penetrate the secrecy of guilt, are considerations well calculated to make us proud of our profession. Yet it is not less extraordinary than true, that a great number of practitioners, otherwise well informed, are content to live and die in a state of profound ignorance of all that relates to legal medicine; and that we have no less cause for mortification at the awkward exhibitions made by some professors of our art, than for admiration of the results produced by the knowledge and acumen of others. The study of legal medicine has been till lately so entirely neglected, and is even now so insufficiently enforced, by the guardians of medical education in these kingdoms, that ignorance of the subject on the part of practitioners has been a matter rather of regret than of reprehension; the importance of this branch, however, is now beginning to be so generally recognised, and the facilities of cultivating it so much extended, that future deficiency will justly entail disgrace, and even involve a degree of criminality. Without wishing to make any disagreeable application of these remarks to indivi-

duals, we may allude to a case that occurred last week, where an unfortunate woman was committed for a murder of which she was entirely innocent, and several medical men found it necessary to retract "a hasty conclusion" at which they never could have arrived if they had kept in view the familiar fact that wounds inflicted after death do not bleed. Such mistakes may sometimes involve most serious consequences to the accused, and must always reflect unmerited discredit on medical science, whose dignity every practitioner should hold himself bound to sustain, as well by a due knowledge of its principles, as by a diligent application of its practical resources.

—o—

Of all men living, doctors are the most liable to be praised where they have no merit, and censured where they are not to blame. Every candid man, on recurring to the history of his own practice, will admit that he has sometimes gained great glory for considerably retarding the recovery of a patient; on the other hand, a luckless son of Æsculapius often acquires a reputation little better than that of an assassin, among the relations and friends of a person who has died in spite of the best directed efforts of the healing art.

The laity are extremely apt to form a judgment from results, to which they are in the habit of applying a criterion which they misname *common sense*; thus if a patient were to be denied immediate admission to an hospital, on the ground that his case was not so urgent as that of many other applicants, and the said patient were to die a few minutes after, many would at once conclude that the physician who examined him was either intolerably ignorant or detestably inhuman; yet a case of this kind occurred the other day, at St. George's without any fault on the part of the physician then officiating. The patient laboured under an organic disease of the heart, which every medical practi-

tioner knows may at any time terminate fatally in a moment; at this very hospital the illustrious John Hunter, who was affected with a similar disease, dropped down dead from the effect of some slight circumstance which ruffled his temper; in the same way the poor man whose case was reported in last week's papers, may have fallen a victim to the excitement produced by his want of success in getting admission to the hospital. Although this case does not reflect, in the smallest degree, on the skill or humanity of the physician to St. George's, is it equally clear that it does not impugn the English hospital system? Even though art could have been of no avail in curing, and perhaps not much in alleviating such a disease, is there not something revolting to the feelings of humanity in the idea of a poor fellow being turned away from a *so called* public hospital, to die in the street? In Paris he would only have had to walk in, or if, as very seldom happens, one hospital were crowded, he would merely have had to go to the next. Whence arises this difference? Whence but from the fact that in Paris the hospitals are *national* institutions, commensurate in their plan with the wants of the population; while in London they are *private* institutions, on a comparatively diminutive scale, and altogether unworthy of a powerful and generous nation.

—o—

"FIRST SURGEONS" AND FRENCH SURGEONS.

THE hireling Gazette having received orders, has treated its readers with a dish of abuse, addressed to M. Baumés, whose remarks on our English hospital-surgeons formed the Leader of our number of June 6th. The poor thing acknowledges that such is the only treat it can offer, for it "never expects to convince by argument." Nor are we wild enough to expect such a miracle: who ever heard of the Gazette bringing conviction by argument! It has been labouring so long to prove that rotten fruit is sound, that empty heads are crammed, and blockheads learned prodigies, that

it has got clean out of the way of persuading any one but the empty and blockheads who pay their annual subscription for a weekly puff.

In the impossibility of imagining any other motive, the Gazette ascribes M. Baumés' annoying parallel to an extraordinary feeling of "nationality;" but what does it advance to controvert his assertion, that our hospital surgeons are behind those of the Continent? For that assertion he has at least given detailed reasons, while our green friend proffers only a general contradiction. But, in fact, the parallel in question cannot be dictated by national feeling alone, for the writer makes it in more places than one, as between London and France, "*et ailleurs*."

But let us ask the Gazette, was it "nationality," or some filthier feeling, that urged "several of the first hospital surgeons in London" to make the attempt on its well-known pliability, and endeavour to stop the publication of Dupuytren's surgical lectures, by "expressing astonishment at their general inferiority to the doctrines and practice taught in the schools here?" How happened it that none but "first hospital surgeons" sent condemnatory letters to the Gazette? Or, is the opinion of those magnificos that of all English surgeons? We should be sorry to think so: we should be sorry to think that of the many who travel among the continental schools none did not return minus the mania for throwing scruple doses of calomel to the liver, antimonials to the skin, opium to the nerves, and, worst of all, the *operating* mania, imparted to them by the sforesaid "first hospital surgeons."

Alas! that we should be unable to include the accomplished Mr. Edwin Lee in this rational band—Mr. Edwin Lee, "who is now in Paris," who "has been in the habit of visiting the hospitals of the Continent during the last seven years,"—(what an ingenious and cheap advertisement!)—who has been "nettled by the manner in which English surgeons are spoken of," and who has written a most magnanimous epistle, in bad French, to the Gazette Medicale, and another, in worse English, to the Medical Gazette! But we dry our tears on this afflicting circumstance when we remember that others than Mr. Edwin Lee have been

in Paris, and deny the insinuation—for no broad assertion is ventured—that none but purely local treatment is practised in surgical cases on the Continent, and to maintain that the "*physiologie pathologique*" entails no necessity for any such exclusive treatment. On the whole, however, we ought to congratulate Mr. E. L. on this opportune championship, for we doubt not we shall one day also have to congratulate him—"thanks to the labours of Sir B. C. Brodie"—on his elevation to some third or fourth assistant-surgeonship of St. George's. Meantime we strongly recommend him and all other hospital aspirants to study the learned baronet's work on the joints and the physiology of flexion, particularly of the vertebral and knee-joints.

Let us not be misunderstood. We give all due credit to English surgery, but we deny utterly that our metropolitan hospital surgeons are the highest authorities, or the most capable of teaching it. We have before shewn how necessary time, patience, and condescension are to the performance of the duty of a clinical teacher, surgical or medical. None of these do our hospital gentry bestow on the patient or the student to the requisite degree. No wonder that so few of the rising students of the time of M. Roux's visit should have failed to answer the expectations of that distinguished surgeon; the mode in which they were instructed was vicious; the mode which they found it necessary to employ for obtaining place and practice was vile, and smothered all nobler ambition of science. Whenever, therefore, such opportunity as that afforded by M. Baumés' strictures presents itself for disabusing these individuals as to their vast importance and authority in surgical science, we shall seize it. For the rest, we could name a score of provincial surgeons, each more competent for the office than nine out of ten of those who now grace our metropolitan hospitals.

—o—

"REMARKS ON DROPSY," AT THE COLLEGE OF PHYSICIANS.

To the Editor of the London Medical and Surgical Journal.

SIR—I have sought in vain for a novel idea or fact in the "*Remarks on Dropsy*," of which Dr. Macmichael lately delivered himself at the College of Physicians, an account

of which a contemporary of your's has published.

In *that* Journal such a congeries of common-places and school-boy twaddle is quite at home: it finds friends and equals in every page, and very probably it may find admiring readers among the subscribers who, I take it, are for the most part of that mental calibre that would induce them to read a paper on dropsy, or any other disease, provided it was the dropsy of some "Royal Highness" or "Noble Duke"—children that delight in reading of lucky fellows who "came to ride in a coach and six all very fine." Poor little dears! how they will gloat over this case of dropsy, not more remarkable for the rank and station of the subject of it than for some of the circumstances with which it was attended. Now, that dropsy should happen in a Duke of York I hold to be by no means remarkable, not more so than that insanity should seize kings: and of the latter instances abound. "Alexander lived, Alexander died," and of delirium tremens too: yet nobody, Dr. Macmichael perhaps excepted, dreams of saying that delirium tremens is more remarkable, because Alexander died of it. Dr. Mac., however, we presume, knew his audience when he related this remarkable case: besides, the President was there, and everybody knows his taste when Royalty is concerned, his "affectionate interest in the comfort and recovery" of Royal Highnesses, and his sense of "duty" when those personages are his patients.

But "the circumstances with which it was attended" were remarkable, we are told. Then is every case of dropsy remarkable; for with all Dr. Mac's amplifications, no symptoms peculiar to a royal dropsy can be discovered. To shew how apt the Doctor is at *augmenting* a hydropic case, I will quote the following old womanish twaddle: "But to return to the narrative: the disease continued to make progress, the dropsical swellings to increase, and there was evident fluctuation of water in the abdomen—in other words, a true ascites was now formed; and (here is a well-placed conjunction)! after mature deliberation, it was resolved to endeavour to relieve the difficulty of breathing, and to lessen the pressure from above the extremities." Wonderful result of mature deliberation! Oh! learned Hakims, "to resolve to endeavour to relieve" the breathing of a suffocating man, and "to lessen the pressure from above the extremities!" We might ask which extremities—upper or lower? if the former, God forbid that Dr. Mac. should relieve the pressure from above!

Five mortal columns of print are wasted on such trash as the above quotation. A parallel case is introduced: one of a *pauper* patient in the Doctor's hands; now mark how much more briefly yet more sensibly he dispatches *this* case; (he had been giving

the Duke broom (the *planta genista*) which he wittily observes "agreed so well with our patient, that it was impossible to avoid remarking that it seemed as if the ancient cognizance of the Plantagenets was destined to be the most auspicious remedy administered to a Prince of the House of York!")

"It happened that at this time I had a patient under my care in the Middlesex Hospital, labouring under ascites; and her abdomen became at length so distended, that, after the trial of various diuretic remedies without much benefit, the operation of tapping seemed to promise the only mode of relief, and in a few days it had been determined that it should be performed. To leave, however, no means unemployed, I ordered the digitalis combined with broom, and in a very short time the remedies acted in so decided a manner that the whole of the fluid was carried off, and the operation of paracentesis rendered unnecessary by the powerful action of the kidneys themselves. This circumstance, occurring at this very moment, increased my confidence."

Here is no mature deliberation, nothing remarkable in the circumstances; how then could the doctor suppose that the poor patient's remedies would apply to the "remarkable" case of his Royal Highness? Doctor, doctor, you have not your lesson so completely as the President: why introduce hospital patients into the history of Royal invalids? why venture to hint at the possibility of the same remedy curing the same disease in both? I dare to say the President was chuckling consumedly when you so roughly laid the Middlesex hospital man alongside the Duke and compared their cases. Such, my friend, are not the tactics of the College of Physicians. Say as much nonsense as can be said; rake up the Royal dead as often as you please for your own purposes (people had forgotten that you attended the Duke), butter the Royal living as much as your powers can effect, and the sounds will be sweet and congenial to all who visit the library of the College; but, as your well wisher, I beseech you never again attempt to give a sensible account of a pauper's case.

Trusting, Mr Editor, that you will allow these short observations and this excellent advice to the Doctor, a place in your Journal.

I remain, Sir,
Your obedient Servant.

JULIUS.

Hospital Reports.

NORTH LONDON HOSPITAL.

Lithotomy—Difficulties of the Case.

JOHN EDWARDS, aged 61, was admitted a few days since under the care of Mr. Liston. He had a short time ago submitted to be examined with a view to the operation of

lithotripsy. The explorer, however, caused so much pain and irritation in the bladder, that he rather consented to be cut than undergo any attempt to break the stone.

On Saturday last, Mr. Liston proceeded to operate; the patient was secured, and the presence of the stone detected in the usual manner. The curved staff was introduced, and an incision of about $3\frac{1}{2}$ inches in length made; when the operator introduced his finger, he had much difficulty in feeling the stone; the forceps was now introduced, but it could not be expanded; the wound was enlarged in the original direction with a blunt-pointed bistoury, and a stone removed with the forceps; a small portion of the prostate came away at the same time, which appeared to be an excrescence; the bladder was examined by the operator, and another stone detected, which was removed with a very long scoop and the finger; the operation lasted ten minutes and twenty-five seconds. Mr. Liston now explained the difficulties of the case: he said that the perinaeum was of an unusual depth, the prostate very large and rigid, and the bladder of very great capacity; another cause for his not being able to reach the stone with his finger was, the continual efforts of the patient to extend his limbs, and draw up his pelvis. It was on the whole a most instructive case, though of a very different kind from that which they lately witnessed in that hospital; it would not be fair to judge of a surgeon's capacities by the quickness with which he operates; the difficulties of a case must always be taken into consideration, and the manner in which those difficulties are overcome; this case was, then, instructive, as shewing the necessity of presence of mind under every occurrence. He did not think the patient run greater risk by the removal of the small portion of the prostate, but thought it probable that that might have caused the retention of urine, with which he had suffered for some time. The lithotrite could not have been used in this case from the very irritable state of the bladder; he was no enemy to lithotripsy, but wished to limit it to those cases for which it is suited, and, therefore, its sincere friend. He had only met with two cases before in which he could not feel the stone with his finger, and ascertain every thing connected with it; he once more cautioned them against losing their coolness and collectedness under any emergency.

The theatre was much crowded. The operator displayed the coolness and self-command for which Mr. Liston is celebrated, to very great advantage.

The first stone was about $1\frac{1}{2}$ inches in length, $\frac{1}{2}$ inch in breadth, and $\frac{1}{4}$ in thickness; the second was somewhat smaller; it had got into the folds of the bladder, which added much to the difficulty of its extraction.

18th. In a most favourable state, and likely to do well.

Foreign Medicine.

Treatment of Mercurial Salivation by concentrated Muriatic Acid.—In a clinical lecture lately delivered, M. Velpeau remarks: "I then thought to inquire what tissue or organ is the actual seat of mercurial salivation; whether it was connected with an inflammation of the salivary glands or with some alteration of the mucous cryptæ in the mouth. All the ancient and modern authors that have treated on this subject stay by the former explanation. For me, I agree with M. Berard in considering the latter the better one, for when a gland is inflamed it no longer secretes: besides which, the patients do not refer the pain they feel to the glands, but to the interior of the mouth.

What is the progress and effects of mercury? By its extreme subtlety it is introduced into the system, saturates it as it were and inflames it; for most generally the gums, the internal lining of the cheeks, the edges of the tongue are covered with a thick layer of lymph, and this is most probably owing to an irritation, generated either by sympathy or continuity, and it is therefore essential to look to the cryptæ rather than the glands. This view of the subject induced M. Berard to make use of muriatic acid, and myself to employ it alternately with a mixture of honey, the acid in question, solution of lunar caustic, and several other remedies. For the last two years I have returned to the use of the acid, but I now prescribe it in the pure or even concentrated state. In a patient who had been labouring under severe ptyalism for four days, and to whom I applied the acid by means of a hair brush pencil, the good effects were immediate. I was afraid, however, lest it should produce mischief, but was deceived: a pellicle forms over the mouth, but there is no inflammation. Of three patients treated with concentrated muriatic acid, one has left the hospital: of the two remaining the second recovered in a few days. In these cases the patients were touched with the remedy four times in two days, and this sufficed. In the third patient the inflammation was less acute, and the effects less marked: moreover, the salivation was of some standing; from all which it may be inferred that the muriatic acid is beneficial in proportion to the intensity of the inflammation. To this patient, therefore I applied alum, and the symptoms were almost directly ameliorated; alum, however, to be useful should be used in substance and in large quantities."—*Gazette des Hôpitaux*, June 2nd.

Influence of a Diet of Pork on the Organs.

The fibrous and fatty parts of pork resist the action of the digestive organs for a longer time than most other alimentary substances, and the organs therefore strive with greater energy to overcome the resistance; by this the healthy condition of them by repetition of the process becomes changed into a pathological state, which consists either in inflammation, hypertrophy or various organic changes. So much for the local changes; the general ones are referrible to two sources; first, the inflammatory irritation of a portion of the digestive canal may be reflected on the other organs, and keep them in a continual state of excitation, or a kind of general chronic phlegmasia, leading to emaciation and actual phthisis; secondly, when sausages or other dishes containing pork have been digested by a powerful effort, all the principles of the food have not been equally acted on; the ozmazome, for instance, and in particular, escapes and passes into the circulating mass, impressing on the lining tissues in so exciting a manner as eventually to cause the same results as those above mentioned. Preparations of pork have not, therefore, been inaptly ranked among the heating and deleterious alimentary substances. In saying this, they are only to be understood as acting in a slow manner, unaccompanied with pain, and not involving the necessity for laying up, in short, only with a dietetic influence.—*From a work intitled "Recherches sur les Accidens produits par l'usage des Preparations de Charcuterie avaries."* By M. Pointe.

Diagnosis drawn from the Saliva.

At the conclusion of an elaborate article inserted in the May Number of the Archives Generales, by M. Donné, and intitled, "Recherches into the Chemical Characters of the Saliva considered as a diagnostic means in some affections of the Stomach," the author, after presenting certain cases in confirmation of his views, states:—

"In the four cases I have cited, I have shewn the coincidence of that lesion of the stomach generally attributed to what is called inflammation, with acidity of the saliva. In order to complete this series, it would perhaps be requisite to produce cases in which the saliva, having been found alkaline throughout the whole course of such diseases as pneumonia, pleurisy, encephalitis, &c., the stomach has exhibited no analogous alteration; and, were it not that I fear to become tedious, I could readily choose from among such cases. In fact, I have seen the saliva of an alkaline nature in a great many diseases, and in several instances I have verified the state of the stomach by anatomical investigation. At the present moment I have two cases, one of encephalitis, the other of pneumonia, in which

the saliva had undergone no alteration during life, and in which also the stomach presented no appreciable change, either in its colour, in the development of its vessels, nor the appearance and consistence of its membranes. I have made no allusion to the chemical characteristics of the fluids found in the stomach itself; their nature depends much on that of the beverage the patients may have employed, and occasionally on the presence of bile; the gastric juice is, as is well known, and has been confirmed by very many experiments, strongly acid."

We add to the above conclusions the heads of the post mortem examinations, from which they are drawn: this will suffice to shew the coincidence alluded to by M. Donné.

Case 1.—Intense bronchitis: symptoms of severe fever: *acidity of the saliva*. Treatment by bleeding and emollients. Death. Numerous ulcerations, with vivid redness in the lower portion of the small intestines: stomach distended with gas: *mucous membrane spotted, softened, raised in a pulp in the great cul de sac: black injection of the vessels in other points.*

Case 2.—Ataxic continued fever; *acid saliva*: injection of the cerebral substance: serum effused into the ventricles: *injection and softening of the gastric mucous membrane throughout a certain extent.*

Case 3.—Continued fever: delirium: stupor: *acid saliva*. Treatment, bleedings and emollients. Death. Injection and ulceration of Peyer's glands: *injection and ulceration of the gastric mucous membrane.*

Case 4.—Pain of the side, shivering, cough, pleurisy of the left, and pneumonia of the right side: sudden nausea, vomiting, diarrhoea: *extreme acidity of the saliva*: vigorous antiphlogistic treatment: repeated general and local bleedings. Death. Purulent effusion into the left pleura: circumscribed hepatization of the superior lobe of the right lung. *Vivid injection of the stomach: softening: almost complete disorganization of the mucous membrane.* No ulceration or marked redness of the intestines.

[This is certainly a subject for further and interesting inquiry: for if the secretions of the tongue are so much relied on as an index of the condition of the stomach, why should not the secretions of the whole mucous membrane communicating with that of the stomach—of the fauces, salivary ducts, and cryptæ—be also accurately examined, and diagnostic conclusions drawn therefrom? The same remark applies to the secretions of the skin: we seldom hear of their being attended to, except as regards their quantity, and it may be the accompaniment of a cold or hot surface, constituting cold or warm sweat.]

**FREQUENCY OF INFANTICIDE SINCE
THE INTRODUCTION OF THE POOR
LAW BILL.**

*To the Editor of the London Medical and
Surgical Journal.*

SIR—It is quite lamentable to peruse the daily papers, and see no less than the history of twenty cases of infanticide in the neighbourhood of St. Pancras and Islington in the course of a few days, the result of a law which was called "a boon to the female part of the population." I very much doubt the justice of this law, which compels the softer sex to support their illegitimate offspring, while it frees fathers from all liability to support their children. It enables the idle, affluent, and licentious of our sex to seduce and destroy female honour and innocence with impunity, while it debases woman to the rank of the savage, by compelling her, when unable to support the innocent cause of her shame, to sacrifice its existence. Thirty years' observation on men and manners in this metropolis, has led me to the conclusion, that men are much more vicious and depraved than women; and that they ought to be punished for destroying the peace of families and female virtue. Physiology informs us that one sex is as much influenced by amorous impulse as the other; but the difference of education, of habits, of men, lead them into more licentiousness. Had our legislators duly considered the interests of morals and of society, they could never have passed a law which is a powerful incentive to female seduction, and to the inhuman crime of child-murder. I am ready to admit that the law required to be changed and improved; but it was running into a great extreme to free our sex from all the responsibility. It is deplorable to think that women may be seduced, scouted by society, driven to desperation, and to the frightful crimes of infanticide or suicide. This law will have much influence on the bills of mortality, on public morals and questions of legal medicine. I am one of those who agree with Mr. Chitty in the opinion expressed in his Medical Jurisprudence, that our laws are most deficient in punishing those who throw disgrace on families, and that the crime of seduction ought to be much more severely punished than it is by a paltry mulct. A man who destroys female innocence ought not to be sheltered under a vicious Act of Parliament, or rendered irresponsible for the support of his offspring. Were the law more just, fewer infanticides would occur.

I am, Sir,
Your obedient servant,
ZACCHIAS.

**REFUSAL OF ADMISSION INTO SAINT
GEORGE'S HOSPITAL—SUDDEN DEATH
OF THE PATIENT—DEFENCE OF THE
PHYSICIAN.**

*To the Editor of the London Medical and
Surgical Journal.*

SIR—As a Subscriber to your valuable and independent Journal, from the first number to the present, and having long admired your liberal sentiments, I am convinced you will give me a corner in your pages, while I allude to a case of importance—namely the sudden death of a patient last week, who was refused admittance into St. George's Hospital. You have often quoted the motto, "*Fiat justitia, &c.*" and I mistake you much, if you will not act up to it. I know you have had great reason to complain of the conduct of Dr. M'Leod on many occasions, but especially for his heartless and cold-blooded attacks upon you, a brother physician, and rival editor, the day after the iniquitous verdict against you. If I may venture to form an opinion of your mind, I should think it is constituted on the principle, "to forget is human, to forgive divine;" and, though you owe him little consideration as a rival and an opponent, I entertain no doubt but you will insert this my defence of him, as regards the case to which I have alluded. It appears that when Dr. M'Leod was on duty at St. George's Hospital, a man applied to him for admission into that Institution. According to the rules of that establishment, the board, twenty-five in number, and most of them of the medical profession, decide upon the cases for admission. In the case referred to, they concluded the man had disease of the chest, rather an indefinite sort of decision; and they refused him admission, making him an out-patient. The poor man leaves the hospital, staggers in the street, and is obliged to sit down within fifty yards of the Institution. He is noticed by a good Samaritan who is passing by, a mechanic, who addresses him,—and inquires what is the matter with him—a dialogue takes place by no means creditable to the hospital, the dying man exclaims with a breaking heart, "there is no use in returning there, for they have made me an out patient;" a gentleman sees him and humanely pays for a coach to convey him to the hospital, and when it arrives there, he is dead! Now sir, is it not as clear as the noon-day sun that no blame attaches to Dr. M'Leod; and that if there be any, it belongs to the intelligent Medical Board that refused this poor man admission? No doubt, the *Lancet* will have a furious attack on the Doctor, on the Board and Hospital system, and there is just ground for some animadversions on the Board.

There are, however, exculpatory circumstances in favour of it. The members of it might not have examined the heart or chest

stethoscopically, the symptoms might not have been urgent, but the refusal of admitting the unfortunate man, might have such depressing effects, as to destroy him before he walked a yard from the hospital. Permit me to observe that the illustrious John Hunter dropt dead suddenly of a similar disease, when apparently in his usual state of health, in the very same hospital, and every practitioner knows that sudden death occurs in similar diseases.

I am Sir,
AN OLD SUBSCRIBER.

[We fully agree with our correspondent, that there is no blame whatever attached to Dr. M'Leod, though the ignorant may think otherwise.—Ed.]

MEDICAL EVIDENCE—THE MEDICAL JURISTS OF CLERKENWELL—VERDICT MURDER AND NO MURDER.

—

To the Editor of the London Medical and Surgical Journal.

SIR,—No doubt you must have observed, in the newspapers of last week, the account of the inquiry at the Hatton Garden Police Office, relative to the death of a girl, nine years of age, who was supposed to have been murdered by her mother. It appeared that the surgeons swore, in the first instance, that the girl was destroyed by the mother having introduced a bodkin or knitting case, ten or eleven inches in length, into the rectum; and that this passed to the gall-bladder, which it wounded. This foreign body was discovered by accident, and the surgeons had previously agreed that the child died of croup or inflammation of the lungs. The magistrates committed the accused for murder, a coroner's inquest is held next day, and the same surgeons contradict their former evidence, and maintain that death was caused by inflammation of the lungs, and not by the foreign body; that is to say, that the child died a natural death. They said that they had arrived at a hasty conclusion the day before; for had the bodkin been introduced during life, it would have caused hæmorrhage, a species of knowledge which they did not possess on the preceding day, when before the magistrates. It is a melancholy reflexion, that personal liberty and fair fame are at the mercy of such incompetent medical witnesses as the above; for had any one of them ever perused a work on medical jurisprudence, he would have known the difference between wounds inflicted before and after death.

I am, Sir, yours obediently,
A MEDICAL STUDENT.

Fissures on the Cranial Bones of Infants, after a Natural Delivery.

—

PROFESSOR SIEBOLD, of Marburg, gives the following case in corroboration of the assertions of Haller, Baudelocque, &c. &c. that fissures and other supposed marks of violence may exist in the bones of the cranium of still-born children, from the effects of the expulsive action of the uterus.

A female aged thirty, was received into the Lying-in Hospital, pregnant for the third time. The first child had been extracted by the forceps, but dead. The second, also dead, had been expelled by the efforts of the uterus, after the administration of ergot. On her entrance, this woman was in the following state: the uterus could be felt three inches above the umbilicus, the neck very high and almost effaced; Baudelocque's compasses gave a diameter of three inches and a half; the sacro-vertebral symphysis could not be felt with the finger. Labour commenced in the morning, the waters came away about 5 o'clock, and the os tincæ immediately contracted, as is almost always the case when the neck is merely dilated by the membranes, and these are not instantly replaced by the head of the child. After a labour of nine hours and a half the child was expelled. It weighed seven pounds, and gave no signs of life. An examination of it was made the next day. The longitudinal diameter of the head was four inches and a half; the transverse, three and a half; the diagonal, five; an enormous bloody tumour was situated on the right parietal bone, and the left temple was denuded of its epidermis. The parietal bone of the same side presented three fissures, one an inch and a half in length, and two others of a smaller size. The os frontis also presented a fissure towards its lower part. Moreover, the right parietal was depressed, and much blood escaped by the fontanelles.

It cannot be doubted, that the sole cause of these fissures was an undue pressure of the head against the sacro-vertebral symphysis, and affords additional proof of the means which are employed by nature to facilitate the expulsion of a foetus. If the forceps had been employed, these fractures would indubitably have been attributed to an undue pressure exercised with them; and it must be admitted that in a case where other circumstances demand a judicial investigation, that it would be difficult to decide whether such fissures were the effects of the efforts of nature, or were caused by external violence; an attentive examination of the lesions, and of the pelvis of the woman, could alone throw light on the subject.—*Revue Médicale.*

IMPROVED MINIM MEASURE.

To the Editor of the London Medical and Surgical Journal.

Sloane-square, Chelsea,
6th month, 1838.

RESPECTED FRIEND,—I was gratified to observe that my improved minim measure, as exhibited at the meeting of the Medico Botanical Society, has obtained a favourable notice in the pages of Dr. Ryan's Journal; and I feel assured that he will allow me the opportunity of replying to a few words, which appear in it by way of note, and imply an *overstatement* on my part.

The inequality in the size of drops in different fluids, as influenced by circumstances, is the subject alluded to; and the results there stated, are, I confess, a little startling; but having repeated some of the experiments, I must maintain their correctness; not as the probable mean, but (as it may be observed, is stated in my paper) as the "EXTREMES" of variation to which the mode of admeasurement by dropping is liable.

This little instrument, represented in the woodcut, is coming into extensive use; but is not intended to supersede the No. 60 measure, but rather as an effectual substitute for the old five minim tube, now gone out of use, in which the required quantity is retained by applying the finger to the upper orifice.

My improvement consists in the introduction of a piston of such length as not to touch the fluid measured; and also in the contraction of the lower orifice to a very small bore, by which the inaccuracy arising from the concavity or convexity of the lower surface of the fluid taken up is obviated.

The instrument has also the merit of uniting cheapness to convenience and accuracy.

I am, very respectfully, thine,
ROBERT ALSOP.

CHINESE DOCTORS.

CHINESE doctors are, usually, unsuccessful literati, or persons fond of study. They claim the title of Doctor as soon as they have read a number of books on the subject of medicine, without shewing by practice that they are entitled to the appellation.

Their minute examination of the pulse, which is frequently very correct, gives them some claim to the title of able practitioners. Anatomy, a correct knowledge of which must be gained from dissection, the Chinese regard as founded on metaphysical speculations, and not in truth. Their materia medica is confined chiefly to herbs, which are the principal ingredients of their prescriptions. They have some very excellent plants, but injure and weaken their effects, by mixing them up, as they do, often sixty and seventy in one dose. They generally foretell the precise time of the patient's restoration, but are often found mistaken. To stand against men of this description, who are so very wise in their own imagination, was not an easy task; but I always convinced them, by facts, that our theories, when reduced to practice, would have the most salutary effect.—*Gutslaff's Voyages to China.*

—o—

Case of sudden and unexpected death, in which the Heart had only a single Coronary artery, the coats of which were studded with patches of cartilaginous and ossile deposition. By Dr. W. Thomson.

Mr. D. aged 49, was found dead in bed with his eyes closed, his arms by his sides, and everything betokening his having died whilst asleep. Some years ago he suffered much from rheumatism, but had recovered, and was in the enjoyment of good health, fat and fleshy. He had had flying rheumatism in different parts of his body, at last settling in a leg and arm for ten days or a fortnight before his death, but complained of no other ailment. It was mentioned by one of his friends that he disliked walking fast.

Heart of natural bulk; depositions of bony matter at the roots of two of the aortic valves; a single coronary artery with bony and cartilaginous depositions, particularly hard at its mouth, and extending in small patches down its ramifications.

CORRESPONDENTS.

A Matter-of-Fact Man.—Our Correspondent is evidently connected with some school in which prizes are awarded. As an anonymous writer, he has no right to call on us for an explanation of the paragraph to which he alludes. If a lecturer, which we strongly suspect he is, we call on him to stand forth in *propria persona*, and if he obtain the consent of his colleagues, that he is to be their champion, we shall be ready to publish the correspondence about the school to which he belongs. We decline publishing correspondence of this kind, for reasons we need not mention; but if the whole of the lecturers in any school sign a letter addressed to us, requesting us to do so, we shall comply with their request. We cannot, however, do it at the individual request of any of them who chooses to address us anonymously.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXII.

Organic Sympathy—Animal Sympathy—The Passions.

THE examples of the operation in this way of sympathy, properly so called, or ORGANIC SYMPATHY, as well in health as in disease, are innumerable. It is by sympathy that the primary irritation of the bronchial tubes, for example, by the momentary accumulation in them of carbonic acid and halitus, and that of the lungs generally, by the momentary accumulation of venous blood in the pulmonary arteries, become a stimulus respectively to the irritability of the *expiratory and inspiratory muscles*, so that the immediate stimulus to respiration, or what may be called the fundamental position of the organized body, is, in fact, sympathy; and if we can prove by what means the direct or primary irritation is, in this case, conveyed to distant organs, it will furnish a strong collateral argument in favour of regarding this means as, in all cases, the vehicle of sympathy and passion or instinct—but to this part of the subject we shall recur presently. Cold water, again, or cold air, applied to the face has, by sympathy, a similar effect in exciting the inspiratory muscles; and it is, in all probability, upon this new stimulus that the first inspiration of the new-born infant principally depends. So, also, with respect to the *Circulating Organs*, there is no part of the body with which the heart does not more or less intimately sympathize, the slightest affection, whatever be its nature, of any organ producing a corresponding, and to a greater or less degree specific action on the irritability of this organ, and, consequently, on the pulse; and indeed it is upon this fact, little as it is by most people adverted to, that is founded all our reliance on the state of the pulse, as indicative of the state of the system in general. Nor is the influence of sympathy upon the irritability of the capillary arteries, as *organs of secretion*, less remarkable, an irritation of the female genital organs, for example, by copulation, utero-gestation or parturition, of the nostrils by mustard or onions, or of the mouth by tobacco, operating as powerfully in producing respectively a flow of milk, of tears, or of saliva, as if the stimulus had been applied to the secreting organs themselves. An equally good illustration of the action of sympathy is afforded by the *digestive organs*, any considerable mechanical irritation of the fauces, as is well known, acting in such a manner, as well on the irritability of the muscular coat of the stomach, as upon that of the other muscles which co-operate with this organ in vomiting, as to produce this effect; and indeed the stomach, like the heart, has a more or less intimate sympathy with every organ of the body, and participating more or less in the affections of each. With respect likewise to the effects of sympathy on the irritability of the *organs of sensation*, the irritation excited by light in one part of the eye, constantly becomes by this means so strong a stimulus to another, as to occasion its expansion, and thus to give rise to a contracted pupil; and the irritation of certain parts of the ear, produced by harsh and discordant sounds, not unfrequently acts by sympathy so forcibly on the capillary arteries of the gums, as, by dilating them, to give rise to the sensation called setting the teeth on edge, and sometimes even to hæmorrhage. Lastly, as examples of the action of sympathy on the irritability of the reputedly *voluntary muscles*, may be mentioned the effect of such an irritation of the diaphragm as produces its convulsive descent upon the muscles which depress the lower jaw, in which the jaw descends jot for jot with the diaphragm, so as to occasion yawning, that of certain irritations again of the stomach upon the diaphragm,

so as to occasion hiccough; and that of the salutary irritation of the same organ by the aliment, upon all the voluntary muscles of the body, so as to occasion that greater degree of healthy contraction of those organs on which the sensation of increased energy and alacrity, so generally found to succeed a meal, mainly depends. The effects of the irritation of the nostrils by tobacco in exciting, by sympathy, the contractions of the abdominal muscles, as in sneezing, have been already alluded to. That of the eye by a strong light has sometimes the same effect; and it is in a similar way that any irritation of the membrane of the larynx, or even sometimes of that lining the external auditory canal, excites the muscles of the glottis and abdomen, so as to produce coughing. It is by sympathy also that the irritation of the rectum by the stools, and of the urinary bladder by the urine, act on the voluntary muscles which co-operate in expelling them; and finally, that an irritation of the arm-pits or soles of the feet, as in tickling, becomes frequently so strong a stimulus to various voluntary muscles at a distance, as to give rise, sometimes to uncontrollable laughter, and at others to almost universal convulsions. These are a few of the most striking isolated instances of the operation of sympathy, as a stimulus to irritability, in the state of health, with which alone we have anything to do at present, or still more remarkable examples might be adduced, derived as well from the action of the ordinary exciting causes of disease, which, when applied, as most of them are, to any other organ than that which is to become the seat of the disease, perhaps generally, if not always, take effect by sympathy, as from the translation of diseases from their primary seat to distant organs, and lastly from the operation of remedial agents, which, when administered, as is generally the case, by any other avenue than that on which they are intended to operate, in all probability act only or chiefly by means of sympathy—but upon this wide field we must not enter in this place. But sympathy is perhaps a much more general and important agent in promoting the ordinary vital actions, at least of the higher tribes of organized beings, than these isolated instances of it, from irritations more or less inordinate, would induce us to imagine—not less so perhaps than caloric, or any other to which such beings are constantly to a greater or less degree exposed—and this quite independently of the mutual subserviency of the results of the several functions to the continuance of the rest, to which allusion has been made elsewhere. If it be true that the vital action of every organ of the body consists in its irritation—in other words, that life and irritation are nearly, if not quite synonymous terms—and if the inordinate irritations of individual parts have so obvious a tendency to be extended to others, is it not reasonable to believe that their ordinary irritations, or natural functions, exert likewise a considerable influence over those of more or fewer distant parts, according to the specific irritabilities of the latter, and that accordingly the natural irritation of every organ is in some degree essential to that of all the rest? A beautiful illustration of the influence of one function over others is afforded by the higher classes of animals, at puberty, when one new irritation being set up in the body, female or male—that of the ovaries in the former, and that of the testicles in the latter—the actions of distant organs are so modified by this new irritation, which is of a very different character in the two, that there is scarcely a square inch in the body which does not undergo some change, and almost every organ becomes, after a time, as characteristic of the different sexes as the proper genital organs, which had previously constituted almost the only distinction (*a*). Nor is it only in establishing these differences that the new irritation operates, but it is essential also to perpetuate them; the subsequent abstraction of either the ovaries or the testicles, or even the cessation of the proper function of each, as in old age, going a great way, as is well known, towards obliterating the characteristic peculiarities which the setting up of this function had established (*b*); and if the natural irritation of this one organ has so extensive an influence on that

(*a*) "Propter uterum," said the ancients, "Mulier est quod est." They should have said rather, "propter ovaria;" but the saying, as it stood, sufficiently indicates their observation of the influence of the actions of one organ over those of all the rest.

(*b*) This effect of advanced age is often very remarkable in birds, the hen frequently, on ceasing to propagate, assuming somewhat of the voice and plumage of the cock; corresponding effects manifest themselves in some quadrupeds; and we may notice something similar in our own species, on the approach of senescence, the silver tones of a woman becoming in general more gruff, as the rough voice of a man becomes more "piping and whistling in the sound," and

her soft chin becoming grisly, as his stiff beard becomes soft and relaxed. The naturally capricious and timid mind of woman also acquires, generally, about the same period, more firmness and courage, while the naturally steady and enterprising spirit of man degenerates in both these respects; and, while her feeble constitution becomes commonly more robust, his strong frame becomes in the same degree more infirm. Whether or not Peter Pindar was right, when, in allusion to the investigation of this subject—at that time a new one—by Sir Joseph Banks, and in support of the doctrine in question, he asserted that it was

"——— denied by no man

That Age had made Sir Joseph an old woman,"

of others, can we doubt that those of all the rest have a similar influence, although it is less observable from the latter not being more marked at one period of life than another? We indeed tacitly acknowledge that the healthy irritation of each part is more or less essential to that of others, when we ascribe, on the one hand, the failure of appetite and digestion to the generally diminished action of the system, produced by sedentary habits and other similar causes, and, on the other, the general languor and listlessness which so commonly succeed a debauch, to the stomach being out of order; and what we so unhesitatingly admit with respect to the function of the stomach, both as acted upon by those of distant parts, and as acting upon these, may be perhaps admitted with as little hesitation, *mutatis mutandis*, with respect to that of every other organ of the body. And how extensive is the application of this principle must be sufficiently obvious. For if it be only during the natural irritation of each organ that all the rest receive their proper stimulus, all being less or more excited than natural, when the irritation of any one is below or above par, it will follow that during inflammation or increased secretion in any one part, as occurs, for example, in dropsy, both which states imply, as will be explained in future, diminished irritation—the consequence, it is true, of a previously increased irritation—of the capillary vessels of the part affected, a less stimulus than ordinary must be communicated to all the other parts of the body, including the other secreting vessels, which, not undergoing therefore the necessary primary irritation, of course secrete less than usual, and hence the generally *diminished secretion* attendant on these states; whereas on the sudden cessation of an inflammation, or the suppression of an ordinary secretion, both which circumstances imply reserved or increased irritation of the capillary vessels of the part in question, a greater than the usual stimulus must now be extended to all the other parts, and of course to the other secreting vessels, which, undergoing now more than the ordinary irritation, will have their secretions, on the subsequent collapse or diminished irritation of these vessels, increased—each set of them according to its specific susceptibility of the new stimulus—and hence arise what are called *critical and vicarious discharges*, or, when the collapse succeeding the sympathetic irritation does not so rapidly terminate by secretion, *metastases*. It is sufficient at present to hint at this, as one of the numerous applications of the principle now under consideration, the full investigation of the subject belonging, of course, to another place. It is however only in the higher tribes of organized beings that this extensive influence of sympathy displays itself, since it is only in proportion to the concentration of the several organs, and the adaptation of each to a distinct function, that it is called for; and it is remarkable that it is exactly in the same proportion that the system of nerves, which seems to be instrumental to the conveyance of this stimulus, becomes developed—but to this subject more particular allusion will be made after a few examples of the operation of Passion or Instinct, or *Animal Sympathy*, as a stimulus to irritability, shall have been adduced.

Assuming then, for the present, what will be demonstrated, as far as possible, in future, that passion or instinct consists in an irritation of the brain, as the seat of every mode of thought, the examples of the translation of this irritation to distant organs, so as to act on their irritability, are perhaps even more remarkable than those of sympathy properly so called: we shall begin with the effects of passion in general, and subsequently enumerate a few of those resulting from that department of passion called instinct. Thus, the shortness of breath produced by almost every emotion is a sufficiently familiar illustration of the operation of passion in the capacity of a stimulus on the irritability of the *respiratory muscles*, and the violent panting which succeeds one of the most intense of these emotions, namely venereal gratification, and which is so very disproportionate to the mere exercise which has been undergone, tends very much to strengthen the belief that it is by the same nerves which are naturally subservient to respiration, as effected by sympathy, that the influence of passion extends to distant organs. The frequent excitement of the *heart* also, producing an irregular pulse, palpitations, syncope, and so forth, from various mental perturbations, are equally familiar to every body; as is also their influence on the irritability of the *immediate organs of secretion*, in producing at one time a constriction, and at another a dilatation—the result of a previous constriction—of the capillary vessels, whence arise paleness or blushing, flaccidity or turgescence, suppressed or increased and vitiated secretions. Every body knows the almost instantaneous effect, on the one hand, of fear in blanching the cheeks, and in rendering the eye dull—which is effected by a very similar process—as well as in producing temporary impotence, and that of almost any intense emotion in occasioning an immediate suppression of the menstrual fluid, the milk, the tears, or the saliva (a); nor is any one ignorant of the equally

it is at least certain that senescence has effects somewhat similar to those resulting from castration, and that, as it turns a male almost into a eunuch, so it converts a female almost into a *vigaro*.

(a) Hence, in intense grief the tears do not flow, and it is always a proof of a moderate sorrow when this takes place; tears do not bring relief, as is commonly believed, but they indicate that it has been brought

speedy operation, on the other hand, of diffidence in producing blushing of the cheeks, of anger, and numerous other emotions in eliciting, as it were, a flash of fire from the eye (a), of venereal desire and other passions in producing the erection of the clitoris or penis, the prehensile motions of the fimbriae of the fallopian tubes, the erection of the nipples of the mammae, and the turgescence of many other organs consisting of erectile tissue, and of various other mental affections in increasing and vitiating the several secretions. Thus, with respect to the perspired secretions, the halitus from the lungs is sometimes almost in an instant vitiated by bad news, so as to produce fetid breath; and the effect of fright in increasing the discharge of the intestinal gases, and in rendering them more than usually offensive, is frequently not less instantaneous. The flow of the menstrual fluid likewise, if it is sometimes suppressed, is equally frequently increased by various emotions; and the effect of continued hilarity, on the one hand, and of absolute despair, on the other, in producing gradually an accumulation of the fat is not less remarkable (b). How instantly, also, the whole surface is sometimes bathed in sweat from dismay, most persons have experienced. Among the follicular secretions the flow of the mucilage of the vagina is much promoted by venereal desire, as that of the stools is, as every body is aware, by almost every depressing passion (c); nor is it less certain that the quantity of the sebaceous discharge from the surface, particularly that of the arm-pits, is increased by bashfulness and other emotions (d). Lastly, with respect to the glandular and folliculo-glandular secretions, it is a prevalent, and perhaps a well-founded opinion that jealousy both increases the quantity and vitiates the quality of the bile (e); and it is certain that, as numerous mental

The cleaving of the tongue to the mouth from violent emotion—the *vox hæret faucibus*—is easily explicable upon the same principles. Every body knows the story of the detection of a thief in an establishment of servants, by the dryness of the rice, which he, in common with the rest, had been compelled to hold in his mouth, while each was taxed with the theft.

(a) The fascinating power of “the magic circle of the eye,” independently of any action of its own muscles, or of those of the eye-lids, which most materially adds to its expression, is by no means a mere illusion. The eye is as capable of turning pale and blushing as the cheeks, but it is with white blood instead of red, so that fewer or more of the rays of light which impinge upon its surface are reflected. The only thing wanting to render the art of the player perfect, is a command, as well over the capillary vessels of his cheeks and eyes, as over the voluntary muscles; and even this is sometimes furnished by the force of imagination, which inspires an enthusiastic actor with some degree of those emotions, the effects of which it is his business to embody. Miss Fanny Kelly has been known actually to faint precisely at that instant when the business of the stage required that she should appear to do so; and it is probably to some such power of exciting certain passions at will that we must refer most of those instances in which the heart and stomach have appeared to be voluntary muscles.

(b) “Laugh and grow fat,” is a common saying, but “Despair and grow fat,” would be an equally true one. Persons left long to pine in condemned cells, without a shadow of hope, become, frequently, in spite of their usually slender frame, remarkably fat. Absolute despair is as incompatible with solicitude, as total thoughtlessness; and it is solicitude which emaciates. Cassius was “lean” because he was anxious to redress

his country's wrongs: had he either been indifferent to them, or despaired of redressing them, he would probably have been as “fat and sleek-headed” as any of those whom Cæsar wished to have about him.

(c) It is not, as is so generally believed, from a relaxation of the sphincter ani, that, as observed by Butler,

— “No man is master
Of his posteriors in disaster,”

but from the sudden increase and vitiation of the intestinal gases and stools, which alone are competent to explain the change in the quantity, consistence, and odour, of the discharge; and nature has even rendered this or some analogous discharge under emotion a means of security to some animals. It is thus that the cuttle (*Sepia*, 10) conceals itself, when in danger, by colouring the surrounding water black; and some quadrupeds, as the American skunk (*Viverra*, 49), when pursued, and of course put into bodily fear, void, in the face of their enemies, a mass of filth, so copious and so intolerably fetid, that they are compelled to desist from the pursuit. Some kinds of vulture, also, are said occasionally, when captured, to have recourse to a similar expedient.

(d) A raw girl, when first called upon to exhibit, before company, a taste of her quality, at the piano-forte, or in any other way, affords frequently a good example of this effect of the passions. The unpleasant odour perceived by those standing behind her is often attributed to want of cleanliness—but most unjustly.

(e) Horace speaks of his liver swelling with bile, when he saw his mistress toying with another man; and the phrase of “Green-eyed monster,” as applied to jealousy, is well known. “I will possess them with yellowness,” says lean Jack; i. e. “I will make him jealous, or give him the jaundice.”

perturbations produce a suppression of the flow of the milk, so love of offspring and other affections in an equal degree promote it, while sadness again vitiates it, and renders it unwholesome (a). The effect, finally, of venereal desire in increasing the secretion of the semen, and those of moderate joy or sorrow, and of moderate desire or disgust, in producing an inordinate flow respectively of the tears, and the saliva, however prone intense emotions may be to suppress these secretions, are abundantly familiar to us all—so familiar, indeed, that they cease to attract any attention, and are generally overlooked from the very circumstance which should claim for them the deepest attention (b). Nor is the effect of passion on the irritability of the *absorbing vessels* less remarkable than on that of the secreting; since it is to this that we must refer the blanching, in the course of a few hours, from strong emotions, sometimes the skin (c), but more frequently the hair (d), so many instances of which are on record. The remarkable effects of passion, also, on the irritability of the several reputedly *voluntary muscles*, is sufficiently displayed in the action of the various muscles by which vomiting, sighing, yawning, groaning, screaming, sobbing, laughing, distending the nostrils, turning downwards and outwards the eyes, winking, frowning, and so forth, are effected, respectively from disgust, sadness, annoyance, deep affliction, sudden and intense joy or grief, childish sorrow, mirth, exultation, rage, momentary apprehension, and displeasure; and the numerous alterations in the sound of the voice, as well as in the general expression of the features, owing to the action of numerous muscles the ordinary stimulus to which is volition, from almost every kind of mental perturbation, is well known. Similar alterations, also, are constantly perceived, from similar causes, in the attitudes and gestures of the whole body, from the tremblings of doubt and fear to the utter relaxation of wretchedness, on the one hand, and from the start of surprise to the full perpendicular of astonishment, the rigidity of terror, and the leaping and dancing of extatic delight on the other. The whole art of the player consists in a delicate perception of these efforts of passion on the muscles of the eye, face, larynx, trunk, and limbs, and in an accurate imitation of them by throwing into the same muscles the stimulus of volition.

(a) The effect, in producing a secretion of milk, of an intense desire to secrete it, have been often manifested, not only in mothers, but in young girls who have never been impregnated, and in old women who have long ceased to propagate—nay, even in males, both of the human species and of quadrupeds. Such cases of the formation of milk in young unimpregnated girls are related by Fodéré, Belloc, and others; in old women, by Stack, Montégre, and Kennedy; and in males, by Aristotle, Benedict, Donati, Borelli, Laurenberg, Paulline, the Bishop of Cork, Humboldt, and Blumenbach.

(b) When we reflect on this tendency of the passions to change the character of the several secretions, and remember that it is by the secretions of the mother that the fetus, during its whole organization, is nourished, we may perhaps be excused from at once chiming in with the accustomed cant that the emotions of the mother “cannot

possibly” have any effect on its organism. We “cannot possibly” explain, perhaps, what is the immediate process by which such vitiated secretions have this effect, till we know a little more of the *vis plastica* than its numerous appellations; but neither can we explain, till then, why this effect should be impossible. It is much easier, in these matters, to look shrewd and *incredulous*, than to give any good reason for our unbelief; and if the result, if no process—however well accredited—is to be believed in, till the nature of that process has been satisfactorily explained, we must suspend, for the present, our belief in our own existence.

(c) Journal of Science and the Arts, 1819. Frorieps Notizen, 1826, &c.

(d) Innumerable instances of this occurred, it is said, during the infatuated scenes of the French revolution; and there are few, whose experience does not furnish one or more examples of it.

LECTURE VI.

Articular Inflammation.

ALTERNATIONS therefore of heat and cold are the necessary condition for the develop-

ment of arthritis, and for its conversion into gout. The latter, however, is frequently not the consequence of the former, as we see in some northern tribes, that are barbarous and habituated to the inclemency of the weather. A traveller who lived seven years with the North American Indians, tells me that the only disease they are afflicted with, is acute arthritis, which they treat by making an oven in the ground, and after heating it, plunging up to the neck in it. Whether this mode cures them or does not, they have

no gout; arthritis is the only articular disease to which they are subject, and even that, they rarely have, inasmuch as they are accustomed to the effects of cold.

Another reason that leads me to think that gout is not always dependant on a chronic affection of the stomach and liver, is that it sometimes comes on in youth, even immediately after puberty, without a shade of gastritis, but solely in consequence of cold. I have seen it in this condition: but it is not often observed, because in youth there is great susceptibility and facility in disseminating multiplied irritations and phlegmasia.

Such is the etiology of articular inflammations, according to the present state of our science. We have now to describe their development and progress in the manner pointed out by our own observation and reflection. I commence with arthritis, because it is the most acute form of articular phlegmasia. It frequently comes on after the impression of cold when the individual is warm, and vice versa. A man that has walked himself warm, and then sits down until cold seizes him, is in a good condition to be attacked with arthritis: or on the other hand, if having the extremities almost frozen, he suddenly approaches the fire to warm himself rapidly, he will be seized with pains upon which arthritis may supervene: whereas had he warmed himself gradually he would not have run the risk. These are very common causes of arthritis. It also appears as a sequela of several kinds of inflammation, variola for instance, particularly in cold seasons. A convalescent from a gastro-enteritis being chilled contracts a peritonitis: you then sometimes see the articulations of the trunk seized at the same time with inflammation, especially the sterno-clavicular joint; and this effect is more probable, as the individual may have been warm when the cold seized him. In such an instance the nature of the arthritis is not changed: it is still the consequence of cessation of the skin's action, a cessation that is succeeded by a transfer of action on more or fewer serous and fibrous tissues, as those of the articulations. But this transferred action, which might have gradually subsided had it been slowly enacted, is transformed into a phlegmasia when the impress of cold has been suddenly replaced by that of heat. The chief causes of this transformation is in my opinion the irruptions of blood into joints that are previously cooled, whereby they are heated and irritated.

Arthritis commences with pain, swelling, but slight redness, and sensibility to pressure in and around the articulation. To ascertain the degree to which the inflammation has penetrated, the joint must be moved and somewhat distended; and thus we learn how far it involves the ligaments and whether it is capsular. The disease may occupy two, three, or four joints at once, remain therein

a day, and then pass into others: it is almost always ambulatory. It is propagated and disseminated. Sometimes one articulation only is affected after another: at other times the propagation is to the limb, the surrounding cellular tissue swelling and inflaming to the degree of phlegmon. You need not be astonished at this: all forms of all irritations are capable of being converted into each other. If then in the course of its peregrinations the irritation falls on an articulation that is well supplied with cellular tissue, such as the knee or hip joint, a phlegmon may ensue upon it, that shall either be confined to the immediately circumjacent cellular texture or penetrate into that of the joint, or even into the capsule. This propagation may take place primarily or secondarily: primitively, when the impression of cold is confined to one large joint and directly causes in it a phlegmonous tumefaction: secondarily, when the arthritis does not produce phlegmon in a large articulation until after it has traversed some smaller ones.

The disease is disseminated. The irritation is first communicated to the neighbouring muscles, which contract, flutter, are convulsively agitated, and then remain motionless; then to the nervous system, whence the heart is stimulated and fever originated, the degree of which is always in proportion with the articular phlegmasia. How often have I not seen two or three painful articulations with febrile movement—seen the latter diminish and the pulse relax on the cessation of the pain, then again the acceleration of the pulse when the pain returned, or when a phlegmon formed: and this in as regular a manner as to obviate all doubt that the febrile state was subordinate to the articular irritation. When that irritation is transferred to a joint more ready to contract a phlegmasia than that which it had left, the pulse becomes stronger and more frequent. Together with the fever we always meet a state of general malaise and diminution of appetite, this last varying, as the fever does, with the degree of phlegmasia, disappearing when it is intense, reappearing when it is subdued. But a febrile movement is not always the only event. The viscera likewise receive their portion of irritation: the secretions become disordered, the tongue is mucous, the biliary secretion excessive, and there is a tendency to vomiting: a specific power is exerted in the follicles of the skin, by virtue of which they secrete a sort of oily matter, and the patients appear as if they had been smeared with some fatty substance. Things may go much further, particularly if the subjects are disposed to inflammation, if, for instance, the disease attacks a man whose manner of living has been too exciting, and such as laid him open to a gastro-enteritis that only required a circumstance to be developed. In such case all the phenomena are exhibited in a much more violent form; the patient not

only suffers in the joints, but also suffers from an overwhelming anxiety and immoderate thirst, the tongue becomes vividly red, and, in brief, inflammation is generated in the digestive canal; and as arthritis disposes to the more acute sense of internal pains, the kind of gastro-enteritis experienced may, like the inflamed articulations, be painful to the touch. Should the patient be one disposed to pulmonary congestion, such a congestion, or only a bronchitis, may occur and accompany the arthritis. Acute pneumonia, however, is not often coeval with intense arthritis, for nature is not able for so many points of phlegmasia simultaneously. More frequently a violent gastritis or pneumonitis put a stop to the arthritis.

The influence on the gastric apparatus is more marked in the other form of the arthritis, which is primitively mono-articular, because that form attacks individuals that have suffered in the digestive canal, and have frequently had the liver and the heart in a morbid condition. If, however, acute arthritis takes place in persons having this ordinary pre-disposition to gout, the visceral phlegmasia may become predominant: but in the contrary event, it proves rather a revulsive and preservative means—at least for a time—to the viscera. Still it does not follow that even failing this predisposition, there is any occasion to be astonished at seeing an arthritis cease, and a gastro-intestinal phlegmasia cause it to be entirely forgotten: this occurrence constitutes what is called metastasis or repercussion of arthritis, an occurrence that should not be confounded with the repetition of the pain of that affection in the viscera. There are, in fact, two principal phenomena of arthritis, pain or neurosis, and sanguineous congestion. Pain may be excited in some internal part, as the intestines, even to an excessive degree; in the heart, with palpitations, without any immediate inflammation: so also there may be retention of urine with pain, yet without cystitis. But if there is as yet no existent inflammation, there is a state of irritation that borders close upon it, and to which we must not trust; for *ubi stimulus ibi fluvius*: where to-day there is only a rheumatic affection, to-morrow an actual phlegmasia may rage. All manner of conversions are possible in the infinite shades of our diseases, and one value that I attach to my method of viewing disease is founded on the fact, that it accustoms the physician to feel no surprise at any phenomenon that may present itself.

The duration of arthritis is various. Left to itself it may be prolonged to a month, six weeks, three months, according to the season, and other influences. At the time when, like you, I was a student in this school, it was recommended to respect arthritis from a fear of inducing metastases; some practitioners, therefore, contented themselves with treating it in a mild and inert manner,

by which time was given for the irritation to take its rambles and produce deposits. Nor was that all: after wandering for an indefinite period about the splanchnic cavities, the arthritis finally penetrated them, and then came a scene of embarrassment, thence arose a source of danger. And as the season has a considerable influence over the progress and duration of the complaint, those who were attacked in the winter had to fear its further prolongation; those who fell under it in the spring time, a period when the visceral apparatus are more disposed to inflammation, had to fear the invasion of those apparatus. Yet it was not always entirely left to itself; various treatments were put in practice. It might be confined to the joints, remain there for a longer or shorter period, and disappear without internal disorder; but it always left behind a certain degree of stiffness and engorgement in the immediately neighbouring parts of the articulation. It had a tendency to return, and was even more or less periodical. Had the capsule been involved, there sometimes remained a dropsical affection, or sero-purulent collection, which in time were dissipated, or were followed by ankylosis or led to irremediable alterations of structure, for which no remedy but amputation remained.

What light do dissections throw on the subject? I have had many opportunities of performing them in the first degree of the disease. We meet with the following appearances:—pus around the articulations, almost always in the cellular tissue between the skin and ligaments, and inflammation of the capsules. Sometimes twelve hours suffice for the formation of pus in an articulation, when the arthritis has taken place in one in a febrile condition, and who was previously superexcited, particularly if he is labouring under an eruptive phlegmasia. In general, when the inflammation is vehement, as it is observed to be subsequently to a repercussion of the transpiration from the entire surface, suppuration is effected with astonishing rapidity, six or eight hours being sufficient to produce it. Blood is occasionally mixed with the pus. When the inflammation occupies a large joint, extensive abscesses may form in it. I say nothing of internal phlegmasia, because this is not the place for it, and it is a bad plan to accumulate descriptions, for if we do so we may repeat them after every particular disease.

The prognosis of arthritis, if it be not extensive, and occupies only the small joints, is not adverse: we may at once attack it in its position, and disperse it. It must be observed that the longer it lasts, the more it tends to the internal parts. At each relapse it approaches nearer to the centre; from the hand it goes to the elbow, from the elbow to the shoulder, then to the vertebra, in their several ligaments and capsules: frequently it fixes itself in the articulation of the first

and second vertebra. In general the further from the centre the inflammation is, the less severe it is. The larger the joints it involves, the greater the fear lest it take on the phlegmonous form, and be followed by fistulæ and caries. As regards repercussions, you need not be over frightened of them; very often internal pains are experienced without any internal phlegmasia. They are, however, possible, and the danger is then proportionate to the intensity of the visceral inflammation.

Arthritis has been variously treated. Large general bleedings have been practised; but few physicians of past times thought of combatting it with local bleedings. Especial regard has been had to the slimy condition of the tongue, and to the secretion over the diseased point, and over the entire skin; and it has been considered as essentially lymphatic and calculous. Recourse has consequently been had to sudorifics and purgatives, and as considerable pain has mostly been an accompaniment, narcotics have been added to them; thus they went on to the end of the attack. Some have specially opposed emetics to it: at one time I used to see this in great vogue in Paris, as many as seven or eight emetics being administered. Some of the more robust stood out this treatment, but the majority thereby contracted one or more phlegmasiæ of the viscera that killed them. I knew a professional brother, who gave his wife seven emetic doses in quick succession, in arthritis; from the latter she recovered, but she continued in a state of extreme nervous susceptibility and a few years after died of a chronic gastritis and diseased heart, the consequence of this mode of treatment. An attempt has also been made to apply Rasori's method of administering tartar emetic in divided doses so as not to produce vomiting. I have made inquiries of practitioners that have put this method into practice in a rational manner: for, as regards myself, I make very little use of it except in cases of urgent character, since it appears to me that we have no more right to play with tartar emetic, than with arsenic, a loaded gun or a double edged sword. However, it appears that when it has been given to persons of dull susceptibilities the large doses of tartar emetic have been tolerated, have slackened the progress of and occasionally cured the disease; yet many practitioners have given it up whilst others persist in using it with varied degrees of daring success.

The best method, I opine, is to attack the disease vigorously in the very point it occupies. Thus, the diseased part should be covered with leeches, unless a plethoric condition or congestion of the great viscera indicate that we should begin with a general blood-letting. If you only put on a small number of leeches compared with the intensity of the inflammation and the quantity

of blood in the individual, you will not cure, and may very possibly stimulate, the inflammation. But if you follow it up for two or three days successively, with copious local bleedings, you may almost always succeed in putting a stop to it. This practice I have found to answer remarkably well; but there are cases in which the stomach seems inclined to retain the irritation. In such you must combat it with leeches to the epigastrium as well as the articulation; do not, however, imagine that you can cure every arthritis by treating the stomach. After leeches, you should employ local demulcents; ice has been lauded, but its employment should be regulated by the degree of reaction; it may be good when the heat is excessive, otherwise not; and we have reason to fear lest it should produce a transfer of the irritation to the interior. Emollient poultices are preferable, or combined with narcotics, according to the pain and inflammation; do not believe what has been said about their relaxing the part until it is œdematous. After these means come oleaginous liniments, flannel, resolvent liniments, mercurial or iodated, and, in cases of serous infiltration, compression and revulsives.

If the phlegmasia has fixed on the viscera, after leaving the joints, it should be brought back to the points it last occupied, or where it was in greatest force. Baths should also be used. Sudorifics are useless, particularly if there be a febrile movement; they are only proper when the viscera are entirely free, and the local gorging alone exists; indeed, as a general rule, sudorifics and warm baths are hurtful during the acute stage. The fæces should be got rid of by laxative and emollient glysters, or even by a purgative, care being had that it does not injure the digestive organs. Narcotics should be given for the pain. The fever past, nutriment may be given; but it should be suspended immediately on the slightest tendency to its return. After which, you should be inactive, and not insist, with a sort of systematic obstinacy, either on sudorifics, or purgatives, or emetics, or even on antiphlogistics, but always be led by the case and the indications.

Gout.—We now proceed to speak of gout. I told you that, like the preceding, gout was an affection of the joints, of which people have always strived to make an entity; but I also told you it appeared under different circumstances. I shall endeavour to give you a notion of it that shall exhibit facts in the most accurate way, without any prejudgement of nor commentary upon its nature.

By the term gout is designated an articular phlegmasia, which ordinarily commences in a single joint—a mono-arthritic phlegmasia—most frequently by a small one—a micro-mono arthritic phlegmasia, we may call it, in order to make ourselves in-

telligible in the smallest number of words. This phlegmasia may develop, under the influence of cold alone, without any internal predisposition, without an advanced age, without a plethoric constitution, in short, independently of all the conditions on which the gouty entity has been grounded. But that we may stay by facts, we must state that most frequently it is manifested in persons advanced in age, particularly in those whose parents have been affected with it, who are plethoric, who live well and in the midst of plenty, who have lost some customary sanguineous evacuations, and who have been affected for a varied period with a gastro-duodenal irritation, with more or less congestion of the liver. This phlegmasia commences in a small articulation of the foot or hand, but does not immediately spread over a number of them as in the preceding arthritis.

Sydenham has described the gout remarkably well: we shall follow his description, not because it is Sydenham's, but because it is consonant with nature.

A sthenic or hypersthenic gout has been erected for robust persons, and an asthenic or hyposthenic gout for delicate persons; we shall see how far this distinction holds. Individuals in whom gout is commencing experience, most commonly, during the night, pains in the articulations, generally in the great toe of one foot, or in the index or thumb of one hand, but most frequently in the great toe; they look at the foot and observe a swelling and a kind of sub-erysipelatous redness; they have a shivering fit and febrile movement when the pain is acute. The fever and pain pass away in the course of the following day, and the patient thinks himself well; and in fact he sometimes does get off for so much; but at other times the articulations are again seized, and the symptoms reappear several successive times. At length they cease entirely. Such is the nature of the first attacks.

Subsequently, these attacks are observed to be preceded by some internal disorders, and we remark an excess of irritability, an increase of the venereal appetite, foul mouth, heaviness of head, malaise, and a vague inquietude. These phenomena, which indicate a disordered state of the visceral apparatus, have been considered by the humoral pathologists as the effect of a humour seeking where to fix itself; by the solidists, as a state of nervous debility; by the philosophico-abstractive physicians, as a restlessness of the vital principle, and of the gouty entity. We may remark, en passant, that all classes of authors are reducible to three—the material solidists, the material humoral theorists, and the abstractives.

Such attacks as this may happen in a young man of from fifteen to twenty years, in consequence of cold feet, and in a man of from twenty to forty from a similar cause, without the accompaniment or pre-

lude of any gastritis: of this fact I have certain evidence, though it is more usual to see a gastritis. One, two, or three years afterwards the paroxysm returns, and is then longer, and a greater number of articulations is implicated. The returns most commonly occur in spring and autumn, seasons in which vicissitudes of temperature are more frequent. Sometimes, five, six, eight, or ten years pass over without any return; but more generally gout returns every year, and finally is reiterated several times in the same year, not only in one or two fingers or toes, but in all of them successively. The irritation communicated to the interior is not so readily dissipated: it is no longer confined to a slight febrile attack ending in sweats: an internal malaise is always present, which is frequently the more distressing, as together with the gastro-duodenitis, a stimulating diet, or other causes are in action, this gastro-duodenitis meantime advancing at the same time that the articular phlegmasia does. Arrived at this point, the disease may return three or four times in the year, and even in the summer; it may disappear in a fortnight or six weeks, or be prolonged two or three months. Like arthritis, it tends to the production of engorgement around the joints, especially if it returns before the previous congestion has had time to be entirely dissipated. At each fresh afflux towards the joint it becomes larger, and the engorgement that remains after the acute stage establishes in it a permanent sub-inflammation.

On the other hand the internal phlegmasia advances; the patient becomes more and more subject to the phenomena of chronic gastritis, duodenitis, and hepatitis, or even to pulmonary congestions, and he becomes valetudinarian. Thus two phlegmasias are going on at once, one external, visible, the other internal, invisible, dependant on the former, but sometimes pre-existing, either being capable of existing without the other, and in an independent form.

At length a period arrives when the articulations remain swelled, mis-shapen, and painful, and when there is no longer a necessity for any very active causes to develop the gouty attacks. The visceral impulse consequent on the lesion of the gastric apparatus becomes less essential to their return. In a further stage, when both these causes concur, that is, when to the permanent sub-inflammatory state of the articulations a similarly permanent state of the viscera is superadded, the slightest disorder taking place in the functions of the latter reacts on the joints and produces pain therein; and should this disorder amount to some considerable degree of irritation, it gives rise to fresh and well characterized articular inflammations, which may in turn diminish, and for a short time even efface the visceral affection, so that the irritation

shall predominate sometimes in the internal, sometimes in the external parts. This is observed through a long series of years in a gouty subject, with varied frequency, with varied degrees of violence, according to his way of living and his diet. You may imagine that at length, when disorganization is considerably advanced in the joints, there is no possible chance of affecting resolution. Yet the patient never dies from *their* disease. Were the end of his career dependant on them, he might live a couple of hundred years, according to Hufeland's calculation, who thus reckons the duration of man's life, grounding his reckoning on the principle that every animal is capable of living eight times the period of his incrudescence, and as man requires twenty-five years to arrive at his full development, it follows that he ought to be able to live two centuries. I know not whether this conclusion be correct, with reference to the natural condition of man, but in society, as it now exists, it is far from being correct. In proportion then as the disease advances, the visceral affection makes progress, and by it death at last closes round. Do not suppose, however, that it happens in a fixed and certain manner, and by a cause exclusively peculiar to gout. Gouty people die sometimes by a chronic gastritis, or duodenitis with hepatic turgescence, sometimes by cerebral congestion or effusion, sometimes by pneumonia, or by aneurism of the heart, consequent on rheumatic affections. In general, gouty subjects live to an old age, and the vulgar axiom, that they die by a repelled gout, means nothing more than it is under a disorder of the brain, of the heart, or some other important viscus that they sink.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN,

*Delivered at the Medical School, Westminster
Dispensary, Gerrard Street, Soho;*

Session 1834-35.

LECTURE XLI.

Ulcerous, Pustulous, and Gangrenous Stomatitis—Glossitis. Development, and Diseases of the first Dentition.

GENTLEMEN—I concluded the description of the aphthous form of stomatitis at our last meeting, and shall now direct your attention to other species of that disease.

4. *Ulcerous Stomatitis*.—This species of stomatitis is caused by inflammation of the mucous membrane of any of the parts which compose the mouth, cheeks, and throat; and is a different disease from aphthæ.

It appears as the result of inflammation or ramollissement of the mucous membrane, and is not preceded by any aphthous appearance.

The treatment should be antiphlogistic when leeching, purgation, warm bath and counter-irritation are to be employed; and when ulceration is established, the same remedies used for aphthæ are necessary. Slight escharotics are useful in obstinate cases, and if gangrene supervene, we should have recourse to the remedies for that disease which I shall mention immediately.

These ulcers appear on and under the tongue, on the cheek, and soft palate, arch of the palate, and roof of the mouth, and according to M. Billard, are often fatal. We frequently see them in cases of adults whose degeneration and general health are bad, and also towards the termination of certain chronic diseases.

5. *Pustulous Stomatitis*.—M. Billard employs this term to characterise the inflammation of the buccal mucous membrane, which is developed during the progress of small pox, and which gives rise to pustules analogous to those on the skin. He does not state the exact seat of this form, but says that it is to be treated on the same principles as small pox.

6. *Gangrenous Stomatitis*.—This was termed gangrenous aphthæ by Dr. Underwood and subsequent writers, and is graphically described by M. Billard. Gangrene of the buccal mucous membrane, or of the soft parts that form the cavity of the mouth, may succeed the different forms of stomatitis already described, but particularly the follicular species of that disease.

When aphthæ terminate in gangrene, their edges assume a burned, torn, and soft appearance; they present a brown eschar, which when detached, leaves an open surface, of vermillion and granulated aspect. The eschar is sometimes covered with a soft pultaceous substance of a brown colour, and with an evident gangrenous odour. The surrounding parts become swollen, are of a violet colour, and are soft and easily depressed. The mouth of the infant, always open, allows the escape of the saliva, the face is pale, there is great prostration of the vital powers, and an absence of the fever. The pulse is extremely feeble, the skin is cold, pale and insensible. After some time, vomiting, diarrhoea, tumefaction of the abdomen, and sometimes hiccup supervene.

Gangrene consequent to aphthæ is extremely fatal, as it is accompanied by great prostration of strength, or to use a common term, by debility. The indications of treatment are to support the strength and correct the state of the affected parts. The best means to accomplish these indications, are to support the strength by aromatic spirit of ammonia, wine, quinine, animal and vegetable jellies; and to touch the gangrenous parts

with a solution of chloride of lime or soda, or with sulphuric, nitric, or muriatic acid, by means of a capillary glass tube. A mucilaginous fluid acidulated with some of the chlorides or acids just mentioned, may be applied to the gangrenous parts of the mouth with a piece of soft sponge, or some lint tied on a piece of wood or whalebone. Some advise the application of a solution of alum, and others prefer the nitrate of silver (lunar caustic), or the fused potass formerly called the lapis infernalis. The first mentioned remedies are most efficacious according to my own experience.

There is another form of gangrene of the mouth, which is not preceded by inflammation. This disease is well described by some modern French physicians. MM. Baron, Guersent, Jadelot, and Isnard, have most graphically described it. The first and last of these authors have treated of it the most successfully*. Van Swieten in his learned Commentaries on Boheraave's Aphorisms on Diseases of Infants, has described gangrene and destruction of the gums; but the disease under notice extends to and affects the mucous membrane, and the parietes or structures that compose the cheeks.

I have already stated that the hands, feet, and external genital organs of female infants may be attacked with gangrene, and so may the soft parts that compose the mouth. Infants who are feeble at birth, or affected with chronic or severe diseases, are most liable to it.

According to MM. Baron and Billard, there are two forms of this disease. The first presents a circumscribed œdematous swelling, characterized by an oily appearance of the skin, and by a central point, which is more or less hard, over which there is a dark red spot either on the internal or external surface of the cheek. In cases of young infants there is no fever. An eschar forms on this central spot from within outwards, the mucous membrane becomes disorganized, all the soft parts to the periosteum mortify, and fall off in shreds, mixed with a sanguineous dark fluid, the parietes of the cheeks and gums are destroyed, are expelled from the mouth, and exhale a foetid odour. This is the second degree.

This disease must not be confounded with gangrene of the mouth, accompanied by malignant pustule, which commences on the cheek; or as M. Rayer has remarked, the first differs from the malignant pustule, as the gangrenous inflammation commences in the interior of the mouth, and extends consequently to the skin. This form of gangrene

often succeeds small-pox, measles, and scarlatina, and the face and extremities are œdematous at the same time. A similar disease to this attacks the external genital organs of female infants, and they often die of gangrene of the vulva. Dr. Percival and Mr. Kindar Wood, of Manchester, have graphically described this gangrene, and their account of it will appear in the article on the diseases of the genito-urinary organs.

Treatment.—The treatment must be modified according to the stage of the disease. When there is œdema of the cheek it is to be treated like that of other parts, by purgation, diuretics, diaphoretics, cold applications, as spirit lotion, or one composed of hydrochlorate of ammonia with nitrate of potass. When the œdema is circumscribed, it may be removed by frictions with the liniments of ammonia, and if the part become red a leech or two should be applied.

When these remedies fail, and the disease advances, the affected part becomes purplish or black, and there is erosion of the cheek internally, it will be necessary to cauterize the central point of the tumefaction with hydrochlorate of antimony introduced through a crucial incision made on the external surface of the cheek, or to apply a wire at a white heat, as strongly advised by M. Baron. He prefers it to potential cauteries, as these destroy too much surface and cause greater deformity than his application. Fomentations and emollient cataplasms are necessary after either application, and the mouth ought to be washed with a mucilaginous acidulated gargle, to detach the eschar and moderate the inflammation. This plan often arrests the progress of the disease much better than constitutional remedies. The constitution should, however, be supported by the use of beef-tea, chicken-broth, milk, light wine, in small quantities and diluted with water. The best wines are Malaga, Bucelles, or Sherry. It is always to be remembered that though there is great debility, the digestive tube is often the seat of irritation or inflammation (gastro-enteritis), and therefore stimulating medicines or drinks will only increase it. If there is no symptom of gastro-enteritis, no pain on pressing the abdomen, no vomiting, a cautious use of stimulants is indicated. Modern pathology teaches us, however, that abdominal inflammation often exists without the usual symptoms. M. Billard has related two cases in point. The French are too fearful of intestinal inflammation, and withhold the use of stimulants on this account in almost all diseases. This is very often correct, but the universal application of it in all diseases is decidedly erroneous according to my experience. Thus I treat numerous dyspeptics with tonics combined with aromatics, both at the Hospital and Dispensary with success, as you daily observe; and many of these patients would be treated on the antiphlogistic plan by others. The diagnosis between func-

* Baron, Mem. Sur une affection gangreneuse de la bouche. Bullet. de la Faculte, 1816. Isnard, Dissertation Sur une affection gangreneuse particulière aux enfans. Paris, 1818.

tional and structural dyspepsia is easily drawn. If the symptoms be aggravated by warm fluids, such as tea, dilute spirit of any kind, there is every reason to suspect gastric or intestinal irritation, caused by congestion or inflammation of some portion of the gastrointestinal mucous membrane, and in such cases mucilaginous drinks, leeches to the stomach, and enemata are the remedies. But if the patient is relieved by warm stimulants, which is the case in nine instances out of ten, the bitter infusions with ether, and oil of peppermint, with proper attention to regimen, will effect a cure.

I have also repeatedly observed the good effects of stimulants in the last stage of infantile remittent fever, in which there is great reason to suspect intestinal inflammation or ulceration; and similar good effects are derived in the last stage of typhus from stimulation. I have been in many consultations during which some opposed stimulation on the grounds already stated, the majority advised it, and a marked improvement was the result. The reverse has happened in other instances. It appears to me that if the patient be sinking, even though there be reason to suspect intestinal inflammation, and when the time for employing antiphlogistic means has gone by, we are justified in using stimulants. Glossitis or inflammation of the fleshy part of the tongue is not a disease of infants at the breast, though sometimes observed in children from the seventh year to the adult age. The mucous membrane which covers the tongue is very often inflamed in young infants when affected with stomatitis (inflammation of the mouth), aphthæ or thrush. Glossitis of adults may terminate in scirrhus or cancer, a result I have observed in two cases.

Development and Diseases of the First Dentition.—I have slightly alluded to this subject on a former occasion, and contended, that dentition or teething is a natural function, and would not be productive of pain or any diseases, were the infant in perfect health and its physical education properly conducted. Repeated observation has convinced me of the truth of this conclusion. I have frequently known a vast number of infants, who were managed according to the principles I have laid down for their physical education, that suffered no inconvenience or pain during dentition: in fact, they cut their teeth without their parents or nurses having been aware of it. But infants, in general, suffer severely during dentition, as most of them are affected with irritation in the stomach and bowels, in the organs of the head and chest, in consequence of errors in diet, clothing, exposure to cold, &c. Irritation in the digestive apparatus will extend to the gums, or irritation in any part of the body may derange the whole economy.

There is great importance attached both by medical practitioners and the public to the

pathological phenomena connected with the development of the first dentition. These are very erroneously, in my opinion, attributed to the effort which nature makes in effecting the eruption of the teeth. I shall therefore describe the teeth from their first appearance in their sockets, to their eruption through the gums; and then consider the pathological phenomena of dentition.

There is a vast discrepancy of opinion between physiologists on the development of the teeth. I shall, therefore, quote those who have most minutely examined the function of dentition. Among these are the industrious M. Billard, who not only adduced the chief conclusions of preceding writers, but made numerous dissections, on the results of which he bases his own views on the subject. These I shall give in a condensed form, avoiding all hypotheses.

There exists between the dentary follicles and those of the maxillary bone, which conceals them, very remarkable relations.

The alveolar process of both jaws, in the infant about the third month, consists in a unique groove straighter towards the median line than towards the molar region, and this groove contains a mass of follicles, which, without uniting, are nevertheless so intimately grouped, and appear to form a unique multilobate mass. From the fourth to the fifth month these lobules, which are dentary follicles, are more distinct, instead of being grouped, as it were, one over the other, form an elongated cluster, usually composed of eight distinct follicles; they are so contiguous that they may be raised from the maxillary groove, and if care be taken in the dissection, we may raise with them the dentary artery and nerve, which serves them as a pedicle. If we now examine the alveolar cavity, we find that it presents on its lateral surfaces small projecting points which adhered to the follicles already mentioned. As the infant advances in age, both unite and form transverse septa or partitions, the spaces between which constitute the alveolar processes or sockets of the teeth. The follicles between the sockets are now supplied with nerves and arteries.

Most physiologists admit that the fang, or root of the tooth is supplied with blood, but that the enamel is not, as no injection has ever penetrated it. John Hunter concluded that the teeth were not vascular; and Blake concluded directly contrary. Beclard observes, "we can, I believe, say that the ivory of the crown has not vessels continuous with those of the pulp, but that, nevertheless, it receives continually a fluid which penetrates it by imbibition, that it is probable in regard to the pulp there is the same relation with vessels, as between the hairs, nails, and horns with the skin. *Dict. de Médecine ou Repertoire General des Sciences Med. &c.* t. 11, Paris, June 1835.

At the period of birth there are generally

five distinct sockets in the lower jaw. Each follicle is isolated in its socket.

The alveolar processes are lined by a very thin fine membrane, and the follicle is composed of two membranes, which are discovered with difficulty, according to John Hunter, Fox, Blake, Bichat, Meckel, and others. Meckel says there is a fluid between them, which is more or less abundant in proportion to the age of the foetus. The external one is, according to him, more relaxed, soft, and spongy, than the internal. It is continuous with the gum. The internal membrane is harder and thinner. It forms a sac distinct from the external one and the gum. Its connexions with the teeth are more intimate than those of the external one, for it is properly speaking the formative organ. The dentary vessels expand upon it, in a very evident manner, and when injected are very evident*.

About the fifth month of uterine gestation, the rudiments of the incisor teeth develop themselves in two or three points on the superior part of the internal membrane. These points unite and form a bifurcation, of which the incisors often retain the form on their appearance. These primitive points of induration form scales, which are surrounded by a soft pulp, to which they firmly adhere. It is evident that they are the product of a secretion from the surface of the dentary germ, and the ossification proceeds from above downwards, takes the form of the crown of the tooth, presents a depression or circular neck, from which the neck or root is developed. It is also necessary to state that the ossification proceeds from within outwards. The process of dentition commences in the lower jaw, and advances more rapidly than in the upper. On the fullest consideration of all the facts observed on this branch of physiology, the following conclusions have been drawn:—1, that the teeth are the produce of a secretion, as maintained by the illustrious Cuvier; 2, that their development advances regularly, according to the progress of ossification of the maxillary or jaw-bones; 3, that their appearance above the gums, results in some measure from the development of the teeth, and from that of the alveolar arch; 4, that the cause of the successive appearance of the first and second incisor teeth, of the first molar, and next of the first incisor, is altogether mechanical; that it depends on the more or less perfect formation of the alveolar process intended for each of these teeth, and on the more or less perfect manner in which each tooth is implanted in the maxillary bone.

Many other eminent physiologists besides those already mentioned, have considered the progress of the development of the teeth

in relation to that of the alveolar processes and maxillary bones*.

All the world knows of the changes which the teeth pass through in the different periods of life—that at birth there are none to be seen—that by and by they present themselves—then again disappear, to be replaced by another set, which are themselves in turn frequently cast away before the termination of a natural life; and yet few persons, even those most apt to pry into the causes of passing events, ever think of inquiring why or how do those changes come about? They manifestly take place in accommodation of the stationary character of teeth, as regards size, with the varying dimensions of the jaw-bones at different ages. The teeth, in consequence of the chrystalline enamel which encrusts their exterior, have not a power of enlargement like the other bones of the body, and consequently those which are suited to the capacity of the mouth of a child would be ill adapted to the enlarged jaws of an adult; they are then thrown off and new ones of an appropriate size generated. The shedding of the teeth in old age arises from a different cause and is followed by a very different result. The teeth like their possessor become old and infirm; the circulation of blood in them is obstructed by a clogging up of the holes in their fangs, through which the nutritious vessels find an entrance; and they undergo a premature death. In this state, no longer acting in reciprocity with the living parts about them, they are loosened and ejected from the mouth.

It would be foreign to our present purpose to notice all the anomalies of dentition: how some infants are born with teeth, King Richard III.—Louis XIV.—Mirabeau, and others—how other individuals arrive at the adult age without a single tooth, as was exemplified by a former pupil known to some gentlemen now present; and lastly, how persons at the age of 70 or 80, who had lost all their teeth, were supplied with a new and complete set. You will find a vast deal of information on this subject in Good's Study of Medicine, and in the various treatises on physiology. Some of our surgeon dentists have also accumulated many singular facts of the same description. To these writers I must refer you.

For this reason I shall not cite examples of molar teeth having been developed in place of incisors, or when many of the teeth are wanting or are in close apposition by tartar, or bony union of the crown and roots, as mentioned by Fox. I am only noticing at

* Manuel d'Anat. general. descrip. et path. par J. F. Meckel traduit par A. Jourdan et G. Breschet, Paris, 1825.

* M. Lévillé Mem. sur les Rapports qui existent entre les premières et secondes dents, etc. Mem. de la Soc. Med. d'Emulat. op. cit. Miel, t. 9. M. Delabarre, Methode Naturelle de diriger la seconde dentition, Paris, 1826.

present the anomalies of the teeth before and immediately after birth.

Dentition is a natural function and is often accomplished without disturbing the health. It is generally accompanied by an increase of saliva, the infant drivels, the gum is red, hot, painful, and swollen. The infant puts its fingers or whatever it can grasp into the mouth and presses its gums upon it, which excites absorption and promotes the cutting of the teeth. Pressure, however, is not borne when true inflammation is present, but only when there is the natural excitement, pruritus or itching of the gums. In some cases there is intense inflammation or congestion of the gum, in others there is hæmorrhage into the alveolar processes, or ulcerations, but these cases are of very rare occurrence. M. Billard gives autopsies or dissections of such cases. In other instances there is general redness of the mucous membrane of the mouth, with all the characters of erythematous stomatitis, fever, vomiting diarrhœa, and sometimes gastro-enteritis. In other cases, a severe aphthæ, gingivitis, or gangrene supervenes. A vast number of infantine diseases is attributed to dentition, and it is said to destroy many infants. It is true that inflammation of the gum may irritate the whole digestive tube, the brain, and the respiratory organs, in the same manner as local irritation or inflammation in any part of the body may derange the whole economy. The injury of one nerve may derange the whole, produce convulsions, tetanus, or death. It is for this reason that we have not only the usual symptoms of pain in an inflamed or irritated part, but also in many remote organs, a fact that those uninitiated in medicine cannot comprehend. Thus dentition may cause determination of blood to the head, inflammation of the brain or its coverings (cerebritis, meningitis), water in the head, and likewise inflammation of the throat, œsophagus, stomach and bowels, diarrhœa, cough, and inflammation of the lungs or their coverings.

Many infants have disturbed sleep, and become fretful during dentition. There is a natural salivation which supple the gums; and the infant, like all young animals, bites all bodies it can grasp. This pressure is useful in causing absorption of the gums; and it is for this reason that rings of ivory, bone, glass, coral, and gum-sticks, are employed with advantage. These, however, are hurtful when the gums are red, hot, and inflamed, as the point of the tooth presses on the inflamed gum. At this time softer substances are used—such as India rubber rings, dried figs, &c. These substances are moistened and softened by the saliva, soothe the tissue of the gums, and prevent inflammation.

The treatment of the local complaints of the first dentition, ought to be simple. The plan proposed by the celebrated Boerhaave

is one of the best. He advised the application of emollient, mucilaginous, and refrigerant lotions to the gums; antiphlogistics, hard gum-sticks, and incising the gums with a lancet. He recommended cream, the white of egg with syrup of violets, or rose water. This gargle was to be applied to the gums on lint. Others have added a small quantity of laudanum. This is the chief ingredient in all patent vegetable soothing syrups for cutting of the teeth. It requires to be used in a very small quantity, not more than two or three drops at a time. It may be swallowed with the saliva and narcotise or poison the infant*. When there is heaviness and constant tendency to sleep, we suspect congestion of the brain, and follow the advice of Harris, by applying a leech at the angle or affected part of each jaw, or behind each ear. The infant should be placed in a warm bath, and a cap or napkin wetted with cold water, applied to the head while the infant is in the bath. If this be omitted, the bath may do as much harm as good. The cold drives the blood from the head, while the heat diffuses it to the rest of the body; and in this way the quantity in the brain is very much diminished. In such cases the bowels should be properly regulated. When there is fever, and it is accompanied by great thirst, a copious use of barley-water, cold water, milk and water, toast and water, should be given freely.

When there is inflammation of one or more points of the gums, leeches and incision are necessary. Van Swieten has given a very wise direction as to incision. It is not necessary, he says, to incise or cut the gum until it is evidently elevated by the tooth, and is hard, red, and painful; for if the tooth is deep in the gum, it cannot be forced to make its appearance by incision; this cicatrises, the cicatrix or scar is harder than the tissue of the gum, and will give more resistance to the advance of the tooth than the latter. The practitioner will, therefore, in such a case, compromise his reputation, if he hazard incision until the tooth is pressing on the upper part of the gum. I have known one case, says Van Swieten, in which the tooth did not appear for eight months after the incision (*Morbi Infantum*). It must be obvious that cutting the gum, while the tooth is undeveloped and is buried in the jaw, is a useless and injudicious practice; because the operation cannot possibly favour the growth of the tooth. Yet the operation is recommended by one of our eminent surgeons, on the grounds that a cicatrix being a new part is more readily absorbed than the gum. I agree, however, with those who entertain the opinion that incision ought not to be practised

* Bracelets and amulets for cutting the teeth, are gross impositions on the credulity of the public. I need scarcely state, they are perfectly useless.

unless the gum is swollen, hot, and painful, in consequence of the pressure of the tooth against it. In making the incision prematurely, the appearance of the tooth, so far from being accelerated, is retarded, on account of opening the capsule of the tooth before the latter is perfectly ossified. As to the practice of scarifying the whole gum from one side of the jaw to the other, when a single tooth is protruding, it is a disgrace to modern surgery. I have heard of such incisions having been made several times, when each tooth advanced, which showed, in my opinion, the grossest ignorance on the part of the operator. The cruelty, the barbarity of cutting the whole gum from one extremity to the other, whenever a tooth projects, deserves the strongest reprobation. The mode of incising the gum deserves attention. The head of the infant is to be held, while the operator opens the mouth and separates the jaws. He then introduces a bistoury, three-fourths of whose edge is covered with lint, and makes an incision parallel to the alveolar margin; and then, separating the jaws still more, he makes another incision transverse to the first. These incisions should be made down to the tooth—the gum ought to be completely divided, and no flap or bridle allowed to remain. This crucial incision discharges the congestion or inflammation of the gum, and removes the irritation caused by the pressure of the hard tooth on the irritated nerves of the gum which are subjected to it. This operation is by no means so painful as is generally imagined by mothers; indeed, I have repeatedly performed it, though the infants never cried during the operation. But in other instances they screamed loudly, and in a few seconds fell into a tranquil sleep, from which they awoke apparently in perfect health, even after they had been in convulsions, to the moment at which the incision was practised.

Some writers have lauded this operation in the most extravagant terms, as having miraculously saved the lives of numerous infants. Others cannot believe that it has ever saved the life of a single infant. Experience has convinced me of its importance when there is a cerebral congestion, convulsions, spasmodic cough and breathing, excessive diarrhoea, inflammation of the fauces or throat, and of the stomach and bowels (gastro-enteritis). When dentition is complicated with these diseases, and the gum is swollen and painful, an incision will be followed, in most cases, with decided advantage. I feel convinced that I have observed infants die for the want of it. I have never observed it followed by ulceration, gangrene, aphthæ, or stomatitis. The treatment of the sympathetic diseases, excited by dentition, such as those already mentioned, will be described in that of each of them.

It is also foreign to the object of these lectures to notice the whole pathology of den-

tition and the teeth at different periods of life, their irregularities, and the diseases caused by them; and for the same reason I omit dental surgery and hygiene. I cannot, however, but allude to my introduction of pure nitric acid as an application to caries in teeth of children and adults as a remedy which affords instantaneous relief of toothache, without causing any pain, provided it be used soon after the pain commences, and that the nerve of the tooth, the gum, and the alveolar process are free from inflammation or suppuration. It is much easier to apply it to the lower than to the upper teeth; and it should come in contact with every point of the caries to afford relief. This cannot always be accomplished when the upper teeth are affected, or in those cases in which the diseased part is on the side of the tooth and the next tooth in close contact with the affected one. The acid should be pure and carefully applied so as not to spatter on the mouth; and after its application, the mouth should be washed out with tepid water. In most cases, instantaneous relief is afforded; and the extraction of the tooth, which is a painful operation, rendered unnecessary. It is erroneously supposed that a tooth to which the acid is frequently applied decays very rapidly, but this is certainly not the fact. I have known several instances which prove the contrary. I have not known this remedy fail in a single instance of children or adults, when applied in a few hours after the commencement of the tooth-ache, that is to say before the nerve of the affected tooth has had time to become inflamed. It has frequently relieved patients whose cheeks were swollen and inflamed, when there was reason to suppose the nerve of the affected tooth was more or less inflamed. The acid excites severe pain in some cases, but these are rare exceptions.

Diseases of the Salivary Glands.—The salivary glands are very rarely diseased in newborn infants. M. Billard, whose observations were the most extensive, remarked but one case of ranula. The soft palate, its pillars, the amygdalæ or tonsils and the pharynx, in other words all the parts that compose the throat are liable to various vices of conformation and to congenital disease. I shall now consider these affections.

Vices of Conformation.—The vices of conformation of the velum palati or soft palate, consist in its division, more or less complete; or it may be too long, impeding dentition, and requiring excision. When the palate is divided, the infant cannot suck properly, and the milk or other food it takes, may in bad cases escape through the nostrils. In cases of adults, the operation of staphyloraphy proposed and first performed by Baron Roux, is resorted to in most cases with success. The pharynx or throat is too short in some infants, and impedes deglutition. When an infant cannot suck the breast milk, or that which it drinks, there is

either malformation of the pharynx or oesophagus, or inflammation. Of two hundred infants from one to ten days old, whose bodies M. Billard examined, he found the isthmus of the throat injected or inflamed in ninety. He also found that this state of the throat existed in infants of eight or ten days old, who had redness of the derm or skin. This proves an intimate relation between the skin and mucous membrane of the digestive tube.

The tonsils are occasionally congested in new-born infants, and in some cases covered with a layer of blood. These, and all other soft parts of the throat are occasionally inflamed. MM. Roche and Sanson have described these varieties as palatitis, pharyngitis, palatopharyngitis; but as each of the parts included under these terms, are rarely the exclusive seat of inflammation, which usually attacks all of them in succession, I shall describe them under the term Inflammation of the Throat, at our next meeting.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 660.)

Symptoms.—Some time after sexual intercourse between a healthy man and a diseased woman (and the period varies), the symptoms of urethritis commence. These are a sensation of heat at the orifice of the urethra, extending more or less into the canal, and sometimes confined to the glandular portion alone. A titillation, more or less urgent, accompanied by a slight sensation of heat, an almost incessant desire to evacuate the bladder, an increase of venereal impulse, frequent and long-continued erections, more especially in the company of the other sex, or during sleep. Those symptoms are often accompanied or succeeded by unpleasant sensations in the testicles, spermatic cords, and groins, with a sense of fulness, weight, and tightness, in the inferior surface of the penis and perinæum. In the course of two or three days, the titillation is confined to the extremity of the penis, is soon converted into pain, which is more aggravated during the expulsion of the urine. The orifice of the urethra now becomes very sensitive and inflamed, its lips are reddened and tumefied, they are separated from each other, sometimes appear excoriated, and give passage to a small quantity of serous, limpid, whitish, yellowish, or greenish fluid, which stains the linen. The patient very soon experiences in the whole length of the canal, which becomes hard, and projectile externally, a tension accompanied by a disagreeable heat, and lancinating pains. The desire to pass urine becomes more and more urgent; but the contraction, and tumefaction of the mucous membrane causes such a

diminution of the canal, that the stream of urine is rendered very small, and rapidly diminishes. The jet of urine is frequently interrupted, curved, spattered, or bifurcated; and is so often solicited by the irritation or titillation at the neck of the bladder or about the anus, that it becomes so imperious, the patient is obliged to yield to it immediately. The urine in passing, causes a burning and painful sensation to which the French give the name of *chaude-pisse*. The pains are most vivid, at the moment the urine begins to pass; they diminish during its evacuation, and return with greater intensity while the last drops are being expelled. The frequency and durations of the erections are chiefly increased during the night, especially if the patient reposes on his back on a soft warm bed. The violent pains that they excite, disturb the sleep, and often oblige the patient to rise, and these pains render sexual congress very disagreeable, and sometimes impossible, while the emission of the semen produces such an intense degree of heat, that patients have compared it to the application of a red-hot iron. In some cases the erection or emission induces hæmorrhage; at this period the patient experiences in the whole length of the inferior part of the urethra, an unpleasant sensation, sometimes accompanied by a sense of weight and darting pains, which prevent him from walking, standing for any length of time, crossing his legs, or sitting. He is now affected with obstinate constipation, and a distressing tenesmus. The urethral discharge continues uninterruptedly, gradually increases, and becomes more or less copious. It consists at first of a thick whitish matter, which soon becomes yellowish, sometimes streaked with blood, or mixed with pure blood, and finally brownish or greenish; when it exhales a peculiar odour. This discharge stains the linen, yellowish, greenish, or greyish, the spots being paler at the circumference than at the centre, and not removable by friction after their desiccation.

After the inflammation has continued for twelve or fifteen days, it generally begins to decline, more or less, the dysury diminishes, as also the sensation of heat, caused by the passage of the urine and semen; the erections are less frequent and less painful; the discharge becomes thicker and more opaque; it is more viscid, gradually increases, and in a short time the disease generally terminates. The duration of the disease usually occupies a period of from two to seven weeks; but it may be protracted for a much longer period. It will be modified by the age and constitution of the patient, the condition of other organs, the regimen, the state of the urethra as regards former affections, and perhaps by atmospheric vicissitudes.

The symptoms vary in different cases; sometimes the discharge commences in a

few hours after sexual connexion, though in general it does not occur before the eighth or ninth and sometimes not before the thirtieth day. According to some writers, it has not appeared until after the sixth or eighth week; but such cases rarely, if ever occur.

When urethritis is not produced by internal causes, it commences in the anterior part of the urethra, and in most cases irritates the glans and prepuce; it is supposed to be confined to the fossa navicularis, beyond which we seldom discover traces of inflammation on dissection. The orifice of the canal is generally affected when the disease arises from contagion; but irritation of the neck of the bladder, disease of the prostate gland, or urinary calculus, will excite the same sensation in the extremity of the penis. Some writers maintain that the whole urethra may become inflamed, that the disease may advance along the entire of the mucous membrane, and sometimes into the bladder. The celebrated Swediaur was of this opinion; and it is important to know this fact in forming a prognosis, as the disease will be of much shorter duration, when confined to one point than if it occupies the whole canal. In some cases urethritis is so very slight, especially in those who have had the disease previously, that it excites very little inconvenience, and this is also the case when it arrives from mechanical causes or from leucorrhœa, but it is generally severe in young persons, who are affected for the first time. Each of the symptoms may vary in intensity, and some of them be entirely absent. The pain may be slight or severe, during the passage of the urine or semen, or it may present during the interval of the emissions, being sometimes characterized by a sense of weight and irritation, or even burning heat, in the external genitals and perinæum. These symptoms may commence before or after the appearance of the discharge; they are so violent in some cases as to cause total suppression of urine, they may continue severe, for several days, or during the whole course of the disease, though they cease in general after a few days' duration.

The discharge usually precedes, but sometimes succeeds, the pain; its quantity varies very much in some subjects; it may be sparing or very abundant; its qualities differ in individuals, and according to the stage of the disease. In general it is clear at first, thickening by degrees, then assumes the appearance of pus, then becomes yellow, green, and finally whitish with the consistence of cream, when it is viscid, transparent, and less abundant; it often remains always yellow, or towards its termination assumes a green colour; sometimes it is more or less brown, or streaked with blood.

Diagnosis.—Much contrariety of opinion exists, as to the diagnosis between non-contagious and contagious urethritis; but it is

generally held that the former is less painful, less durable, and produces less serious complications than the latter.

Another question of importance is, how long contagious urethritis is communicable. Sir A. Cooper has stated, that the disease may be communicated at the expiration of fourteen months subsequent to its apparent cessation. I have known the disease communicated, by a newly married man, at the lapse of eight months after he had been supposed to be cured by his medical attendant. Bell thinks that the disease ceases to be contagious so soon as the inflammation that caused it is dissipated; but that if this be renewed, the discharge becomes contagious.

Urethritis may be very much aggravated by errors of regimen, or of treatment, as the incautious use of exciting drinks, the application of cold to the penis, acrid astringent injections, the use of saline, or drastic purgatives, violent exercise, coition, &c. The effects of these causes will excite sympathetic derangement of the visceral organs, which will participate more or less in the irritation of the mucous membrane of the urethra, and in such cases the surface of the glans penis becomes tense, red, or livid, and acquires a degree of transparency, particularly about the meatus urinarius. It frequently is excoriated, extremely sensible, and furnishes a yellow foetid exhalation more or less copious; sometimes we observe ulceration, and when we press the surrounding integuments, a puriform matter escapes from a number of small points. The glans, as well as the rest of the penis, is swollen; but the latter often remains in an habitual state of semi-erection, the slightest touch or motion in walking excites in it the most severe pains. Many patients, however, do not present all these symptoms.

The tumefaction of the glans may be so great as to cause phymosis or paraphymosis; the first is often induced by inflammation, or œdema of the prepuce; this last symptom is often excited by walking, riding on horseback, or even sitting, when the penis remains pendant.

The pains of the penis generally extend to the groins, and often excite inflammation of the inguinal glands or buboes, which may be followed by suppuration; but in most cases this inflammation may be dissipated by resolution. Inflamed buboes are often caused by suppression of the urethral discharge.

In some subjects, the lymphatic vessels of the penis become inflamed, and form hard cords, extending to the root of the organ, or to the groins. In other cases there may be erysipelatous inflammation of the organ, which excites acute pain during erection, and the irritation is usually propagated along the vasa deferentia and other portions of the spermatic cord. In other instances the whole cord from the testicle to the groin is affected; but in the majority of cases certain portions

of it only are tumefied. Some patients suffer severely from an unpleasant sensation in the testicles; these glands frequently acquire such a degree of sensibility, that they cannot bear the slightest contact, without becoming inflamed. The primary inflammation does not always remain in the urethral mucous membrane. It extends to the subjacent parts, the submucous cellular tissue, and the reticular tissue, both of the urethra and corpora cavernosa, especially at the inferior part of the penis; in this state of things, the urethra cannot elongate itself in proportion to the distention of the body of the penis during erection; there results a curvature, or inclination of the organ to one side, which is usually called *chordee*. This morbid state excites the most severe pains, which generally deprive the patient of repose and sleep, and are sometimes accompanied by tenesmus, dysury, pains of the spermatic cords, groins, and loins.

On drawing the finger along the inferior surface of the urethra, from behind the scrotum to the extremity of the pubis, several tubercles about the size of a pin's head are perceived, which are produced by inflammation of the submucous cellular tissue.

The inflammation frequently propagates itself along the excretory ducts of Cowper's glands, and attacks the cellular tissue itself, where it surrounds them. There may be one or more circumscribed tumours, of greater or less size, in the part between the scrotum and anus, which cause the pain to be more or less acute. The pain is increased upon pressure and on passing the urine, the desire to do which is more frequent than ordinary. The discharge is commonly of a dirty green colour tinged with blood, and foetid. Sometimes it is suppressed, or there is dysury.

This inflammation sometimes attacks the prostate gland, and this complication of the disease is extremely dangerous, and will be described under the head proctitis.

In some subjects the irritation of the mucous membrane of the urethra is propagated to the bladder, ureters, and kidneys. The neck of the bladder is most commonly affected with inflammation, though the whole organ may be implicated. When the neck is inflamed there is a frequent desire to pass urine, accompanied by acute pain in the root of the penis, and sometimes about the perineum and anus. The body of the bladder becomes spasmodically contracted, overcomes the resistance of the fibres of the neck, and excites the most imperious desire to micturate, which obliges the patient to obey it the instant, in whatever situation he may be placed, without which it would pass involuntarily. At the same time the rapidity of the jet increases the pain, especially at the extremity of the glans. The urine is passed in small quantities, sometimes drop by drop, and finally there may be a total retention of it.

Urethritis in some subjects causes pains somewhat resembling rheumatism, in the fibrous tissues of the joints, muscles, or in their sheaths, or aponeuroses. These pains affect the thighs, hips, and abdominal muscles chiefly; but they sometimes become general. This symptom, though rare, ought nevertheless to be taken into consideration when we have muscular rheumatism and pains in the joints, which terminate spontaneously in inflammation of the urethra the suppression of which often gives rise to the like affections, and consequently there is in some individuals a manifest connexion between the two diseases.

Urethritis, and the secondary inflammation which it often gives rise to, may terminate either in resolution, suppuration, mortification, and may pass into a chronic state.

Resolution is the most ordinary mode of termination, although the disease may always run on, if no error of diet, no neglect of cleanliness, and no error of treatment, has arrested its natural course.

Its duration may be estimated according to the degree of inflammation, the constitution, and general health of the patient. In some persons it lasts only for three weeks, in others for six weeks, two, four, or six months or even more. According as urethritis disappears or diminishes slowly and gradually, or with a visible rapidity, and another organ becomes affected, it is said to have terminated by *delitescence* or metastasis. The testicle generally becomes inflamed, but sometimes also the conjunctiva, and a more or less acute ophthalmia results. On the other hand, though more rare, the pituitary membrane or the auditory canal becomes affected, and complete deafness is produced. The symptoms of irritation of the mouth, larynx, pharynx, and bronchiæ, are sometimes produced; and there may be a discharge from ulcers in these places, and almost always there are excrescences around the margin of the anus. In some subjects the articulations of the knee, and hips, the shin, and feet become the seat of chronic or dropsical swellings.

In other instances, the periosteum, and the tissue of the bone itself become inflamed, which gives rise to thickening of the former, to pains in the bones, to exostoses, and necrosis. The skin is sometimes covered with various eruptions, and the different organs present various morbid appearances; for example the brain and its membranes may be affected, and cephalalgia and mental derangement have been produced.

But all those complaints which succeed the delitescence of urethritis, are commonly owing to the direct action of some irritating cause upon the organ which was affected; these do not differ from what we observe in a perfectly healthy subject, because they are sometimes accompanied by a sudden suppression or a visible diminution of the inflammation of the

urethra; for it is a rare occurrence that it is entirely stopt by delitescence, unless the inflammation is very slight or on the point of disappearing spontaneously.

As to the discharge in urethritis, it is only the product of the diseased state of the mucous membrane, is sometimes mixed with pus, and produced by one or many ulcers on the surface of the canal, or sometimes by abscesses in the prostate or Cowper's glands.

The urethral, as well as all other mucous membranes, is, though rarely, the seat of ulcerations; but it has been ascertained by Mr. Hunter and many others, that the discharge in gonorrhœa—as was generally imagined in his day—is not produced by ulceration.

It is also well known to pathologists, that mucous membranes may become thickened or adherent to each other by inflammation, and that the canals which they line, may be partially or totally obliterated. They have also been the seat of adventitious bands, which may tend to the same result; hence urethritis is the exciting cause of stricture of the urethra.

In some cases the lymphatics of the penis suppurate, and form several small abscesses; but this is a rare occurrence, unless in the inguinal glands. The testicle and prostate may also become the seats of suppuration. The submucous tissue may be affected in like manner, and, in such cases, generally finds its way into the urethra, or externally. All collections of pus caused by urethritis may appear successively or simultaneously, and those situated near the neck of the bladder are often followed by urinary fistulæ.

Urethritis seldom terminates by gangrene, but there are examples recorded.

Reviews.

Outlines of Comparative Anatomy. By Robert E. Grant, M. D. &c. Professor of Comparative Anatomy in the University of London, &c. Part I. 8vo. London. pp. 144.

THE name of Dr. Grant attached to a work on Comparative Anatomy, is a sufficient guarantee of its excellence. The part before us contains an admirable survey of the osseous and ligamentous systems throughout the animal creation; the myology also commences, but is cut short by a solution of continuity extremely frequent in the books, or rather fragments of books, successively put forth in the present day, and which in us is wont to "wake emotions both of rage and fear," lest all literature should become periodical, and mar our occupation: we hate books in parts.

As a specimen of the work we extract the following account of the osteology of the upper extremity in birds.

"The scapular arch is very strong in birds, to form a solid resisting fulcrum for the powerful movements of the humerus; and the magnitude and strength of these bones corresponds in the different species with the power of flight, or the resistance they have to oppose to the pectoral muscles on the one side, and the brachial on the other. The scapulæ are long, curved, and compressed bones, extending along the back, on each side of the dorsal vertebræ; they become more narrow and rounded as they approach the glenoid cavity, where they suddenly expand to enlarge that cavity, and they are partially ankylosed at that place to the large and strong coracoid bones. The two coracoid bones extend from the articular cavity for the head of the humerus downwards and inwards, to rest their broad expanded base in a deep groove on each side of the anterior margin of the ento-sternal bone. These coracoid bones almost alone resist the approximation of the humeri on the median plane, and their descent in the direction of the pectoralis major on each side, and they have generally more than double the thickness and strength of the scapulæ. The two clavicles descend converging from the upper or humeral ends of the coracoid bones, and they are ankylosed together at their lower ends, where they commonly present a flat compressed prominence connected by cartilage, by tendinous expansions, or sometimes by ankylosis, with the anterior projecting point of the crest of the sternum. The clavicles are very thick and strong, and meet at an obtuse rounded angle in the most powerful of the rapacious birds, and are long, thin, and slender, and meet at an acute angle in the gallinaceous and other birds of feeble flight. In the ostrich the clavicles are very small and short, and disunited on the median plane, as in mammalia. In the arm of the bird there is a great development of the proximate bones, which by their magnitude and strength are best able to withstand the resistance to which they are so frequently opposed, while the more delicate and the more distant bones of the hand are few and less perfectly developed. The humerus has a broad, compressed, and curved head, the large articular surface of which plays freely in the shallow glenoid cavity formed by the scapular and coracoid bones. In the concavity at the back part of the head of the humerus, are the large apertures by which the air from the axillary cells gains admission into the capacious interior cavity of this bone. The distal extremity of the humerus, is curved forwards, and presents a broad articular surface with a double condyle, on which chiefly rotates the large ulna, the radius being a more slender bone. The radius and the ulna are so articulated as to resist pronation and

supination of the hand, these motions being partially admitted at the head of the humerus. The arm of the bird is fixed in a state of pronation, the position best suited to strike the air with effect, and the hand moves upon the arm, not in the common mode of flexion and extension, but by abduction and adduction. At the extremity of the radius and the ulna, there are two carpal bones, which are succeeded by a single long metacarpal bone composed of three pieces ankylosed together. One of these pieces on the radial side of the hand is very short, and supports the single small phalanx of the radial or fore finger. the middle meta-carpal piece is by much the largest, and supports at its extremity generally three phalanges of the middle finger, the last of which is very short and slender. The first phalanx of the middle finger has a flat compressed form, like the meta-carpal bone. At the ulnar side of the distal termination of the meta-carpal bone is a small single phalanx of the outer or little finger, which is more immediately connected with the exterior slender portion of the meta-carpal bone. When in a state of rest, the hand of the bird is folded along the exterior edge of the ulna, and the large primary feathers are thus extended along the sides of the trunk to the tail. These fingers appear to be the analogous of the three middle fingers of the human hand, and there is sometimes a single phalanx covered with a spur on the radial side of these three fingers of the hand of the bird."

We beg to recommend Dr. Grant's outlines to all who take an interest in comparative anatomy, that is, to all who understand what is the true basis of physiology, and the real source from which nearly all that is certain and permanent in this science is derived.

OUR HOSPITALS AND HOSPITAL SURGEONS.

To the Editor of the London Medical and Surgical Journal.

SIR—The opinions of not only continental medical men, but of those nearer home, have been freely expressed of our hospitals and hospital surgeons, but in vain, as they still remain dead to the voice of truth and fair fame, by sacrificing science, and forgetting an awful futurity in the adoration of their favoured deity, Plutus.

There is nothing sound in the present constitution of their body, into which new life can be infused—all is rotten, mentally as well as bodily. This system they have had the effrontery to declare the only one calculated to make the profession respectable. The joy that swells the human heart under the prospect of diminishing the miseries of this life,

by the extension of judicious medical aid to the remotest habitation of the species, they have never felt. The king and the peasant are subject to the same infirmities, therefore the same laws, religion, and medical aid, should, if possible, extend their beneficent influence over all. The obstinate opposition on the side of these corporate bodies to all plans likely to open our hospitals to the gratuitous education of the diligent and humble student, sufficiently establishes their aversion to give efficiency to these philanthropic ideas. They have done their utmost to render our hospitals like the immense resources charitably appropriated to education, the heir-looms of the wealthy instead of being devoted to the poor. In a late number of your valuable journal, you speak of picking pockets, but in no age or country has this system been carried to the extent it has arrived at in this metropolis, as the hospital adepts in this line have neither blushed, nor denied their crime. They stand flagrante delicto with the maner in their possession, and nothing more is wanted but their committal. Their offences will not admit of bail, therefore suffer they must; and there can be no hesitation in averring, that when they be sifted under your cross-examination, their crimes against science, genius, and humanity, will place their vices in a higher range of culpability in the eye of an all-searching providence, than many who have expiated their offences against the law, in that classical, that pastoral, and suspending vicinity, where some of the most eminent of these hardened and offensive sinners still continue to carry on their trade of iniquity. In the construction of the edifice about to be erected for the management of the medical affairs of this great empire, those who have committed so many unbecoming and high misdemeanours must be debarred from interfering when the work of reformation shall be decidedly entered on—they must be removed to a respectable distance, and duly ticketed, so that they may be known. In order to expiate their former misdeeds, they must be compelled to betake themselves to sackcloth and ashes, and signify their readiness to supplicate an entrance, even by the back door. Some step of this kind is absolutely necessary, otherwise the wise efforts of the legislature will be defeated by these unrelenting adherents to his satanic majesty.

These hospital surgeons are now doing their utmost to decry the operation of lithotomy, which is one of the greatest improvements in modern mechanism and science, when judiciously and honestly applied in the early stages of calculus. It will obviate the tragical events which in too many instances have disfigured the hospital practice of this metropolis, in which patients have often been cut for the stone, where no stone existed in the bladder. To such murderous proceedings lithotomy must ever remain a stranger. These events never could have happened, where diligence and skill

were the attributes of the operator : but carelessness and an anxiety for display were the causes of these dismal catastrophes, which we have been informed have taken place more than once in the practice of the same operator. Such an individual, on the supposition of his having any brains, should have taken an early opportunity of blowing them out. The awkward hospital operators, under events of this untoward nature, invariably shelter themselves under the name of Chesselden ; but the very circumstance of his having committed so gross a mistake, instead of being an apology, is an aggravation of their misdeeds. Chesselden erected a beacon on which no man entitled to the name of a surgeon ought afterwards to have stranded himself. It is to be hoped that you will lay before us the names of the cutters for the stone in the single and duplex ratio, as they will be found to greatly outnumber the dry tappers, with which these men of science amuse themselves. To cultivate the understanding, has great influence in correcting the vices of the heart, and thereby inspiring generous deeds ; but if these diploma and certificate-mongers—these Christian Jews—are examined by this rule, we shall be compelled not only to adopt, but to inculcate an unfavourable opinion of the feelings of their hearts, as well as the faculties of their minds, as far as the discharge of their corporate and public duties are concerned.

I have the honour to be, Sir,

Your humble servant,

CÆLUS SECUNDUS.

June 10th, 1835.

DR. BAIRD'S CLAIM AS THE FIRST NON-CONTAGIONIST.

To the Editor of the London Medical and Surgical Journal.

SIR—In the leading article of the last number but one of the London Medical and Surgical Journal edited by you, I noticed your statement, claiming the credit for being the first to pronounce on the *non-contagion* of cholera. Very probably, you only meant this in an *editorial sense* : if so, I should think your claim is just ; for you are, I believe, the very first journalist who nobly stepped forward to expose, in a decided manner, the erroneous and pernicious views, thus so prevalent, of cholera being contagious in its nature.

However, with all due deference to your claim so far, founded as it was too on a zealous love of truth, justice, and science, I consider that Dr. Baird has a *priority* of claim in every other point of view, not only over yourself, but over every physician in London, on the following grounds :—

Having waited on that gentleman immediately after my arrival in London from Dantzick, in the middle of November, 1831,

just as the panic had begun to spread, it was, I beg to assure you, no small consolation to me to find that a physician of his distinguished perspicuity, enlightened views, and vast experience in disease, more especially in endemics and epidemics, had *fully decided* that the cholera was in *nowise* contagious. With his characteristic integrity and quickness, I well remember that he also condemned the absurd, yet pernicious views then begun to be so generally entertained of the epidemic, as well as the illiberal spirit which had betrayed itself in promoting such views, and spreading the consequent panic throughout the united kingdom. This, to say the least of it, now that time and facts have verified the opposite views, was certainly sinning against social life, which calls for deprecation, otherwise every liberal mind cannot but reprobate it.

Long, therefore, before the first appearance of your able and liberal journal in the beginning of February, 1832, or before the appearance of Dr. Gilchrist's talented and spirited letters in the *Times*, exposing the false views of the alleged contagion of cholera, as founded not on ungrounded assumptions and fabricated facts alone, but rather on some abominable policy, Dr. Baird *had decidedly* promoted and maintained the correct views, now verified by time, of the *non-contagion* of that disease, not only to myself and the profession, but *according to what I heard at large*, to the high and extensive circle in which he moves. In fact, he was, I verily believe, the *very first* physician in London ; at any rate, he was the *very first I met with after my arrival in town* from Dantzick, who had arrived at the conclusion, that cholera was *not at all contagious*.

I further know that, throughout the period of the epidemic in this country, he continued to pronounce, and occasionally to give in able anonymous communications, facts shewing the fallacy of that doctrine, which time at length has so providentially upset. Having visited numerous miserable objects of the disease in their wretched abodes, consoled, and every way relieved them, he was reasonably entitled to proclaim, in the decided manner he did, the *non-contagion* of cholera. In short, medical science and the profession, both, must always remain largely indebted to Dr. Baird, not only for the able and decided part he acted throughout the late epidemic cholera, but for the kind and liberal support which he afforded to several conscientious and scientific observers of that epidemic, and to none more than for that afforded in the hour of need.

Sir, your most obedient humble servant,

JOHN HAMETT, M.D. F.R.S.

One of the late Medical Commission in the North of Europe, &c. &c.

Birmingham, June 20, 1835.

[In reply to the preceding observations, we beg to state that we urged our claim in an

editorial as well as a professional sense. We were not aware, nor are we at this moment of any publication of Dr. Baird's, avowing this advocacy of non-contagion before February 1832, when we attacked the opposite doctrine in this Journal and in the different medical societies. We certainly stood alone at the time, and did not know so high an authority as Dr. Baird was in our favour. We need scarcely remind Dr. Hamett, that anonymous publications, when the Contagion Boards were in their glory, were of no avail whatever. If he will look to the *Lancet* of that period, he will see a violent attack on the editor of this Journal, in which he is singled out as the only advocate of non-contagion, and as such, designated an enemy to the whole profession, whose harvest he proposed to destroy. He shall be most happy to insert any communication intended to prove the priority of Dr. Baird's claim to his own.]—ED.

—o—

BAD EFFECTS OF PREMATURE EDUCATION—EVILS OF THE RACE OF INTELLECT—A HINT TO LORD BROUGHAM.

THERE cannot be a second opinion among well educated medical practitioners, that attempting to teach a child of three or four years old, by book learning, is highly injurious to the brain, mind, and body. It is the fertile source of fatal water in the head, of great injury to the whole constitution, to the development of the intellectual faculties and corporeal powers, and the preventive of a sound mind in a sound body.

When a child, of the age mentioned, is confined for several hours, every day, in a sitting posture, it is deprived of that motion and exercise which circulates the blood throughout the body, develops every part, establishes health, and lays the foundation of a sound mind in a sound body, of good sense, and of happiness in after life. Physicians, as well as some few of those who do not belong to our profession, but who possess powerful minds, are of this opinion. Thus Mr. Cobbett makes the following remarks, which would do honour to any member of the faculty.

“ ‘*Hedekashun*’—*Education*.—I have always held the opinion—an opinion originating in that of a very sensible father—that early teaching of book-learning had a tendency to enfeeble, if not to destroy the mind. I am sure that I owe my astonishing capacity to labour mentally, to the circumstance of my not having known at all of books, worthy of being called knowledge, until I was fourteen years of age. In divers parts of my writings I have strongly urged parents to abstain from attempting to make their children little prodigies of learning; and to no one of seven children have I ever given, or caused to be given, a copy to write from, or a lesson in

reading. The females are as learned as any women need be; and the three eldest sons may fairly and justly be called scholars; and my real opinion is, that if I had pursued the course which parents in general would have pursued with regard to these children, they would have been persons of a character and description very different from that which they are now. In my English Grammar, I tell the son to whom I addressed it, and who was then about 14 years of age, that, up to that time, he had not been requested even to look into a book; that his elder brothers learned to write of themselves from seeing me write; that he had learned to write from seeing them write; that I had done my best to give him the greatest blessing described by Lord Bacon, ‘a sound mind in a sound body;’ that he had them both; but that it was now time, as I did not intend him to live by bodily labour, for him to begin to be a scholar, and to learn things which it was unnecessary for labourers to know any thing about; but that, at the same time, however book-learned he might become himself, he ought to take care never to consider, and particularly never to call, labourers ‘ignorant men;’ seeing that they would always have a sort of knowledge, and ability, which he would never possess. Grammar, I told him, and grammar of his own language, was the only foundation of all book-learning; and that, as I was going to write an English Grammar, he ought to copy it word for word, and letter for letter as I proceeded. This he did; and in his hand-writing it went to press, while I was in Long Island.

“ Do we see young birds flock together, or young any things? No—we see them mix with the old ones, and thus learn their manners, and their modes of getting their living. Can a child who converses with nothing but children learn to be a man? If a hundred children were brought up till they were twenty years of age, to see nobody but one another, it would be a mass of half idiocy altogether; and we should see all the lords and baronets and ‘squires little better than idiots, if they did not set at nought the commands of their schoolmasters and parents, which, very fortunately for themselves, they generally do; and hence they become, generally speaking, men of sounder sense, and infinitely more pleasant persons to come in contact with, than the intolerable wretches who spend their time in poring over books, and who become what are called literary men, who are the pests of the community; and to knock whom on the head, if it could be made conformable with the peace of society, a mallet ought to be kept in every parish church, to be used by the churchwardens and overseers, and which would very seldom endanger the parson himself, he generally understanding shooting and hunting a great deal better than any thing else; and miserable is it for any parish where the parson is a

pedant, and a sort of bastard lawyer, with Burn's Justice everlastingly in his hands, wherewith to disturb the peace, to the everlasting torment and curse of the people."

Mr. Cobbett made these remarks before introducing the opinions of an American physician, which we are about to notice: and our recorded opinions are similar to his, though we delivered them to our students. It would, if Lord Brougham and other advocates of Sunday Infant Schools, as part of premature education, would peruse and reflect on the following opinions on the subject, from which no well-educated medical practitioner can possibly dissent.

Consequences which have resulted from inattention to the connexion between mind and body. The best minds not produced by early mental culture. By Dr. Brigham of Connecticut.

"I beseech parents, therefore, to pause before they attempt to make prodigies of their own children. Though they may not destroy them by the measures they adopt to effect this purpose, yet they will surely enfeeble their bodies, and greatly dispose them to nervous affections. Early mental excitement will serve only to bring forth beautiful, but premature flowers which are destined soon to wither away, without producing fruit.

"Let parents not lament because their children do not exhibit uncommon powers of mind in early life, or because, compared with some other children, they are deficient in knowledge derived from books. Let them rather rejoice if their children reach the age of six or seven, with well-formed bodies, good health, and no vicious tendencies, though they be at the same time ignorant of every letter in the alphabet. If they are in this condition, it is not to be inferred that their minds are inferior to those of children who have been constantly instructed. It is a great mistake to suppose that children acquire no knowledge while engaged in voluntary play and amusements.

"They thus do acquire knowledge as important as is ever acquired at school, and acquire it with equal rapidity. Many think that the child who has spent the day in constructing his little dam, and his little mill, in the brook, or the stream that runs in the gutter; or in rearing his house of clods, of snow, or in making himself a sledge or cart, has been but idle, and deserves censure for a waste of his time, and a failure to learn any thing. But this is a great error of judgment; for, while he has thus followed the dictates of nature, both his mind and body have been active and thereby improved. To him, any thing which he sees, and hears, and feels, is new, and nature teaches him to examine the causes of his various sensations, and of the phenomena which he witnesses. For him the book of nature is the best book, and if he is permitted to go forth among the

wonders of creation, he will gather instruction by the eye, the ear, and all his senses.

"He is, for a while, just as ignorant that stones are hard, that snow will melt, that ice is cold, that a fall from a tree will hurt him, and a thousand other common facts, as he is of a 'parallelogram,' or the 'diameter of the sun,' or the 'pericarpium of flowers,' or of many other similar things, which some think important for infants to know*. If his time is constantly occupied in learning the last, he will grow up ignorant of many common truths, and fail in the best of all learning—common sense.

"The child, when left to himself, manifests a true philosophical spirit of inquiry. The story related of the celebrated Schiller, who, when a boy, was found in a tree, during a thunder storm, trying to find where the thunder and lightning came from, is an instance of the natural tendency of every child to self-education. This tendency is highly important to encourage, for it involves the cultivation of that spirit of inquiry, 'which is far more valuable than limited acquirements in knowledge; a spirit which teaches us to distinguish what is just in itself, from what is merely accredited by illustrious names; to adopt a truth which no one has sanctioned, and to reject an error of which all approve, with the same calmness as if no judgment were opposed to our own.'† But this spirit will never be acquired, when the child is taught from his infancy to depend upon others for all he knows, to learn all he does learn as a task, and not from the desire of ascertaining the truth, and gratifying his curiosity.

"Let not the parent, therefore, regret that his child has passed his early years out of school; for in all probability the knowledge he has gained while running and exercising in the open air at play, is more valuable than any he would have gained at school. At all events, he has gained what is far, very far more valuable than any mental acquirements which a child may make, viz. a sound body, well developed organs, senses that have all been perfected by exercise, and stamina which will enable him in future life to study or labour with energy and without injury.

"The remarks which I have made, relative to the danger of too early exerting and developing the minds of children, are not made without some knowledge of the education of children in various parts of our country.

"That children do have their mental powers prematurely tasked, is a fact which I know from personal observation. I have seen a course like the following pursued in many families in various parts of the country, and I know that this course is approved of by many excellent persons. Children of both sexes are required, or induced, to commit to memory many verses, texts of Scripture,

* See Infant School Manual.

† Brown's Philosophy.

stories, &c. before they are three years of age. They commence attending school for six hours each day, before the age of four, and often before the age of three; where they are instructed during three years in reading, geography, astronomy, history, arithmetic, geometry, chemistry, botany, natural history, &c. &c. They also commit to memory, while at school, many hymns, portions of the Scriptures, catechisms, &c. During the same period, they attend every Sunday a Sabbath school, and there recite long lessons; some are required to attend upon divine service at the church twice each Sunday, and to give some account of the sermon. In addition to these labours, many children have numerous books, journals, or magazines to read, which are designed for youth. I have known some required to give strict attention to the chapter read in the morning, and to give an account of it; and have been astonished and alarmed at the wonderful power of memory exhibited on such occasions by children when but five or six years of age. I have known other children, in addition to most of the other performances, induced to learn additional hymns, chapters of Scripture, or to read certain books, by the promise of presents from their parents or friends.

"The foregoing account fails to describe the amount of mental labour required of many children in intelligent and respectable families.

"The injurious and sometimes fatal effects of such treatment have been already mentioned. But I cannot forbear again to state that I have myself seen many children who were supposed to possess almost miraculous mental powers, experiencing these effects and sinking under them. Some of them died early, when but six or eight years of age, but manifested, to the last, a maturity of understanding which only increased the agony of separation. Their minds, like some of the fairest flowers, were 'no sooner blown than blasted.' Others have grown up to manhood, but with feeble bodies and disordered nervous system which subjects them to hypochondriasis, dyspepsia, and all the Protean forms of nervous disease. Their minds, in some cases, remained active, but their earthly tenements were frail indeed. Others of the class of early prodigies, and I believe the most numerous portion, exhibit in manhood but small mental powers, and are the mere passive instruments of those who in early life were accounted far their inferiors. Of this fact I am assured, not only by the authority of books, and my own observation, but by the testimony of several celebrated teachers of youth.

"The history of the most distinguished men will, I believe, lead us to the conclusion, that early mental culture is not necessary, in order to produce the highest powers of mind. There is scarcely an instance of a great man, one who has accomplished great results, and

has obtained the gratitude of mankind, who in early life received an education in reference to the wonderful labours which he afterwards performed. The greatest philosophers, warriors, and poets, those men who have stamped their own characters upon the age in which they lived, or who, as Cousin says, have been the 'true representatives of the spirit and ideas of their time,' have received no better education when young, than their associates who were never known beyond the neighbourhood. In general their education was but small in early life. Self-education, in after life, made them great, so far as education had any effect. For their elevation they were indebted to no early hot-house culture, but, like the towering oak, they grew up amidst the storm and the tempest raging around. Parents, nurses, and early acquaintances, to be sure, relate many anecdotes of the childhood of distinguished men, and they are published and credited. But when the truth is known, it is ascertained that many, like Isaac Newton, who, according to his own statement, was 'inattentive to study, and ranked very low in the school, until the age of twelve;' or like Napoleon, who is described, by those who knew him intimately when a child, as 'having good health, and in other respects was like other boys,'* do not owe their greatness to any early mental application or discipline. On the contrary it often appears, that those who are kept from school by ill-health or some other cause in early life, and left to follow their own inclination as respects study, manifest in after life powers of mind which make them the admiration of the world."

PURE SURGERY—ODD SUPPOSITIONS.

WHATEVER absurd people may choose to say against the mode in which surgeons are elected to our metropolitan hospitals, it is clear that these eminent functionaries possess a degree of professional skill approaching to infallibility, and never by any chance are guilty of the gross blunders, which occasionally entail loss of reputation and payment

* *Memoirs of the Duchess of Abrantes.* This lady says, "My uncles have a thousand times assured me that Napoleon in his boyhood had none of that singularity of character attributed to him."

of damages on the hybrid practitioner who wields the scalpel with one hand and the pestle with the other. How would the public be astonished if they were to hear of such a case as the following!

A young woman is bled by the assistant of a general practitioner, and is thereafter incommoded by a tumour at the bend of the arm. She applies for relief at a large metropolitan hospital, and one of the surgeons, conceiving the tumour to be a false aneurism, arising from a puncture of the brachial artery, assures the patient that the evil has resulted from the venesection, and is remediable only by an operation: this is consented to, and after a very tedious piece of work the vessel is *said* to be secured.

The patient, on the strength of what she has heard, institutes a legal process against the aforesaid general practitioner for the injury she has sustained, through the ignorance or clumsiness of his assistant. The general practitioner has recourse to a gentleman who deservedly stands very high as a surgical authority, and the latter, on investigating the case, declares positively *that the brachial artery was not punctured by the phlebotomist, and was not secured by the hospital surgeon!!!* The affair is hushed up, and the costs incurred by the defendant are paid by the operator. Some queer fish of a correspondent has sent us this catenation of preposterous suppositions, and asks with great gravity whether any such transaction has actually occurred since the year 1800.

Gramercy! what is the man dreaming about? Why, look you, the operator is by hypothesis a *pure* and an *hospital surgeon*, and on this account we should be inclined to regard the thing as simply impossible—but really we don't know—can any body tell us?

—o—

EARLY PRACTITIONERS OF MEDICINE —AN INGENIOUS PARALLEL.

WHEN we consider the various sources from which the art of medicine has been derived, we cease to wonder at the numerous distinctions of cast, as well as of opinion among practitioners.

In times of old we find medicine invented and practised by gods, by monarchs, by priests, by slaves, and by birds and beasts. Antitypes of these may perhaps be discovered among us in the present day.

In old Greece, some of the divinities were in large practice, particularly Apollo, of whom we ourselves are evidently entitled to be considered as the recent analogue, for having killed the python of medical corruption with the shafts of our wit: it should seem that the artist who produced the statue of the *Apollo Sauroctonus** recognised our affinity to him of the silver bow, and had a prospective allusion to our dealings with the *green lizard*.

Monarchs, especially in the East, have been greatly addicted to physic. Mithridates is well known to have had such a turn for pharmacy, that he discovered an antidote against all poisons; had he lived in the present day he would no doubt have used prussic acid as a *liqueur*. The class of royal practitioners seems nearly extinct—its only remaining representative is King Harrison, who has much more to do with medicine than he ought. To the priests we are greatly indebted—to those of Asia and Egypt, as, perhaps, the earliest cultivators of the art, and to those of Modern Europe, as the depositories of medical, and all other kinds of lore, during the dark ages; the descendants of the latter are extant in Pall Mall, where the *monkish system* is still preserved in great purity, as evinced by a mortal abhorrence of surgery, to say nothing of a mortal ignorance of it.

* *Σαυρος* a lizard and *Κρίνω* I slay.

In ancient Rome, medicine was chiefly practised by slaves—their posterity are Halford's *toadies*, and those persons throughout the profession, whom we cannot inspirit into a due resistance of the oligarchs.

Beastly medicine took its origin in Egypt. We learn from Strabo, and other ancient writers, that the Hippopotamus, when oppressed with plethora, was wont to phlebotomize himself with the sharp points of Nilotic reeds, and thus taught men the use of blood-letting; some other useful hints were also communicated by the sacred bird—the Ibis. Viewing the matter generally, we should say that the beastliness of the *modern* profession was obvious *partout*; with regard to birds we do not know of anything precisely analogous—there is, however, a species of “ferocious wild fowl” called bats, that offer a sort of approximation, though Heaven knows, they do anything but teach men medicine!

Foreign Medicine.

Historical Passages in the Homœopathic Doctrine.

It was in the year 1796, and in Hufeland's *Journal der Praktischen Heilkunde*, vol. 2, p. 391, that Hahnemann first emitted his ideas on the system of treatment founded on this doctrine. Of it and the ground on which it stood, Sprengel at that time spoke in the following terms: “Samuel Hahnemann endeavoured to renew the ideas of the ancient methodic sect, regarding the changes of the body, by shewing, *by a strict induction*, that the majority of powerful medicines, known by the name of specifics, are only useful because they produce an artificial excitement that develops phenomena very much resembling those of the disease itself. In fact, his theory is *perfectly confirmed* by the daily observation of the counter-excitations produced by art, and by which the morbid irritation is destroyed.”

It is difficult to pronounce upon this sort of approbation accorded by the learned author of the *Essay of Pragmatic History of Medicine*, to this renovated doctrine of the Greeks; and it would be interesting to know whether he maintained that opinion to his death. It certainly leads us to think that the judgment of Kurt Sprengel did not equal his profound erudition.

Hahnemann appears to have always thirsted after notoriety. In 1792, he published a popular medical journal at Frankfurt-on-the-Maine, entitled “The Friend of Health.” It was at this time that he denounced the physicians of Leopold II. to the whole of Europe, as having slaughtered the prince by their treatment of his last illness. In 1800, the patriarch of Doethen boasted that he had discovered a remedy against scarlet fever, but he would not disclose it. (*Talzbürger Medicinische Zeitung*, 1800, vols. 1 and 2). No doubt it was belladonna. Every one knows what boast he made of his soluble mercury. The first French thesis in which mention was made of the homœopathic system is that of Doctor Theodore Bockel, published at Strasburg in 1826.

Lithotomy and Lithotrity.

A discussion founded on the report of M. Velpeau, touching a rumour on the latter of these subjects, has lately occupied the Académie de Médecine for several successive sittings. The learned reporter took this opportunity of expressing his decided opinion that the dangers of lithotomy have been much exaggerated, while on the other hand the harmless nature of lithotrity has been far too much credited. The report and opinion urged with all the eloquence and backed by the accumulation of statistical tables, which no one knows better than M. Velpeau how to employ and collect, gave rise to much acrimony of language in the speakers on both sides, and afforded considerable interest, and occasionally, amusement to the Academy at large. The principal speakers in favour of lithotomy were, M.M. Velpeau, Roux, Larrey, Sanson, Souberbrielle, Lepelletier de Mans, and Breschet. On the other side were ranged MM. Amussat, Lisfranc, Labat, and Segalas. The Academy, however, testified its sense of the question in distinctly receiving the report of M. Velpeau.

In the course of the discussion M. Lisfranc informed the Academy, that M. Du Bois and himself had undergone personally the operation of lithotrity several times.

Case of sudden and repeated suspension of Cerebral Action.

G. B. formerly a soldier, aged 53 years, of a lymphatic temperament, enjoyed good health up to last year. Being obliged five years ago to give up his calling of tailor, in consequence of the failure of his eyesight, he became foreman of tile-makers. This new calling exposed him considerably to inclemencies of weather, and caused him to take several catarrhs that were treated antiphlogistically.

On the 30th March, 1834, being four leagues from home, he set out on foot to reach it: when half way he lost all sense, and fell

down. In this state he remained for three or four minutes; his companions picked him up, and he continued on his way. In the course of the whole journey he had twenty attacks exactly resembling the first, only that instead of falling he was kept up by his companions. He always fell on the right side, and was not convulsed either in the limbs or face. Arrived at home, he ate a very slight supper, went to bed and felt no consequences from what had happened. Seventeen days passed without any attack, and he returned to his work. On the eighteenth day he had a similar attack to the first one: during the day he had several, but this time there was sufficient warning given to allow him to sit down on the ground, and some sense remained. Without the precaution of sitting down, however, they would certainly have thrown him down. He consulted a medical man, who bled twice largely in twenty-four hours.

A week passed without any attack; on the ninth they were more frequent than before. During the attacks the man was giddy and had drumming in the ears. He was again bled twice. The day after he complained of great pains of the belly, and had several large motions, in which a great quantity of worms was observed. Two days afterwards he had an emetic and a purgative; under the influence of those, the attacks became still more frequent, amounting to fifty or sixty in the day. At this period another medical man was consulted, who gives the following as the state in which he found the patient.

The pulse beat twenty-four in the minute; the skin was something warmer than usual; the tongue slightly red at the point and edges: pressure caused a little pain at the epigastrium; the belly was something distended with flatus. Percussion shewed the chest to be clear all over, except the cardiac region and a little above the right breast, where there was a tumour of the form and size of a small hen's egg. The stethoscope applied over this part gave a bruit similar to that produced by the heart's beating. At first an aneurism was suspected, but the patient said he had had the tumour from infancy, and it had never increased nor diminished. During the examination of the patient he had several attacks; his face became red, the beatings of the heart were accelerated; he complained of seeing objects quintuple or sextuple, and of some heat at the stomach; in a minute all the symptoms disappeared.

The first attempt made was to subdue the gastro-enteritis, by the application of leeches to the stomach and belly, by poultices, demulcent glysters, and dieting. By this means the pain of the stomach vanished, the belly became pliable, and the tongue recovered its natural colour. Notwithstanding, the attacks were not diminished. Antispasmodics were of no use whatever; neither blisters to the legs, sinapisms to the feet, nor irritating

glysters procuring any relief from the attacks. A large blister was applied to the nape of the neck; two days after, the attacks were visibly diminished, after and in consequence of which, a seton in the same place was substituted, since which time the patient has been progressively getting better. At the present time (March 1835), he can walk quietly, and is about to commence work.—*Journal de Medecine pratique de Bordeaux.*

—o—

OBSERVATIONS ON QUARANTINE LAWS. BY SCRUTATOR.

— . —

As it is not improbable that Cholera may again appear in this country, and as bowel complaints are now rather prevalent, a few observations on quarantine laws may be allowed; inasmuch as they will open the eyes of the profession to the shocking consequences of such enactments. It is right to premise, that such laws are nearly abolished in all countries except our own; and they would have been erased long since from the statute book, had the College of Physicians kept pace with the progress of science. The quarantine laws in thousands of instances have excited suspicion, and, as it were, generated contagion where it never existed; as these laws can find infection or contagion in every quarter suited to deceptive purposes. The Dutch have no quarantine laws, and they are not more the subjects of contagious diseases than those who, to their sorrow, are so amply and expensively provided with them. This phlegmatic people regulate affairs of the nature in question on the spur of the moment, and they, therefore, do not keep a body of men in pay whose interest it is to excite unnecessary alarm. The abolition—or at least a modification—of the quarantine laws would do more to annihilate ideal contagion, which is a source of the greatest mischief to the commerce of Great Britain, than any other measure I know of*. The doctrines of contagion are supported by selfishness, ignorance, and tyranny, on the Continent; and as these are on the decline, there can be no doubt that the present extravagant opinions on the subject will yield to the light of reason and just inquiry. The expense of maintaining the quarantine laws of this country is great, and, consequently, many are interested in upholding them. The more we study the law of animal life, and the causes influencing it in health and disease, the more shall we be on our guard against adopting contagion as the cause of epidemical diseases, however fatal these may be in their results. When epidemical maladies assume a fatal tendency, the imbecile, the ignorant, and

* Such laws were the offspring of the dark ages.

those interested in deception, invariably, but unjustly, trace their origin to contagion.

In short, to be plain, all the "reflecting men," as I have good authority to aver, believed that there existed on the side of contagionists, *an inclination to prove too much*, a species of evidence which every one knows how to appreciate. Sir ——— had long erroneously confounded epidemical with contagious diseases; and, therefore, while he continued to regulate the Board of Health, there never could be any lack of such cases, either in existence, or ready to be adduced, when circumstances rendered their development favourable. He was regarded, while I was at Gibraltar and in the Mediterranean, as *CONTAGION personified**; and the extension of this principle, by every means in his power, constituted his beau ideal. From frequent intercourse with those who have studied the malady called Cholera in this country, in Prussia, and Russia, and in France, I have no hesitation in avowing, that there was a great deal more made of the disease on the continent, France excepted, than truth will bear out, and the Boards of Health of this country seemed to have been exceedingly willing to enlist themselves in the cause, and under the ominous banner of "contagion." The deaths were invariably over-rated, as many of those events were classed with cholera which originated in a very different cause, or were the product of the means of prevention, or of disease long in existence, or of poverty and wretchedness.

By way of illustration, I shall for one moment quit physic for law, and state the case thus:—Contagion was plaintiff, and defendant was Common Sense. Plaintiff sought the right of establishing quarantine laws, boards of health, &c. &c., to ensure the payment of certain sums annually to those of his friends who supported his pretensions. This claim was opposed by the defendant on the grounds of humanity, the commercial interests of the country, and as hostile to the cause of truth, justice, and honour; and thereupon issue was joined: but ere the case was decided, we ought to reflect upon it, since, doubt not, if a wrong judgment be awarded, there will be a rule moved for, to show cause why a new trial should not be granted.

We may rest assured such was the result, that hunger, want of clothing, and a broken spirit, doomed to linger out its flickering spark of vitality in a noxious den of wretchedness, wait not for an easterly wind ere they attack their victims; and which, where such evils are suffered to exist, no quarantine laws will preserve. Such evils, it is true, engender

the most formidable diseases; but no honest object can be attained by attributing them to contagion.

Such men as Young, Johnson, Foote, Ryan, Searle, and the faculty of Paris, ought to have had an opportunity of examining this disease minutely, and of reporting thereon; since their experience cannot be overturned by all the verbiage of all the contagionists in the universe. Yet, the temerity with which many of the *dictionnaire* advanced their opinions as to the cause of a disease, of the nature of which they were, as far as personal observation was concerned, entirely ignorant, was no less impudent than disgusting.

It is now admitted in France, Russia, and Austria, that quarantine restrictions were useless. Proceedings therefore, in the way of precaution in this country, which in their very essence are calculated to beget evils of great magnitude, by generating disease on an extended scale, ought to be adopted with peculiar circumspection; but instead of this, in the case before us, the ablest reasonings of practical philosophy were urged in vain, whilst the baseless theories of the visionary and the experimentalist were alone received as the offspring of science!

Drs. Barry and Russell were honoured with titles, as well as Sir William Pym, the godfather of contagion before them; but Dr. Hamett, one of the ablest surgeons in the Navy, who was promised the same rewards as the former, was nearly ruined for his honest conviction that cholera was not contagious. The medical world has since declared that his investigation of the disease at Dantzic was the most laborious and correct ever offered, and even the Board composed of the College of Physicians declared that his Symptomatology was for accuracy equal to that of Aretæus. The Collegiate Board, however, cushioned his proofs of the non-contagiousness of cholera, and had he not a second copy, the world, would never have known them. He, however, was not honoured with a title, as he presumed to differ from the Halfords, the Pym, the Barrys, Russels, *et hoc genus omne*.

But to return to quarantine.—The industry of thousands not only in Sunderland, but on the River Thames also, was paralyzed by restrictions on the coal trade, and thus their means of providing against winter denied to them; and should a sickly season ensue, under quarantine regulations, combined with want of food, clothing, and other necessities, maladies of fully as dire a consequence as cholera itself will follow. Thus, in seeking to avoid an ideal Scylla we encountered Charybdis.

The imperfections of human nature require that both sides of a question should be heard ere even a partial decision be recorded. The disease which existed at Sunderland, I will venture to affirm, in many cases was not cholera, but a modification of scurvy or

* Though he never visited the hospitals during the prevalence of yellow fever; and hence his opinions were scouted by the French Academy of Medicine.

scorbutic dysentery, a malady which the individuals sent to investigate the nature of the occurrences at Sunderland probably had never before seen.

All measures, however well intended, which are adopted under the influence of alarm, whether in reference to nations or individuals, generally prove unsatisfactory, and often dangerous; and in proof of this opinion, I beg leave to advert to events long anterior to the present period, as well as to occurrences of a more recent date, all, however, bearing upon the point in question.

The plague of 1665 gave rise to the quarantine laws; and on weighing the evils they have inflicted on humanity, and the extraordinary embarrassments they have thrown in the way of trade and commerce, from the period of their commencement to the present moment, they will be justly regarded, by all reflecting men, to have been, and still continue to be, a plague of portentous omen, as bearing injuriously on life and the resources of the country, without any thing like commensurate benefit. The elements have been hitherto merciful; but had it proved otherwise, the quarantine laws enacted would have been the means of offering up many human victims at Sunderland, as they did in America.

Between the circulars of the Board of Health (certainly not emanating from Apollo), and the restrictions on the commerce of Sunderland, as also the payment of the various itinerant quarantine contagionists, great and small, the country has suffered to little less than a million sterling. The evils arising to our commerce throughout all Europe, and at a time too when such obstructions could be so ill borne, are subjects of grave and painful consideration, particularly when we reflect that they ought to have been prevented by a more considerate course.

There was a Board of Health at the India House; another of a similar description at the Horse Guards, and a third at the Admiralty; the members of all which are men of high character, combined with great practical knowledge; men who have witnessed the malady called Cholera at home and abroad, and whose character and situations would have been vouchers for the accuracy of their proceedings; and they were further recommended as not possessing the empyrean moral virtue of Oxford and Cambridge, so much dreaded by M. D's. of Ireland and Scotland, when in operation at the sanctuary, Pall Mall East, in subjecting their pockets to an ungracious evacuation. It does, therefore, appear somewhat extraordinary that the Government should have gone so much out of its way as to apply to the President and Fellows of the College of Physicians, with such able and honourable men, as army and navy surgeons, all, doubtless, ready to have obeyed its commands,

from their constituting an integral part of the public service. Had the Government required a treatise *de rebus omnibus et quibusdam aliis*, certainly the College of Physicians might be properly chosen; but as the state of the country at large demanded a *practical* opinion, it could not have gone to a worse mart. This corporate body, from the period of its creation, has never failed to exhibit a strong sense of its own interests, regardless of the welfare of the profession, or of the community. Need a more positive proof of this be offered, I repeat it, of their sacrifice of humanity to patronage, than appears by the revolting circumstances which took place while those labouring under mental derangement were placed under their care, as well as by the nomination of men as members of boards, physicians of hospitals, and professors, celebrated, not for their talents, but for their want of knowledge and experience? Those medical men of the army and navy who have honourably and conscientiously served their country, have just cause to complain of such preference of the fellows of the College of Physicians; and the more particularly when they beheld an individual a member of two boards, who possessed little experience*.

Had the government acted wisely it would have appointed a Board of Health composed of certain members of the College of physicians, certain dispensary and hospital physicians who were well acquainted with the insalubrious parts of the capital and sources of disease, together with a certain number of Army and Navy physicians and surgeons who had observed cholera in Asia and other countries; but such a board would go between the wind and the nobility of their high mightinesses—the Fellows of the College of Physicians.

Medical men were much too busy in the management of a truly formidable malady, because like the community at large, they allowed themselves to be bewildered and led astray by the morbid instructions emanating from the President and Fellows of the College of Physicians and Board of Health.

Both these bodies were adepts in the

* It is in their corporate capacity that we censure, because we have no personal enmity. Lord Durham, as well as the Lord Chancellor, were well acquainted with the moral virtues of the College in the department of the insane, which must be remembered by these illustrious statesmen as having been, as a corporate body, corrupt, rotten, and defiled; and, at present, to use the language of a celebrated knight, a compound of villainous smells, that can only be cured by the Warburton chloride. The cholera had prevailed a year, before Sir H. saw Lady Durham, though he and his board were advising the profession how to treat it.

drama of contagion; and, like their predecessors in all ages, involved themselves in mystery, and thus engaging the public imagination by false views of the causes and cure. Hence fumigating, roasting with hot plates, steaming, boiling, bleeding, transfusing, vomiting and purging, cupping and pickling were all employed in turn; but, as all know, without any salutary effect that can be considered satisfactory in a curative or preventive point of view*. Such counsels, from which wisdom was expelled, caused alarm throughout the kingdom, and the unfortunate patients were often abandoned by their friends, and in danger of being buried alive †. These efforts of the pestilential stars, with contagion for their stage, were attended by much that was very disingenuous, in choosing none but confirmed contagionists at home and abroad as their travelling scene-shifters; but all would not do, and truth prevailed.

The cause of cholera was the morbid condition of the atmosphere, moving in currents, and acting on the human frame, rendered highly susceptible of disease by the pre-disposing causes just adverted to. In arresting the extension of disease, quarantine laws and cordons sanitaire have not only been useless, but actually dangerous and destructive; so that in many instances on the Continent they have been regarded, by the intelligent and humane, as the laws of human sacrifice rather than the sources of its protection. Thus their extension to this country excited disgust and indignation, by unnecessarily separating the diseased individual from his friends at a time when his life depended on their aid and consolation.

The Collegiate Board gravely contemplated surrounding cholera patients with a troop of dragoons, in imitation of the Plague Boards, but they did not, like the latter, order the doors of the infected to be marked with a red cross, headed with the words—"The Lord have mercy on us," as mankind had none. Neither did they analyse the contagion like the former, and find it, like Hodges in his *Lomologia*, after having been breathed on a piece of glass, "composed of all poisons, arsenic, hemlock, &c., &c., and devils frightful to behold." They did not go to this extent, but they nearly approached it. They ordered the dead to be buried with indecent haste; and many instances occurred, as already stated, in which the supposed dead revived on the closing of their coffins. They hesitated to allow Lord

Durham to gaze for an instant on the countenance of his mother; they advised him to change his clothes as soon as possible, to fly into the country to avoid contagion, while the bodies of cholera subjects were, in the anatomical theatres, undergoing the scrutiny of numerous students.

My object in directing the attention of our profession, and, through it, the public, to quarantine laws, is to show how useless they are in preventing epidemic diseases, and how injurious they are to trade, commerce, and the happiness of the community. To you the British public is indebted for rendering such a law a dead letter; when the cholera re-appeared in 1832 and 1833, you were a non-contagionist from the first appearance of the disease to its disappearance: you were well abused by the *Lancet*, whose sub-editor, at that time, was a paid cholera hunter. He denied that your statement was correct, that the members of the Board of Health had 60*l.*, 40*l.*, and 20*l.* a month for their services in diffusing alarm throughout the country, and, in time, throughout the world; and you replied the following week by stating the exact pay of each of the meritorious members of the Board. The public press promulgated your exposure; the Faculty of Paris confirmed your opinion of the non-contagiousness of cholera; the Board of Health now declared the disease non-contagious, and advised the large hospitals to admit patients, just as the disease was about to leave us.

In stating these recorded facts, I cannot be accused of complimenting you undeservedly. They stand recorded in your journal of the period to which I have referred. I revive this subject now, because the Warburtonian Chloride has not as yet been applied at head quarters. The focus of mischief exists, and may perchance once more diffuse its pestiferous influence over the nation, and the rest of the world*. This is possible, but very improbable. But I anxiously wish to put the profession on its guard against the humbug of the paid contagionists. To me, the conduct of Boards of Health is perfectly indifferent. I have nothing to gain or lose by Cholera or any other epidemic disease. The public has enabled me to retire from practice, but the interests of humanity impel me to expose the ignorance, avarice, and fraud of those who ought to be above suspicion, and exercise the noble and beneficent art of medicine, in the manner in which it has ever been exercised, with few exceptions, for the good of humanity.

* The whole offers a most revolting example of empiricism, unsupported by either anatomical, physiological, or pathological truths.

† In fact, instances occurred in which the supposed dead revived when the undertaker was about to screw down the lid of the coffin.

* The present ministry is scion of that which was duped on the first eruption of cholera, and the College is still the *sons et erige, malorum publicorum, et medicorum*.

DR. GOLIS'S TREATMENT OF THE
DISEASES OF CHILDREN.

Diseases of the Abdomen.

Diarrhœa.—When diarrhœa in children is accompanied by pain in the belly, we may always admit the existence of a sub-inflammatory state. Diluents alone must then be administered. In simple ordinary diarrhœa, a mixture is prescribed, consisting of two ounces of a decoction of mallow and saloop, and two drops of Sydenham's laudanum. The dose is a teaspoonful every hour or every two hours.

In catarrhal diarrhœa Dr. Gölis prescribes as follows: *Rx.* Decoct. althææ, \mathfrak{z} iij; Extr. daleam. gr. iij; Laud. sydenh. gtt. ij; Syr. papav. \mathfrak{z} ss; M. sit dosis coch. j. min. omni horâ.

If a diarrhœa of this kind lasts long, camphor in small doses becomes an excellent remedy; it produces a peculiar and comfortable sensation of warmth in the stomach. Thus he prescribes, *Rx.* Camph. solutæ, gr. ss; Decoct. emoll. \mathfrak{z} j ad \mathfrak{z} ij; Laudani, gtt. j ad ij; M. sit dosis coch. j min. omni horâ vel omni 2 â h.

When a tonic is required in chronic diarrhœa, he uses calumba; but there must be no fever, and the intestines must not have been despoiled of their mucus by violent alvine evacuations. Half a drachm of calumba and ten grains of saloop are to be boiled for a quarter of an hour, so that the strained decoction may amount to three ounces; half an ounce of syrup of chamomile is then to be added, and the dose is to be a tea-spoonful every hour. Or a mixture may be employed, consisting of two ounces of a decoction made with eight grains of saloop, eight or ten grains of powdered calumba, two drops of laudanum, and half an ounce of syrup of poppies. To be given like the last mixture, shaking the bottle every time.

If atony already exists, fifteen drops of Hoffmann's elixer (Sp. æther sulph. C.) may be substituted for the calumba.

In a chronic diarrhœa following a mucous fever, Dr. Gölis prescribes, *Rx.* Arnicæ rad., \mathfrak{z} ss; Calumbæ rad., \mathfrak{z} ij. Macera per horæ quartam partem, et post colationem restent uncie quatuor, tum adde laudani, gtt. ij; Syr. menth., \mathfrak{z} ss; the dose to be a tea-spoonful for a child three years old. When diarrhœa causes a flaccidity of the intestines, Dr. Gölis prescribes, Aq. destill. ceras. nigr. \mathfrak{z} iij; Extr. taraxaci, \mathfrak{z} ij; Extr. rhei, \mathfrak{z} ss; Ammon. muriatis, gr. vi; Syrupi menthæ, \mathfrak{z} j. M. sit dosis coch. j min. He orders, moreover, the whole abdomen to be rubbed with the ung. nervinum, made stronger by the addition of camphor.

When a chronic diarrhœa is complicated with worms, Dr. Gölis prescribes as follows: *Rx.* Valerianæ rad., \mathfrak{z} ss; Calumbæ rad. \mathfrak{z} j.

Aquæ q. s. ut post colationem infusi, restent, \mathfrak{z} v, quibus adde, Camph. solutæ, gr. j; Laudani gtt. ij vel iij; Syr. aurant., \mathfrak{z} ss. The dose to be a teaspoonful for a child four years old.

In rachitic children diarrhœa produces prolapsus of the rectum.

The Cholera of Children.—When this disease is of an inflammatory kind, it is very serious; gangrene is apt to occur, and the child is lost. A sinapiam applied to the belly until the skin begins to grow red may sometimes save the little patients. In ordinary cholera, Dr. Gölis gives the following medicines internally: *Rx.* Inf. Glycyrr. c. Decoct. Emoll. \mathfrak{z} ij; Laudani, gtt. ij; Sp. æther. sulph. comp. gtt. vi; Syr. papav., \mathfrak{z} ij. And the following ointment to be rubbed upon the epigastrium: *Rx.* Ung. nervini, \mathfrak{z} ss; Camph. \mathfrak{z} ss; Opil, gr. ij.

The ether, however, is not always advisable at the beginning of the disease, and Dr. Gölis then prescribes a potion, consisting of a decoction of three ounces made with eight grains of saloop, with two drops of laudanum, and half an ounce of syrup of poppies.

Vomiting.—Dr. Gölis treats cases of obstinate vomiting in the same manner as cholera.

Constipation.—The following remedies are prescribed against ordinary constipation: *Rx.* Inf. glycyrr. et decoct. emoll., \mathfrak{z} iij; Magnesiae sulph. \mathfrak{z} j ad \mathfrak{z} ij; Syr. \mathfrak{z} ss. Or else, *Rx.* Inf. fœniculi, aq. fœniculi, â â \mathfrak{z} ij; Tr. rhei aquosæ, \mathfrak{z} ij; a teaspoonful to be taken every hour.

Colic.—Colic may be easily recognized in children; they are restless, cry constantly, stamp on the ground, draw the thighs up to the belly, have twichings of the face during sleep, and awake crying. When we examine a child whom we suppose to be suffering from colic, we must not neglect to see if its sufferings proceed from some external cause, such as the pinching of some part of its dress, or the pricking of a pin. During attacks of colic, children pass their water often and in considerable quantity. Different internal causes may cause colic; such as,—1st, *Acidity*, which is known by the stools being green; in this case the following mixture is given; *Rx.* Inf. et aquæ fœniculi aa \mathfrak{z} ij; Magn. carb. gr. xv; Laudani sydenhami gtt. ij; Syrupi \mathfrak{z} ss; 2dly, *flatulence*, which is known by borborygmi and wind. The following mixture is then given, with or without the addition of magnesia: *Rx.* aquæ fœniculi \mathfrak{z} ij; Mucil. acaciæ \mathfrak{z} ij; Laudani gtt. ij; Syrupi anthem. \mathfrak{z} ss;—3dly, *indigestion*, in which case the following mixture is prescribed: *Rx.* aq. fœniculi \mathfrak{z} ij; Tr. rhei aquosæ \mathfrak{z} ij; Magn. muriatis \mathfrak{z} ss; Syrupi \mathfrak{z} ss.

Worms.—Dilatation of the pupil is not a pathognomonic sign of the existence of worms, for this symptom is also found in

cases of infarctus of the intestines. Dr. Gölis's ordinary remedy against worms is as follows: *Rx.* hydr. subm. gr. iij; Valerianæ pulv. \mathfrak{z} j; Sacchari albi \mathfrak{z} j. This is divided into four or six powders, according to the age of the patient, and three are to be taken daily.

Sometimes he adds a scruple of wormwood seeds. He also prescribes the following formula: *Rx.* Inf. glycyrr.; Decoct. emoll. \mathfrak{a} \mathfrak{a} \mathfrak{z} ij; Extr. valerianæ. \mathfrak{S} ss; Oxym. scillæ, \mathfrak{z} ij. The dose is a teaspoonful.

And afterwards the following purgative: Hydr. subm. gr. iij; Jalapæ pulv. \mathfrak{z} j; Sacchari albi, \mathfrak{z} ij. This is to be made into four or six powders, one of which is to be taken every evening.

The following anthelmintic is also employed by Dr. Gölis: *Rx.* Inf. glycyrr.; Aq. tanacetii, \mathfrak{a} \mathfrak{a} \mathfrak{z} ij; Fuci helminthocorti pulv. \mathfrak{z} j; Oxym. scillæ, \mathfrak{z} ss. A teaspoonful to be taken every hour.

In cases of ascarides clysters of milk are administered in which garlic has been boiled, or clysters of a decoction of garlic and wormwood. To draw out worms of this species, the children are placed on a chamber vessel into which warm milk has been poured.

Infarctus of the Intestines.—In this disease Dr. Gölis gives merely resolvent medicines. *Rx.* Inf. fœniculi; Aq. fœniculi, \mathfrak{a} \mathfrak{a} \mathfrak{z} ij; Potassæ supertart. \mathfrak{S} ss; Oxym. scillæ, \mathfrak{z} ij. The dose is a tea-spoonful.

Some other resolvent salt may be substituted for the cream of tartar. Externally he employs equal parts of mercurial and juniper ointment rubbed upon the abdomen; and at the same time he puts the patient on the use of acorn coffee and tepid baths. According to Dr. Gölis there is a certain globular shape of the cheeks, which is a true diagnostic sign of intestinal *infarctus* (obstruction) in children. This bulging out corresponds to the malar bones, and looks as if an almond had been placed under the skin: it is particularly obvious when the child laughs or cries. When this symptom is present, the case is hopeless.

Icterus neonatorum (Jaundice of new-born children.) The following prescription is used in such cases; *Rx.* aq. fœniculi; Inf. anthem. \mathfrak{a} \mathfrak{z} j; Magn. subcarb. \mathfrak{S} ss; Tr. rhei aquosæ, \mathfrak{z} ss; Syr. papav. \mathfrak{z} ss. The dose is a teaspoonful. If the bowels are confined, the following mixture may be given: Inf. glycyrr. aq. communis, \mathfrak{a} \mathfrak{z} j. ad \mathfrak{z} ij; Extr. taraxaci, \mathfrak{z} j. ad \mathfrak{z} ij; Sodæ; Sulph. \mathfrak{z} ij; Syr. man. \mathfrak{z} ss. The dose is a teaspoonful.

Prolapsus of the rectum.—When the intestine has been reduced, Dr. Gölis orders clysters of cold lime water.

Poisoning by opium.—In this case he ordered a bath with vinegar of half an hour's duration, and a teaspoonful of the following mixture every quarter of an hour. *Rx.* inf.

glycyrr.; Decoct. emoll. \mathfrak{a} \mathfrak{z} j. Ammon. uccin. gtt. viij.

STRUMOUS OPHTHALMIA.

MR. HUGH NEILL, Surgeon to the Liverpool Ophthalmic Infirmary, speaking of strumous ophthalmia, says that it often receives its beginning from either measles or scarlatina. There is the characteristic fever, intolerance of light, red tongue, full belly, &c. Although I have tried every treatment, none has ever had such happy effect as a long continued, but gentle, use of some of the milder preparations of mercury. The blue pill mixture is the best form for its administration to children—it will be weeks before its effects are developed, in some cases. To treat this disease with success, the surgeon must possess the confidence of the parent—for the attendance is always tedious; but by this blue pill mixture, or calomel, the complaint will be overcome; and unless there be ulcer, no other remedy need be applied to. I could relate a multiplicity of cases successfully treated upon this plan alone.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXIII.

*Instinct and Passion as Stimuli to Irritability—Mode of transfer of a Primary Irritation—
Rationale of Sympathy.*

SUCH, then, are a few of the principal isolated effects of passion, collectively considered, as a stimulus to the irritability of the several organs; and some of those of instinct—a term which, as will be in future shown, is applied only to that form of passion which is attended with desire, and the actions excited by which conduce always to some definite end—are of course identical with some of them, but, while, on the one hand, they cannot with propriety be made to embrace all the actions excited by passion in general, they include, on the other hand, not a few which are more properly regarded as instinctive, and which accordingly are seldom referred to passion in general as their stimulus. Among the irritations which may be said with equal propriety to result from either passion or instinct, in the sense of the latter term, above specified, are those by which the mucilage of the vagina becomes accumulated preparatory to copulation; by which the intestinal gases and stools are, in some animals, increased in quantity and vitiated in quality, as a means of self-defence; by which an increased secretion of milk is effected, for the purpose of affording nourishment; by which the quantity of semen is augmented, as instrumental to propagation; and by which the saliva becomes accumulated, preparatory to manducation. The irritation, likewise, on which indirectly depends the erection of the clitoris, of the fimbriae of the fallopian tubes, of the nipples of the mammae, or of the penis, conducive as all these actions are to a definite end, is referable indiscriminately to passion collectively, or to instinct in particular, as its stimulus. And the same thing may be said of the various irritations whence result vomiting, the effect of which is to expel any matters which excite disgust; sighing or yawning, both which tend to relieve the sensation of general oppression arising from sadness or annoyance; winking, the end of which is to defend the eye-ball from a threatened injury; starting, for the purpose of withdrawing the body from any object of alarm; and general rigidity, as a means of bearing up against danger of any kind. The other actions above enumerated as resulting from passion in general, as their stimulus, cannot with equal propriety be referred to instinct; while, on the contrary, there remain to be mentioned some, which, although, strictly speaking, they should be comprehended under the effects of passion—since a whole must of course embrace all its parts, and instinct is merely a department of passion—still, in common language, are referred to instinct exclusively. Of this nature are the action of respiration as excited, not by sympathy, in the ordinary way, but by a desire to breathe, produced by an uneasy sensation, arising from some impediment in this function, but without any distinct act of volition as prompted by a deliberate persuasion of the competency of such action to alleviate such sensation; that of taking food or drink by animals in general, and of sucking by the young of mammals, as excited by a similar desire produced by the uneasy sensation of hunger or thirst, and that of voiding the stools or urine, and of copulating, as excited, each in like manner, by a desire produced by an uneasy sensation: and it is remarkable that all these actions, as prompted thus by an impulse far less fallible in its proposed end than that of reason, and as immediately excited by a stimulus far less fallible in its operation than that of volition, are always precisely such as are best adapted to the end in

view, and are as perfectly performed the first time they are attempted, as at any subsequent period. It appears, indeed, that these circumstances may be taken as a kind of test of an instinctive, as opposed to a rational action—that it springs from a blind impulse produced by an uneasy sensation, without any reasonable conviction of the adequacy of the means adopted to attain the end in view, that it is nevertheless always precisely that which most directly conduces to this end, and that it is consequently quite unsusceptible of subsequent improvement. It is hence obvious that, while the greater number of the actions of man are rational, not a few of these actions are instinctive; and, on the other hand, that, while a comparatively small number of those of the lower animals are excited by volition, the majority of them are excited by instinct (a). To the latter head are referable in both, not only the actions of respiring, under any uneasy sensation excited by a temporary suspension of this function, of taking food and drink, of excreting the stools or urine, and of copulating, but also numerous others, more or less connected, as well with these functions, as with that of voluntary motion—that is to say, of the motion of muscles, the usual stimulus to the action of which is volition. Thus, the return by every animal, terrestrial and aquatic, to that element, whether air or water, in which alone its respiratory process can be exercised, and from which it has been for a time excluded, is excited, not by volition founded upon a deliberate persuasion of the subserviency of either medium to the end in view, but by the blind impulse in question; and the same is the case with the selection by all animals, herbivorous and carnivorous, of their own character of food, as well as by each individual of its own particular variety of this, in the same way as in certain states of the human stomach, we swallow acid, and in others alkaline substances, without any thing like a reasonable conviction of their efficacy in removing the uneasy sensation which produced the desire to do so. The actions, likewise, of hoarding up grain by the ant, and honey by the bee, as well as that of burying its superfluous food by the dog, and numerous other similar actions of the lower animals, all manifesting apparently the most admirable foresight, are, in all probability, to be traced to a similar desire, produced by an uneasy sensation, which a neglect of these actions, like a suspension of any one of the natural functions, occasions; and it is as actuated by some such impulse that the cat is accustomed to cover her excrement with earth, and, like an automaton, makes the movement of doing so, even when she has been compelled to void it on a floor, and when of course such movement cannot conduce to any useful end. In like manner, the deposition, by insects, of their ova in putrescent matters, calculated to afford nourishment to the larvæ upon their being hatched, is probably ascribable to a similar blind impulse: they think nothing of the furtherance of any ultimate end by their operations—for they do not in general live to see their offspring—but they are excited to the action by a desire, produced by an uneasy sensation, which arises probably from the peculiar odour of these substances, in the same manner as a dog is excited to void its urine by the odour of certain plants, or by the stale urine of other dogs; and, accordingly, such insects, misled by the putrescent odour of some plants, not unfrequently deposit their ova in the heart of them. Again, it is to such an impulse or desire produced by an uneasy sensation, which that kind of locomotion adapted to the peculiar organism of each, can alone allay—although without any such purpose on the part of the animal—that we must attribute the selection, by every animal, of that medium in which alone this locomotion is possible. It is this which leads the tadpole, immediately, upon becoming a frog, from the water to the land; the duckling, the first time it has an opportunity, from the land to the water; and the fowl of the air—the native inmate of a cage—immediately on finding itself at liberty, into the atmosphere; and it is thus that, without exciting any individual exercise of such locomotion, the ordinary stimulus to which is volition, the impulse in question carries each animal into that medium in which alone it can be exercised. Such, likewise, appears to be the indefinite desire, dependent in like manner indirectly upon their organism, and quite independent of any deliberate object of either resisting danger or procuring aliment, which excites some animals, as most of the herbivorous tribes, to become gregarious, and others, as most of the carnivorous, to avoid the society of their fellows; and it is as actuated by a similar blind impulse that so many tribes, at certain seasons, engage in their several migrations, and accomplish, in the course of them, undertakings which reason would not have dared to prompt, and which volition would have been inadequate to execute. The degree of desire, in these cases, appears to amount to a kind of enthusiasm; and all enthusiastic actions are instinctive, and therefore, in our own species, frequently such as to surprise even the en-

(a) It needs hardly be observed that the present is not the place for discussing the abstract nature and differences of reason and instinct—a subject manifestly appertaining to the head of Thought. Instinct is spoken of here merely in its character of a stimulus to irritability, exciting motion sensible or

insensible; and it is no more necessary, for the purpose of following it out in this relation, to begin with a full description of its abstract nature, than it was to begin with a description of that of caloric, light, or electricity, in treating of these agents in a similar capacity.

thusiasm himself, on again subjecting himself to the sober dictates of reason and volition. They are like those of a person somewhat elated by wine, or one partially insane; and if a special providence seems sometimes to preside over the actions of a drunken man and a maniac, it is only because they are actuated, under circumstances of difficulty, by a power less fallible both in its end and the means employed to attain that end, than reason and volition. It is hence obvious that many motions commonly excited by volition, may, under certain circumstances, be excited by instinct—and this without reference to habit, which, as will be presently shown, seems always to render motions which were at first exclusively voluntary, ultimately instinctive also; and it is hence easy to understand how, in the lower animals, the blind impulse of instinct should be competent to excite numerous actions, corresponding to those which, in man, can be excited only or chiefly by volition. Thus, when the latter would construct a fabric, or build a house, he proceeds upon a plan more or less deliberate, adopts means which are at first in a greater or less degree inadequate to the end in view, and it is only after efforts more or less frequently repeated that he attains any thing like perfection in his manufacture; but the spider in constructing its web, or the silk-worm its cocoon, the bee in building its comb, the bird its nest, or the beaver its hut, without any deliberation, adopts at once the most effectual means of attaining a certain end, and the resulting fabric or edifice is as perfect the first time it is attempted, as it can ever by any possibility become. These are the criteria of instinctive, as distinguished from rational actions; and the more nearly man, in attaining perfection in his manufactures, approaches to these conditions—in other words, the more he is actuated in their production by instinct—the greater is his genius—the more by reason and volition, the greater his talent. It is most erroneous to imagine that we detract from the proper rank of the lower animals by representing them thus as a kind of automata; since we are in fact raising them to that of artists, acting under an impulse by which it is the highest glory of man to be actuated (a).

It is the consciousness of the existence within us of a power superior to any over which we have control, which has led poets in all ages to invoke Apollo and the Muses to inspire their verse—in other words, to call upon Passion or Instinct to supersede Reason; and that some such instinctive power actuated the mighty hand of a Michael Angelo and a Raphael, and excited the merely physical movements destined to develope works on which ages were to ponder with admiration and delight is unquestionable. It is true the instinct thus running riot over the reason, is, in man, very liable to become morbid, and it is this subserviency of many of the actions of a great genius and a maniac to the same blind impulse, which produces that close alliance of the sublime and the ridiculous, the lofty and the bombastic—as well in works as in thoughts and words—which has furnished, in every age, so fertile a theme of animadversion: both equally recede from the reasonable—and the only difference between them appears to consist in this, that, while the former so far carries with it the mind of the judge, as to warp his judgment, by inspiring him with some degree of that enthusiasm in which the conception originated, the latter fails in this object, and by leaving him in full possession of his reason, stands exposed at once in all its native deformity. An unhappy point in the most majestic statue or picture, like an ill-timed word in the most elevated sentence, frequently has the effect of suddenly awakening us from a day-dream of admiration; and what we were perhaps about to pronounce a model of the grand, becomes at once a beacon of the ludicrous—the insignia of royalty differ only in the spirit in which we contemplate them from the tinsel of Punchinello. One more remark remains to be made respecting instinct, as the stimulus to the irritability of the various organs, particularly of those which, under ordinary circumstances, obey rather that of volition, and that is, that it is probably the source of that ease and accuracy in the several movements which are gradually acquired by habit. It has been already remarked that an instinctive action is unsusceptible of improvement; but this furnishes no objection to the above proposition, since it is not as instinctive that such actions are improvable. In every step which is made towards progressive perfection, the agent in effecting this is volition, but at any given stage of this progress they may be further excited by instinct, which thus perpetuates the improvement which volition has made, and at length renders such habitual actions as prompt and correct as if they had been originally instinctive. The action of sucking, for example, is instinctive; it is perfect from the first, and not only is the exercise of this action in any given instance determined, but all the motions requisite to it are excited, and excited readily and accurately by instinct alone: on the other hand, that of speaking is voluntary; many and many failures are made before a single word can be articulated, but when the difficulty has been once

(a) The instinct of animals, which appear frequently to be so much wiser, in their generation, than the sons of men, is accordingly called by Sir Isaac Newton “the wisdom and skill of a powerful ever-living

agent;” by Addison, “an immediate impression from the First Mover;” by Hartley, “a kind of inspiration;” by Hancock, “the Divine energy;” and, by Mason Good, “the Divinity that stirs within them.”

thoroughly overcome, the action becomes habitual, and so on with respect to every other word, till the language formed of these words has been mastered, and now volition determines only the exercise of speech on any given occasion, and excites the motions which are the effect of it, but it is instinct or desire, produced by the uneasy sensation which a suspension of a function, not indeed in this instance natural, but acquired, always occasions, which calls them into action with facility and precision. But this subject will fall to be resumed under the head of Volition, regarded as a stimulus to irritability.

These then are a few of the most remarkable examples of the operation of passion or instinct as a stimulus to irritability during health; and, were it consistent with our present object to regard them either as agents in the production of diseases, as constituting a feature in the symptoms, or as instrumental to their cure, still more striking instances of this operation might be adduced. Suffice it to say at present, there is scarcely any disease, organic or functional, which may not be excited by one kind of passion or another; that there are few or none in the course of which the passions do not play a more or less active part; and that upon almost all, the several passions have been brought to bear with greater or less effect, as a remedy, from the times of the priests and prophets, through those of the magicians, sorcerers, wizards, necromancers, astrologers, conjurers, exorcists, and Rosicrucians, to the days of the followers of Gatorex, Messmer, and Perkins, the worshippers of Hohenloe and the proselytes of St. John Long. "A merry heart," saith the preacher, "doeth good like a medicine;" and, he might have added, often much more abundantly—a fact known to charlatans from time immemorial, but which regular practitioners, in the pride of their superiority, for the most part have yet to learn, or, if they know it, have at any rate yet to avail themselves of that knowledge.

Nor is passion or instinct in all probability a less general and important agent in promoting all the vital actions, at least of the higher tribes of animals—in addition to these more or less isolated examples of its operation—than sympathy. If the healthy irritation of each of the other organs of the body be in some degree essential to that of all the rest, it seems to follow *à fortiori* that that of the brain—the seat of passion or instinct—will be at least equally necessary; and it is accordingly this stimulus which we allude to when we speak of a permanent influence from the brain, as conducive to all the natural functions of the body. The irritability of the respiratory muscles is indeed immediately excited principally by an especial sympathy, that of the heart and capillary system principally by the blood, that of the stomach principally by the aliment, and so forth; but to the perfectly healthy action of each of these organs many other stimuli, including the one now in question, are requisite, as is obvious from the laborious respiration, the slow pulse, the diminished secretions, the torpid digestion, &c., which characterize those states of the system in which the action of the brain is suppressed or impaired. Such however is of course the case with animal sympathy, as well as with organic, only in those tribes of animals in which the brain, in common with the other organs, is so concentrated, as to call for this indirect association of its functions with those of the rest of the system; and in precisely the same ratio that system of nerves, which we shall presently find is, in all probability, the means by which this association is maintained, is found to be developed (a).

The question now arises, by what channel is the direct and primary irritation of one organ, so translated to a distant one, as to become there a new stimulus to irritability? And in the first place, it may be observed that irritation, consisting as it does in the action, either sensible or molecular, of solid tissues, may be as easily supposed capable of exciting the irritability of parts directly contiguous to those which are undergoing it as the direct application to them *de novo* of any chemical or mechanical agent; the immediate stimuli to irritability not being, any more than irritability itself, in any case substantial, but merely a power attached to something that is so, and dependant probably as much upon a new mode of being of substances already present, as upon new substances being brought into operation. Irritation, then, is not only the result of a stimulus acting on irritability, but may be itself a stimulus to irritability, and thus excite further irritation, at least of contiguous parts, as well as under certain circumstances to sensibility, and thus excite sensation, as sensation again may be to the faculty of thinking, and thus excite thought. All this will be more particularly explained in future; but in the meantime it becomes a

(a). Passion has never been quite identified, like caloric and so many other stimuli to irritability, with life; but it was regarded by the ancients as the next thing to it. This is sufficiently indicated by the fable of Prometheus, who, after he has vivified his clay statues with fire, as before stated, is represented to have found, as Dean Swift says, that "they looked so like the latter end of a Lord Mayor's feast, that he could not bear

the sight of them." He was obliged, accordingly, to actuate them by various passions, which he culled, for the purpose, from the different tribes of animals, "and so tempered together before infusion, that they became the most amiable creatures that heart can conceive." The passions, as before observed, were one of the six non-naturals of after-times.

question, by what means is it that, passing over contiguous parts, a direct and primary irritation, whether of other organs or of the brain, becomes so frequently an indirect and secondary stimulus to the irritability of parts at a distance, and that apparently on grounds altogether indefinite and arbitrary? Previously to entering on this inquiry, however, it is to be observed, that by some authors the immediate seat of passion or instinct has been presumed to be the several viscera of the chest and belly (a); so that it would appear that the translation of the irritation is, in this case, rather from the organs in question to the brain—if the brain have anything to do with the matter—than in the opposite direction; but there is a fallacy in this view of the subject, which must be met *in limine*. That passion or instinct, as a mode of thought, must be preceded by sensation, as sensation must by irritation, has been already admitted; but it is absurd to call the seat of this primary irritation that of passion or instinct, or to confine it to the viscera of the chest and belly, if we do so. Passion or instinct, as a mode of thought, can no more be seated in any organ except the brain, than palpitation of the heart can be seated in any organ except the heart; and though such passion or instinct may be produced by the sensation of touch or tact, in one or other of its innumerable modifications, arising from irritations of some of the viscera in question, as is the case of a desire to eat, to void the stools or urine, or to copulate, indirectly from irritations respectively of the stomach, rectum, urinary bladder, or genital organs, it is much more frequently produced by the sensations of smell, sight, hearing, or taste, arising from irritations severally of the nostrils, eyes, ears, or tongue. But speaking, as we are now doing, of passion or instinct merely as a stimulus to irritability, we have nothing whatever to do with its origin: we regard it as a ready-made irritation of the brain; and, in this view of the matter, have now to attempt an explanation of the manner in which this irritation, in common with that of sympathy in general, is translated to other parts.

The first opinion entertained upon this subject was founded upon the tenets of the ancient humoral pathology, which inculcated that wherever irritation—which term was always employed by them in a morbid sense—was excited in any part by the application to it of some peccant matter, one or other of the four principal fluids of the body, already alluded to, set off, urged by the everlasting vital principle, on an expedition against it; and hence the vague and absurd axiom, *ubi irritatio, ubi fluxus*, still unhappily too often in the mouths of pathologists. But in the course of the disease, thus excited, the vital principle seems sometimes to have changed its mind; and the fluid in question being drawn off, in some arbitrary way or other, from the part which it first occupied, proceeded elsewhere, and excited the critical discharges and so forth, a consummation which it was so much their object to effect by the use of reputedly revulsive remedies, the operation of which is still so frequently, and so idly, referred to counter-irritation. The seat, then, of the primary, and that of the secondary irritation, were accordingly said to sympathize with each other; and the presumption of these spontaneous influxes of imaginary fluids was received as an explanation of the manner in which they did so (b). On this hypothesis of course any comment would be quite superfluous.

(a) This was the opinion of all the ancient philosophers and physicians without exception, who, while they placed reason in the brain, uniformly consigned the passions to the viscera of the chest and belly, or to these organs and their contents collectively; and hence we find the words breast, heart, belly, stomach, bowels, liver, reins, or kidneys, *στήθος, καρδία, φρένες, σπλαγχνος* &c. constantly used by them as synonymous with passion in its various modifications—a practice which still extends, as will be more particularly insisted on in future, a very remarkable influence over our most familiar expressions. Nor have modern authors been wanting to follow this conceit, Bordeu, Buffon, Bichat, Cabanis, Reil, Broussais, and many others, having represented the passions as rather springing from, than giving rise to certain states of the viscera. Broussais, indeed, defines passion to consist in “the triumph of the viscera over intelligence;” (Principles of Med. § 47); but, as has been aptly asked by Dr. Wilson Philip,

“Can the passions belong alone to that life (the organic) in which they never can be excited—on which they never could operate?” (On the Vital Functions, 1817). No irritation of the stomach or genital organs can by any possibility constitute the desire for food or venery; and if the irritation in which these desires consist be not there, they must be elsewhere, and translated thence, so as to act as a stimulus on distant organs, by some means or other, which still remain to be explained.

(b) This was the doctrine of all the ancient dogmatic or rational physicians (heaven save the mark!) in opposition to the empirics, who honestly confessed that they knew nothing at all about the matter; and it prevailed of course during the twenty centuries that the humoral pathology held an almost undisputed sway over the schools of medicine, and every physician employed the word humour, like Corporal Nym, as a convenient substitute for almost every other. Few are aware how much of the heaven of

Analogous to this vague doctrine of alternating influxes—nobody knows by what channel—of various imaginary fluids, as a cause of sympathetic irritations, is that of either alternating, or simultaneous determinations of blood, which superseded it soon after the discovery of the circulation of this fluid, and which is still not unfrequently alluded to as a means of explaining such irritations. It is in this way, for example, that the participation by the mammæ in the affections of the female genital organs is sometimes explained, the communication between the two, by means of the circulation of the internal mammary and epigastric arteries, being quite competent, it is presumed, to account for such a relation between them (a): but it appears quite unnecessary to enter into the merits of an explanation which is not only quite inapplicable to at least ninety-nine out of a hundred cases of the most obvious sympathetic action, but altogether inconsistent with every thing that is known respecting the laws which regulate the course of the blood, every acknowledged fact tending to the conclusion that, if ever there was one doctrine in physiology more totally unfounded than the rest, that doctrine is the presumption of a determination of blood in any case, and *à fortiori*, of any such alternating or simultaneous determinations as are here supposed. Nor is the doctrine, that it is by means of the blood-vessels or lymphiferous vessels *per se* that the stimulus of sympathy is conveyed (b), in any degree more tenable; since, as it must be obvious that these vessels, without their nerves, are quite incompetent to communicate any vital impression, so what nerves they have are known to be for a very different purpose.

The next hypothesis advanced, respecting the medium of sympathetic irritations, was that it took place through the ganglionic nerves, or system of the great sympathetic, as the name so unhappily given to this system by the first physiologist who well described it sufficiently indicates (c)—and indeed the hypothesis last mentioned is little more than a modification of this, since the only or principal nerves of the blood-vessels and lymphiferous vessels, by which alone, as first observed, they can communicate any vital impression, are derived from the ganglionic system. Nor is it at all surprising that this opinion should have been promulgated. Sympathy and passion are strong stimuli to irritability, analogous to volition; and as it had become established that, while sensibility was the attribute of one of the only two departments of the cerebro-spinal system then known, volition was conveyed by the other, it was very natural to refer the conveyance of sympathy and passion to the ganglionic nerves, as a part of the nervous system hitherto unoccupied, its subserviency to irritability not having yet been thought of. But that this cannot be the office of the ganglionic system of nerves necessarily follows, if the arguments which have been already adduced, at so great a length, to prove what is its office, be admitted. Most of them are indirectly against the proposition in question, and some of them are directly so—in particular the fact that these nerves are developed in all tribes of animals, not in the ratio of their manifestation of sympathy and passion or instinct, but in that of their irritability; that they are, in structure, much more nearly allied to the sensiferous, than to the motiferous nerves; that, like the former, and unlike the latter, they do not readily conduct galvanism; and that, when stimulated, they occasion no irri-

this pathology still clings to us, in this the nineteenth century of human redemption.

(a) Such was the hypothesis of Riolan, the contemporary of Harvey, who was the first to describe the inosculation above alluded to, which, it is remarkable he always met with *in women*. "In mulieribus," says he, *semper animadverti*." How very fortunate!

(b) Blumenbach, *Inst. Physiol.*, 1786; Soemmering, *De Morb. Vas. Absorb.*, 1795, &c.

(c) In speaking of the various alleged uses of the ganglionic system of nerves, it was observed that the above use, among others, had been assigned to them by Willis, followed by Vieussens and Meckel, and that their opinion had been currently adopted by the common-place physiologists of the present day. Mason Good, for example, describes the ganglionic system of nerves as "the emporium of nervous communication, and the instrument of general sympathy," (*Study of Med.*, 1825)—a strong presumptive evidence, if other arguments were wanting, that it is neither the one nor the

other. It is true Bellingeri (*Dissertatio Inauguralis*, 1818), and some others, whose opinions are entitled to more deference, inculcate *in words* the same thing: but they do so, as do also some of the preceding authors, chiefly from regarding the pneumogastric, or, as it has been well called, the little sympathetic nerves, as well as some other nerves as belonging to the ganglionic system, whereas they pretty certainly belong to the respiratory and other departments; so that, *in fact*, their opinion is favourable to the doctrine that it is, at least among others, the nerves which are the vehicles of sympathy and passion. Nor are Dr. W. Philip's proofs that the nerves of the heart convey to this organ extraordinary stimuli, such as those of sympathy and passion, at all less in favour of this doctrine than of the other; since it is not, in all probability, as elsewhere remarked, in that department of them which is derived from the proper ganglionic, but in that which belongs to the respiratory system, that they perform this office.

tation in the muscular parts which they supply—a fact which, although it is easily reconcilable with the presumption of their communicating only a susceptibility of action to these muscles, is quite incompatible with the doctrine that they conduct to them a stimulus. Further, the greater number of the arguments which will be presently brought forward in favour of the opinion that a very different system of nerves, and one which was quite unknown, as a distinct system, at the time that the doctrine in question was first broached, is really the vehicle of sympathy and passion, bear of course indirectly against this doctrine; while there is one which militates directly against it, and that is the fact, that cutting the nerves of the system last alluded to seems at once to put a stop to the conveyance of the stimuli under consideration. It would give rise to endless, and very unnecessary repetitions, on the one hand, to recapitulate here all that has been said in favour of attributing a very different office to the ganglionic nerves, and, on the other, to anticipate all that will in future be said in favour of ascribing this office to a very different system; suffice it to say that every unprejudiced view of the matter must tend to dislodge the ganglionic system from the post which it has, with a certain class of physiologists, so long and so undeservedly occupied.

SELECT LECTURES,

FROM

M. BROUSSAIS'

Course of General Pathology and Therapeutics;
translated and revised

By JAMES MANBY GULLY, M.D.

LECTURE VII.

WITH regard to the duration of gouty attacks, nothing certain can be said. At the commencement they sometimes last twenty-four hours, or not even more than from two to seven hours. In such case they can only be very slight attempts, which leave no marks behind, and after which the resolution of the circum-articular phlegmasia is complete. But when they are further prolonged, the inflammation gets the advantage, and is not so readily resolved. It may induce suppurations in the cellular tissue around the joint: to small pustules, which open, and from under which, through the skin, minute calcareous concretions proceed: to bony affections, that may be followed by caries, when, after repeated inroads on the same point, it becomes concentrated and deeply seated therein. In some individuals no pains occur: the joints swell and become rugged, hard and hot, without causing any sensation beyond a confused inquietude and malaise. This it is that has been erroneously denominated *atonic gout*, instead of simply calling it indolent gout. This indolence is owing to the non-participation of the nervous system in the disease, or the small part it takes in it, as also to the viscera having nothing to do with it. I have seen such persons with their fingers disfigured for twelve or fifteen years, and their hands like bunches of parsnip, and yet without any gastritis—facts that have long since induced me to abandon the opinion I once held, that gout is always dependent on an affection of the stomach and liver. This, however, does not imply that they do not perish from an internal irritation: but the latter comes much more slowly. Thus, then, no-

thing certain can be stated, either on the duration of the attacks, on the entire duration of the disease, or, consequently, on the resisting powers of individuals.

Nor do post mortem examinations present any constant appearances. The dissection of a gouty patient is a rare and valuable thing, for gout commonly attacks the rich ones of the earth, whose relatives do not very readily allow them to be handed over to the anatomist. I had an opportunity of dissecting one last year, and found in his joints all the different degrees of phlegmasia, and there was scarcely one of them that was not either inflamed or sub-inflamed. In the larger ones I met with phlegmons and suppurations; in the cellular tissue, with indurations and fatty degenerations; the cartilages worn and reduced to a pulp; the tendinous and articular capsules inflamed or destroyed; the bones red and injected, some of them carious and their cartilages softened; the subcutaneous tissues, and the external surfaces of the ligaments encrusted with calcareous concretions, or covered with a concrete, gummy, and gelatinous matter. In places where the inflammation had been recent, a redness that attested its last traces was observed, and those where it had just appeared, only a detritus of tissues was remarked. There were bones, particularly of the foot, that had been so worn by the inflammation, that they ended in a sharp point. I also verified what M. Gendrin states, namely, that they do not inflame, but soften into a pulp. In short, I ascertained the existence of all the disorders that are producible on our tissues by acute and chronic inflammations, and inveterate sub-inflammations.

All these facts I examined the more attentively, as there are physicians that have contested them, making gout an almost metaphysical entity. Yet what can be more material? If we will subtilise and look at such facts, only with mental vision, the doctrine alike, and the practice of medicine, is impossible. In medicine at least, we must be materialists—not however, anatomo-patholo-

gists, who only search for disordered tissues, and have no sight for the vital modifications they produce—but anatomo-physiologists, who take into account at once the structure of the organs, and their vitality, and who do not consider these disorders to be the cause of gout, but the effects of an inflammatory or sub-inflammatory irritation usually denominated gout.

In the viscera of this same individual I found a most decided duodenitis, the lungs disorganized, rugous, filled with black tubercles, yellow and degenerated tissue of the liver, brown and black spots of the intestines, with softening and infiltration of their membranes, serum effused in the abdomen: but there was no alteration of the heart, though the coincidence of aneurisms of that organ with gout are common, and I have most generally observed them in other cases. There was also a decided encephalic congestion; not that the gouty matter had fixed itself in the brain and its meninges by choice, or some inexplicable cause, but that a true inflammation caused by transfer of irritation obtained in the organ in question.

Being now made acquainted with the phenomena of gout, its progress, and the disorders* that accompany it, we will proceed to speak of the mechanism of the disease or the manner in which it is developed.

Formerly all articular phlegmasiæ were confounded in the name of podagra. Then came the great distinction, grounded on the etiologic condition of cold, which, while it was admitted for arthritis, was disallowed, or neglected for gout, to which the name *podagra* was given, because it affected the feet in preference, whereas, arthritis manifests itself in all the articulations. I made you sensible of the difference between those two affections, when I told you that the latter was an acute phlegmasia, developed by the influence of cold, in all circumstances of life, but more especially in youth, and that the former was likewise an articular phlegmasia, but less acute in character, and accompanied by less violent pain in the commencement, appearing generally in advanced age, but possible at any time, and capable of being generated by cold alone. I added, that arthritis was to gout what acute gastro-enteritis was to chronic gastro-enteritis, so that after several attacks of one, we are only liable to suffer from the other.

* Broussais uses this term for the most part to signify the alterations of structure that occur in the tissues during the progress of disease: it might be supposed to mean the symptoms, were it not that he commonly speaks of the *phenomena* of the malady in the same sentence with the disorders.—J. M. G.

Referring to authors, we see that some of them admit a corruption of the humours, or of the earthy matters which chose, nobody knows why or how, the joints for an eliminating point; that others say that it is the detritus of the bones or calcareous salts, dissolved by an acid that flows with the blood, which nature directed upon certain parts: that others attribute the disease to a debility manifested by pains: that others again maintain it is purely nervous, and that there are those who believe it consists in a lymphatic inflammation, though it is impossible to imagine all the phenomena of gout springing from such a cause, for if it be lymphatic everything depending upon it should likewise be so. When it had made some progress they said it was a gouty cachexia, that the gouty humour or matter was predominant, that it was deposited in the viscera, the head, the chest, the belly, that it sometimes had a tendency to deposition in the skin, until we could see it exude, in a calcareous form, from different parts of the body. It has even been asserted that this calcareous matter was secreted by the lungs, and that gouty patients actually expectorated matter that changed into plaster. These plaster-like matters were also said to abound in the urine; and as many gouty subjects are affected simultaneously with nephritis and cystitis, all kinds of internal phlegmasiæ are possible in this disease. The latter were attributed to a superabundance of the matter that had been detached from the bones, and directed upon the urinary passages. Then the chemists, taking these facts as constant, explained them scientifically; for remember that their theory is nothing more than the chemical interpretation of the humoral expression as it was presented to them. They said that the bony matter was displaced and transported to various situations, and that it became so superabundant as to surcharge the humours and the economy at large with calcareous and phosphated substances, which encrusted and petrified the organs, just as if they had been kept in petrifying waters. Read Barthez' work; he has crammed all the tissues with gouty matter, and this is the only idea you can draw from it. On the other hand, when people have talked to you about a lymphatic inflammation, producing gout, they talk to you of an unintelligible thing, and still more unintelligible when they make an entity of it. But all this, or any part of it, you cannot see in gout; but you can see successive or simultaneous inflammations and sub-inflammations of the joints, complicated with various shades of irritation in the interior of the body, and leading to the disorganization of the viscera and articulations. If you ask why there is disorganization when there is phlegmasia, I cannot reply: I confine myself to the examination of facts, and do not pretend to rise to first causes.

In the prognosis, we say that the first attacks of gout are not dangerous; and that as the inflammation is less extensive than in arthritis, there is less danger than in it. The serious nature of the disease is proportionate to the intensity of the phlegmasia, which may, when great, cause phlegmon, or even gangrene, or give rise to articular dropsy; and, when obstinate and frequently repeated, encrust the joints, soften the cartilages, wear away the ends of the bones, and render the patient powerless. Generally speaking, whenever a second attack of gout comes on before the first is passed, and resolution completed, the patients are incessantly in a state of suffering, and there is reason to fear for the integrity of their joints.

The viscera are but slightly affected in the commencement, unless the disease makes rapid progress, and reaches the large articulations. In youth, they often remain altogether unaffected. So long as gouty people are well internally, we may in general promise them a long life; I say in general, because the internal affection is sometimes unexpectedly developed: in fact, with a regular gouty attack, they are liable to be all at once made sensible of the displacement of the irritation, by the presence of dyspnoea, vertigo, cerebral congestion, and apoplexy. But such is not ordinarily the case in the early periods, when the individual is vigorous, and is within his fifty-fifth or sixtieth year. Between seventy and eighty years the thing is changed, and every attack of gout is to be feared. It is a general rule, that so long as there is purely and simply an articular inflammation, there is nothing to fear; that can only be founded on some internal phlegmasia, to which the untoward chances are always proportioned.

What are the foundations of our therapeia in this disease? Let us first examine the old practice. Those physicians who beheld a depurative movement in gout, were unwilling that its progress should be stayed, left their patients to suffering, bled them a little, and contented themselves with the administration of sedatives. Those who beheld nothing but debility in it, gave stimulants. Those who thought they were assisting nature, gave sudorifics. Others were desirous of evacuating the humours by purgatives. These kinds of practice were all derived from different theories; but empiricism, which admits no theory, has also its own means: some employed leeches, others had recourse to ice, these used purgatives, those stimulants—specifics, such, for instance, as the preparations of meadow saffron: some again, made use of topical applications of poultices, while others contrived to gorge their patients with water, Cadet de Vaux prescribing as much as forty tumblers in twenty-four hours, which sometimes produced enormous evacuations, and an ill-timed revulsion. Of the specific re-

medies, the alcoholic tincture of colchicum has the greatest celebrity, and I have proved its effects. It first causes a powerful stimulation of the stomach, that quickly induces fever, and subsequently brings on a forced action of the secretory organs, and more especially a copious sweat; generally speaking, gout is thereby relieved.

Reflecting on these different plans, we at once perceive the viciousness of that which consists in leaving nature to mature the inflammatory phenomena until a depuration is effected, inasmuch as it allows the gout to become established; we perceive that the purely cooling plan has the inconvenience of staying the phlegmasia without having previously prepared the internal parts for the change, and that of Pradier—the blistering poultices—often fails; and, by causing a too copious exudation of fluids, produces emaciation of the extremities, leaves the patients exceedingly weak, and sometimes induces so much pain, and so violent a congestion, as eventually to determine gangrene. All these methods ought to be abandoned; at least I will not adopt any of them. The plan I pursue is rational, and consists in extinguishing the inflammation, by leeches, wherever it is developed, as in arthritis, in repeating their application until the disease is got under, and in seconding their effects by emollients, either alone or combined with narcotics, without having any fear of relaxing effects. Should it re-appear elsewhere, I still follow it: if it at the same time exists in the viscera, I also attack it in the viscera. But as in the latter locality it is frequently only consecutive, the irritation also frequently disappears with the external phlegmasia. After this, in order to prevent its return, I endeavour to ward off the two chief causes that might induce a relapse, namely, cold and gastro-duodenal irritation. The importance of this is strikingly illustrated by the fact of gouty patients having so often lost all their gout in getting rid of their wealth, and again becoming gouty when fortune once more smiles upon them, and good cheer warms them. The same remark is verified in persons labouring under nephritis and gravel.

When the attacks become more frequent, they should always be combatted in the same manner. If they come so closely on each other as not to allow time for resolution, and lymphatic effusions remain behind, the case becomes serious, and involves the necessity of uniting the most absolute rest with antiphlogistics, and mild diet, and of producing revulsions at certain distances, until the inflammation is extinguished. If you are called when there is a simultaneous attack of different degrees of phlegmasia and sub-inflammations of all the articular tissues, of the skin, cellular texture, ligaments, capsules, &c., and a purulent collection is already forming, the difficulties of

circumference, and in colour and inequality of surface, appearing to be composed of a number of distinct prominent granules; it bore a strong resemblance to a raspberry.

The deep red colour of the fungus arose from its great vascularity. It bled on being slightly touched, but was scarcely painful; pressed firmly, it diminished for the time in size, giving a sensation to the finger as if it were of a spongy or erectile tissue. There was a very narrow inflamed edge on the skin around its base, but not the least hardness either around or underneath it. The absence of hardness even underneath could be satisfactorily ascertained by examining it through the lip from within the mouth. The little fellow could give no account of its origin, except that about five or six weeks back he first noticed it small in size, and that it gradually increased to its present bulk. What is wanting in the history of the growth and progress of the disease in this case, I can however supply from another lately under my care, and from which I took the casts which I shew you, representing the disease in all its stages (*coloured casts were exhibited*). The first appearance of the disease is as a small eminence resembling a papule of a red colour, not so large as a flea bite, the surface of which slightly projects, and is smooth and glistening, the cuticle over it becoming thin and falling off. The little elevated spot continuing to grow in size, secretes no more cuticle, but becomes more and more vascular, and grows unequal on its surface until it resembles, as already described, a raspberry; it then assumes the appearance of a fungus, and from its surface, instead of cuticle, exudes or secretes copiously a creamy-looking pus.

This purulent exudation, if allowed to accumulate, forms a scab of varying thickness and colour; when of recent formation, the scale is simply the purulent exudation dried, and it is a dirty white, adhering very closely to the surface which has secreted it. In this state, with a thin layer of greyish purulent matter dried over it, the subjacent fungus gives to the touch a feeling of elasticity, such as would be given by a collection of matter. If the scab however be allowed to remain undisturbed for several days, it becomes thickened by successive layers of purulent matter from beneath, and on its outer surface becomes, like most scabs, formed in pustular diseases of a greenish hue. The scab is then liable to be torn off by a very slight touch, for between it and the fungus underneath there is an intermediate layer of purulent exudation. These casts show accurately the appearance at different stages. The smaller shews the disease in its commencement resembling a papule; the second shews the fungus covered with its greenish scab, through which points of the purulent matter from underneath are forcing their way; the third shews the appearance of the raspberry

fungus denuded of its scab, smeared over with its creamy purulent exudation, and dots of blood oozing through the pus, caused by the slight violence done to the prominent points of the granules in tearing off the scab. *An accurate examination shews that the fungus is not a new tissue, but that it is formed of the vascular papillæ of the skin itself hypertrophied, and by their growth and union producing the peculiar granular aspect.* This disease attacks all parts of the skin, but I have seen it most often on the inside of the thighs, on the hams, on the inside of the arms, and on the scrotum. I have seen the scrotum, buttocks, and inside of the thighs, thickly covered with the fungous growths, and in that case the subject of it was positive in his assertion that he was inoculated by the disease from second-hand clothing.

In the country parts of Ireland, where the disease is endemic, there is no doubt entertained of its being contagious. In the case from which the casts before you were taken, the patient said he never had any symptom of the disease, until he lay in the same bed with a man who had a similar eruption. That man I had an opportunity of seeing, and the only eruption on him was a crop of venereal condylomata around the anus. If the history of the conveyance of the disease in this instance be correct, it would tend to establish that this singular fungoid disease is one of the many protean forms of syphilis. Of the duration of "button scurvy," I can say nothing positive. I have known it to last for several months; and when apparently cured in one place, shew itself, after a short interval, in some other.

The diagnosis of this eruption is easy. I know of none indeed (in these countries, so plainly distinctive are its characters), with which it could be confounded, unless from great carelessness. When first presented for observation, the prominence of the scabs might make it bear some resemblance to rupia, but even in colour there is a distinction, for the scab of rupia is blackish, while that of the disease now before us is dark green. And in the scab alone, all the similarity consists; for if the scab of rupia be removed, there is left a depression, the prominence being caused altogether by the thickness of the scab, while the removal of the scab of "button scurvy" exposes the fungus, already described, projecting above the surface of the skin. The situation of the disease, in the present instance, on the lip, and the deformity occasioned by it, might at first cause some alarm, from a suspicion of the affection being malignant, but the absence of hardness, of lancinating pain, and of ulceration, is sufficient to remove all fear. The treatment of the disease, as exemplified in the case before us, is simple, and the same as that employed from time immemorial in the country parts of Ireland—namely, the exhibition of mercury pushed so far as to salivate.

The popular preparation is the bichloride or sublimate. The particular preparation used seems to be a matter of no consequence. I used the common blue pill. I allowed the case to remain for several days without any treatment, to shew you the disease, and then put the boy on the blue pill. As soon as the mouth became slightly affected, the fungus began to wither, and in a few days shrunk to the surface of the skin from which it had grown. Almost any slightly stimulant local application, a weak solution of nitrate of silver, of corrosive sublimate, or of sulphate of copper, will destroy any of the fungi, but the disease will break out somewhere else, unless it be treated by medicine acting through the constitution.

In concluding my observations on this subject, I may direct your attention to the singular resemblance which exists between the disease now before us, and *frambæsia* or yaws. *Frambæsia* or yaws has been supposed by some to be a variety of the leprosy of the East; and if so, the persistence to the present time of a similar disease in Ireland—and in Ireland, I believe, alone, of the countries of Europe, may afford more than a fanciful support to the supposition of the eastern descent of the ancient inhabitants of Ireland, a supposition so strongly supported by the antiquities, the customs, the remnants of eastern rites, and even the names of places still preserved in this country. I call your attention to this similarity in the hope, that, should it fall to the lot of any of you to see *frambæsia*, you may be induced, perhaps, to give—what is very much wanted—an accurate account of that disease. At present, the description of it is confusion itself; for by one, *frambæsia* is described as commencing with a papule; by another, with a pustule; by a third, as being a tubercle. I shall notice, as well as these loose and imperfect descriptions will enable me, the points of dissimilarity and of resemblance which exist between *frambæsia*, or yaws, and the button scurvy of Ireland. I should first, perhaps, observe, for the purpose of preventing still further confusion than what already exists in the descriptions of *frambæsia*, or yaws, that Dr. Thomson has confounded yaws with sibbens, or sivvens, a totally different disease, the latter being a form of secondary syphilis, and attacking the throat, bones of the nose, &c.

I may first notice the points on which *frambæsia* and button scurvy differ from one another. The skin is described, by Bateman, on the authority of Dr. Winterbottom, as presenting the appearance of being dusted over with flour previously to the breaking out of the eruption. I have never seen this precursory state of the skin in button scurvy. Biett states that around the fungoid growth of yaws, the skin and subterraneous tissue grow callous; there is no hardening of the surrounding tissue in button scurvy; but on

this point of dissimilarity little stress can be laid, as Biett acknowledges that he saw but one case of the disease; and this callosity is not noticed by any other writer. In the history of the progress of the disease, all writers state, that there appears, after the ordinary eruption of yaws has been out for some time, a tumour, larger than the others, to which the name of mother pain, or mother yaw, has been given; and the existence of this larger tumour—if the account given of it be correct—constitutes the most marked difference between the button scurvy of Ireland, the yaws of Africa, and the Indies. The description of the mother yaw, or mama pain is, however, unsatisfactory; and it seems, from the description given of it, to be nothing more than a spot of *ecthyma cachecticum*, shewing itself in a broken down constitution. It is described as an unhealthy depressed ulcer, corroding the parts around, and requiring the same mode of treatment as *ecthyma cachecticum*. It wants elevation; and wants, therefore, the most striking character of yaws.

I have fairly put the points of dissimilarity between the two diseases; I shall now mention the points of resemblance which exist between yaws and our button scurvy, and they are very marked.

Yaws is described as "increasing gradually from specks to the size of a raspberry;" and this, as you may remember from my description, and observe from the casts before us, and from the case, is the progress of button scurvy. There are no constitutional symptoms, of any consequence, precursory to the eruption in either disease. When the fungoid excrescences of yaws have shot up above the skin, they are described as "not possessed of much sensibility," and as "bleeding on the slightest touch." These are remarkable features in the fungous growths of the button scurvy; both diseases are communicated by contagion—and both diseases may exist for an indefinite time. And lastly, though not least in importance, in my opinion, is the singular resemblance to the fruit of the mulberry presented in both diseases, the fungus and the fruit similarly constituted of distinct granules—an appearance observed in no diseases of the skin, except these two. Finally, the description of yaws, as given by Biett, would answer so accurately for a description of button scurvy, that I cannot forbear reading it for you to complete the picture of resemblance. "Yaws shows itself by small spots of a dark red, similar to flea-bites, usually in groups. Each of these spots become the seat of a small elevation, at first resembling a papule; the epidermis then peels off in a slight exfoliation, the elevations become more prominent, and there is then a surface of varying extent, bristled with vegetations, united at their bases, the points distinct, of a pale red, and not painful. They resemble strawberries or mulberries. The

disease appears to consist not of new growths, but of the true skin itself hypertrophied and divided into a multitude of vegetations."

I am far from presuming, however, to say that the two diseases are the same: my knowledge of either is not sufficient to support me in such an assertion, but the resemblance between them is very strong; while there is no other skin disease to which either bears the slightest similitude.

Mr. Wallace has published an account of two or three cases of this disease in the Medico-Chirurgical Transactions. He has given the name of morulus to it, from the resemblance of the fungus to a mulberry. His description of the disease is exceedingly accurate; but the plate of the disease, which accompanies the description, is execrable.

—o—

DR. GÖLIS ON THE TREATMENT OF THE DISEASES OF CHILDREN.

Dropsies—Chronic Hydrocephalus.—It is sufficient to have seen one hydrocephalic child, to have a just notion of their physiognomy. These patients are generally known at first by a heavy and awkward manner of walking; they are apt to trip and fall, and often cross their feet. They like to have something continually in their mouth and fingers; they also put their fingers into their nose and ears; and their eyes are convulsed; this is a never-failing symptom.

If a cough accidentally occurs in the course of chronic hydrocephalus, it easily changes into fits of periodic suffocation, which has been treated of above. If the disease passes into an acute form the children soon die.

In the treatment, calomel is the chief remedy. Children under a year old take first of all an eighth of a grain, and afterwards a quarter of a grain, twice a day. At the same time their head is rubbed with equal parts of mercurial and juniper ointment, taking care to keep it warmly covered.

As far as the treatment is concerned, the most essential point in the diagnosis of chronic hydrocephalus, is to ascertain whether or not the disease is complicated with cachexy. When there is cachexy there is generally also some organic disease, as of the spleen for example, or some engorgement; and it is in such a case that calomel is the sovereign remedy, particularly if the bowels are confined. Besides the use of calomel, the hypogastric and splenic regions are rubbed with the ointment mentioned above. But we must never omit to treat the cachexy at the same time. Dr. Gölis combats it with bark. One or two drachms of cinchona are to be boiled for a quarter of an hour, and eight grains of salop then added. The boiling is then to be continued for another quarter of an hour, so that the decoction when strained may amount to four ounces, and half an ounce of syrup of

poppies is then to be added; the dose is a teaspoonful every hour.

In a case of semi-paralysis, the consequence of chronic hydrocephalus, Dr. Gölis prescribed arnica in the following form: *Rx.* Inf. glycyrr. et decoct. emoll. \mathfrak{z} ij; Extr. arnicæ gr. iv; Oxym. scillæ, \mathfrak{z} ij.

Partial External Hydrocephalus.—This disease, which is also called œdema of the scalp, is cured to a certainty by the occasional application of a caustic to one of the œdematous points; the best is lunar caustic. The absorbing power of the lymphatics is excited by this kind of irritation. Dr. Gölis generally moistens the swelling, and then touches it in several places with the nitrate of silver; and if the result is not satisfactory at the end of a few days, he has recourse to caustic potash, of which he takes a few frustula, and applies them to various points by means of adhesive plasters. Lastly, it is right to keep up a uniform temperature by means of bags filled with aromatics.

If the œdema is confined to a small spot, it may be opened; but this would be dangerous if the case were complicated with internal hydrocephalus.

In a case where œdema of the scalp had followed the suppression of a porrigo, we saw Dr. Gölis administer calomel, perhaps with the intention of preventing a dropsy of the ventricles of the brain.

Hydrorachis.—This disease is characterized by a peculiarity in the walk of children affected by it: they totter as they go; at each step they turn their feet inwards, and always put the heel to the ground first. These peculiarities increase from day to day, and the little patients end by being unable to walk alone, and their gait always retains the characteristics which we have pointed out. Hydrorachis is most usually the result of myelitis, (inflammation of the spinal marrow). Calomel is the principal remedy, to which are added blisters to the loins.

Ascites.—In this species of dropsy Dr. Gölis gives three doses of cream of tartar a day, together with the following potion: *Rx.* Inf. Glycyrr.; Aq. fœnic. aa \mathfrak{z} ij; Extr. amari gr. xij; Sp. Æther. nitr. gtt. xv; Oxym. simpl. \mathfrak{z} ss. At the same time he orders the abdomen to be rubbed with a mixture of mercurial and juniper ointment.

He also prescribes the following potion: *Rx.* Inf. glycyrr.; Aq. fœnic. aa \mathfrak{z} ij; Potassæ subcarb. gr. iss; Aceti scillæ, \mathfrak{z} iss; Laud. sydenh. gtt. ij. When worms are present at the same time he prescribes: *Rx.* Aq. fœniculi, \mathfrak{z} iv; Extr. scillæ, gr. j; Camph. gr. iss; Syr. fœnic. \mathfrak{z} iv. And when the dropsy is complicated with scrofula, *Rx.* Inf. glycyrr.; Decoct. emoll. aa \mathfrak{z} ij; Extr. conii, gr. viij; Potass. acet. liquidæ, \mathfrak{z} iss; Oxym. scillæ, \mathfrak{z} ij. The dose to be a teaspoonful every hour.

Scrofulous Diseases.—Whether the scrofulous disease be in its commencement, or al-

ready established, Dr. Gölis always gives the following powder, after having first alleviated the most urgent accessory symptoms: *Rx.* Test. præp. $\frac{3}{4}$ ss; Guaiaci resinæ; Limaturæ ferri, aa $\frac{3}{4}$ ss; Sacchari albi, $\frac{3}{4}$ iij. The dose of this powder is a pinch (greater or smaller, according to the age of the child), taken twice a day.

Such is the powder which Dr. Gölis prescribes at the hospital. In private practice he substitutes his anti-hectic scrofulous powder, which is made of equal parts of laurel berries, nutmeg, and hartshorn shavings. But the berries must first be deprived of their acrimony, which is done by baking them in bread. The antihectic scrofulous powder is then administered, with equal parts of liquorice powder, in the dose of a large pinch three times a day, or in the following form: *Rx.* Pulv. antihect. scrof. Gölis, ij (vel plus); Guaiaci resinæ; Limaturæ ferri, aa $\frac{3}{4}$ ss; Sacchari albi, $\frac{3}{4}$ ij. All these powders may be continued for a length of time; but whenever any inflammatory disposition exists, the resin of guaiac is omitted. In addition, the children are to have a bran bath three times a week. The diet consists of broth and milk.

Scrofulous Exanthema.—In this case Dr. Gölis gives his ordinary powder, taking care, however, to substitute a scruple of antimonial æthiops (sulphuret of mercury and antimony) for the iron filings; and giving, at the same time, wild pansy tea for drink. If there is a syphilitic taint, instead of the iron filings he gives the black sulphuret of mercury.

Scrofulous Eruptions of the Head.—(Achores Scrofulosi). No particular remedy is employed against eruptions of this kind; on the contrary, it is well that they appear, for the scrofulous disease is terminated the sooner. If an eruption on the scalp dries up quickly, the neighbouring glands are apt to swell and ultimately suppurate. There is a close connexion between the abdominal glands and the head; an eruption on the latter often disperses the engorgement and induration of the abdominal glands; and these glandular affections may sometimes be cured by producing an artificial eruption on the head, by means either of powdered cantharides, or by the greyish dust which is obtained by currying horses.

Bony Tumours of a Scrofulous Nature.—Tumours of this kind are principally observed on the fingers and toes, and sometimes on the feet and arms. The tumour grows larger, becomes round and red, and ultimately opens. It is then seen that the bone is carious. Sequestra comes away by degrees, and whole phalanges may be destroyed. Nevertheless, the disease gets well, but slowly, in eighteen months or two years. The limbs, though shortened, can again be employed. We must carefully abstain from stimulating treatment when we have to do with ulcers arising from scrofulous caries; local stimulants would merely aggravate the disease. The best re-

medies are emollient fomentations, cataplasms, and bran baths; and the medicines recommended against scrofula are to be employed internally, and also coltsfoot tea. This method often succeeds extremely well.

When it is a simple scrofulous ulcer, Dr. Gölis generally orders it to be sprinkled with equal parts of powdered rhubarb and powdered charcoal, and sometimes with the latter alone; and for the lotions he uses an infusion of scordium (Teucrium Scordium).

If scrofulous tumours appear behind the ear, they must be opened as soon as possible, as they quickly cause caries of the mastoid process.

Otorrhœa.—This flux almost always depends on a scrofulous taint, and must be treated accordingly. Externally nothing is to be used but a weak decoction of bran as a lotion; if caries exists, an infusion of mallow and scordium is to be employed as an injection. Styptic remedies, used with the intention of stopping the discharge, might easily produce hydrocephalus.

Subcutaneous Lymphatic Tumours.—Tumours of this kind soon yield to the employment of the nitrate of silver, with which they are touched in the manner mentioned, when treating of partial external hydrocephalus. Besides this, caustic emollient fomentations are used. If cachexia or slow fever exists, these affections are separately treated. (See *Slow Fever* afterwards). When the tumours are opened, if they look ill they are sprinkled with a mixture of fine-powdered rhubarb and charcoal, as in the case of scrofulous ulcers.

Sanguineous Tumours of the Head.—Dr. Gölis recommends us not to open these tumours when met with in new-born children, and asserts that children often die in consequence of such an operation. He touches them with lunar caustic, like lymphatic tumours and œdema of the scalp; and asserts that they easily yield to this remedy. He also employs the same method in cases of nævi materni, and removes them by thus exciting suppuration.

Rickets.—This disease is sometimes ushered in by a state of weakness before there is any visible deformity of the osseous system. The children neither can nor will go upon their feet; and they cry and groan when lifted; this is the first stage of the disease. At a later period the patients begin to breathe with difficulty; and they are often seized with fits of periodic suffocation. They perspire abundantly, especially about the head: the state of rickets has now begun.

Rickety children have a peculiar manner of holding up their legs when they are lying at ease upon their back. They keep them crossed and draw them up, so as to enclose the abdomen between the thighs. Their urine has a specific odour—that of mice; their weeping and cries have something characteristic, when the disease is fairly established; and an experienced ear may always

guess the disease by this sign alone. They are seldom thirsty, even when suffering from an inflammatory fever, with or without local affection. Their head is frequently very large, besides the deformity which often occurs in this part, and they have generally more capacity than other children. It is very seldom indeed, that they are affected with hydrocephalus.

Some rickety children, in spite of their disease, present the aspect of health; this is *rachitis florida*. Such children are usually of a scrofulous habit, and in them the malady probably originates from a real want of osseous matter. The treatment is the same in this case; but the prognosis is more favourable and the little patients are sometimes quickly cured in spring or summer. Before beginning the treatment, all the accessory symptoms, such as cough, diarrhoea, &c. must of course be removed; and Dr. Gölis then generally prescribes the following powder with the best results. \mathcal{R} . Testarum præpar. \mathfrak{z} ss; Ferri limaturæ, \mathfrak{z} ss; Sacchari albi, \mathfrak{z} ij.

The dose is a pinch morning and evening. A bath of hay flowers is to be taken at the same time, three times a week. The diet consists of acorn coffee, with milk, once or twice a day, broth, and meat; farinaceous food is forbidden. He does not allow them to sit, or to be much carried in arms; the horizontal position is the best, but they must not lie on feather-beds.

It is an error, according to Dr. Gölis, to suppose that the oxides of iron are borne more easily than the filings. He has never succeeded with madder in the cure of rickets, even when he has used it with great perseverance. The most troublesome complication of this disease is whooping-cough.

Chronic Tension of the Skin (*Cutis tensa chronica*).—This disease, though not very rare, is not at all known; it is characterized by a peculiar tension, of a shining red, of the skin of the face, particularly around the mouth; or of the hollow of the hands, the soles of the feet, and the upper and interior part of the thighs. By degrees the stretched parts become harder and wrinkled; the lips become covered with crusts, which sometimes extend to the cheeks, and under these crusts there is an acrid humour, which corrodes the flesh in patches. Ulcerations also form on the thighs, around the genitals, on the soles of the feet, and on the hands.

This disease usually depends on a syphilitic taint, and the treatment is perfectly in accordance with this theory; calomel is the only remedy, the specific. Dr. Gölis prescribes it in the dose of a quarter or a third of a grain, according to the child's age, three times a day. He gives a decoction of wild tansy in milk for drink, and orders a bran bath occasionally. The disease, however, is rarely, if ever, cured without leaving traces behind, especially about the mouth. Caries,

or some other disease of the osseous system, is a frequent consequence. In less serious cases the disease degenerates into a crusta lactea.

Blue Fever (*Febris cærulea*).—The disease, which Dr. Gölis designates by this name, is an affection *sui generis*, that has not yet been described, and must not be confounded with the *morbis cæculus*, which is caused by a disease of the heart. It occurs only in children between four and twelve months old, and usually among those of the poor, who are fed on coarse farinaceous food, and live in damp unwholesome dwellings. The disease occurs in paroxysms only; the children turn blue suddenly, their breathing is painful, their pulse, small, hard, and spasmodic. The paroxysm lasts for some time, disappears, and returns again; but the intervals are shorter from day to day, and at last the paroxysms become continuous. The skin is often covered with clammy perspiration, and death takes place suddenly. On inspection, the vessels are found gorged with blood. With the exception of the fever, which accompanies the paroxysms, the disease has all the characters of a neurosis, and the medicines from which Dr. Gölis has derived most advantage, are the succinate of ammonia and other antispasmodics, combined with mucilaginous remedies. Here is his formula: \mathcal{R} . Aq. anthemidis, \mathfrak{z} ij; Ammon. succin. liquid. gtt. vj; Laud. sydenhami, gtt. j; Tr. castorei gtt. vj; Mucil. acaciæ; Syrupi papav. aa \mathfrak{z} ss. The dose is a teaspoonful every hour. In addition to the internal remedies, he orders tepid alkaline baths, half a gallon of ley being added to a bath.

When the spasm is relieved, it is proper to give calomel as a purgative, or a mixture of rhubarb and magnesia.

Children, moreover, are subject to a particular chronic sweating, which is not the disease called by the French *la sueur*, because it is unaccompanied by fever. Here the skin becomes blueish, and, as it were, transparent. This may be combated, according to Dr. Gölis, by the administration of a light infusion of bark and milk, and frictions, with almond oil, repeated several times a day.

Slow Fever.—Slow or hectic fever is, as every one knows, the result of very different diseases; emaciation of the neck is one of the first symptoms. Dr. Gölis here gives acorn coffee, or a decoction made by boiling one or two drachms of cinchona for a few minutes, and then adding eight grains of salop. This is again boiled for a few minutes, so that the strained liquor may amount to four ounces, and then half an ounce of syrup of poppies is added. The dose is a teaspoonful every hour. According to circumstances he orders the following ointment: \mathcal{R} . Ung. althææ, \mathfrak{z} ss; Ung. Hydr. \mathfrak{z} ij; M.

A piece, the size of a haricot bean, is to be rubbed upon the abdomen morning and even-

ing. In the morning, the children have acorn coffee; at noon and in the evening, a panada, with the yoke of an egg or ground rice. When the hectic fever is in an advanced stage, and is accompanied by diarrhoea, Dr. Gölis prescribes as follows: *Rx.* Decoct. althææ rad; Inf. Glycyrr. aa \mathfrak{z} ij; Laud. sydenhami gtt. ij; Ammon. succin. liquid. gtt. xv. Sometimes, also, an equal quantity of rue water is substituted for the decoction of mallow.

On the following formula is prescribed: *Rx.* Aq. tilis flor. \mathfrak{z} ij; Mucil. acaciæ, \mathfrak{z} ij; Ammon. succin. liquid. gtt. xv; Syr. papav. \mathfrak{z} ss; M. The dose to be a teaspoonful every hour.

When scrofulous children are attacked by hectic fever, the disease terminates in hydrocephalus six times out of seven.

Intermittent Fever.—Dr. Gölis often treats this disease with perfect success, by giving fifteen grains of powdered oyster shells alone, three times a day. He also prescribes: *Rx.* Inf. glycyrr; Decoct. althææ, aa \mathfrak{z} j; ad \mathfrak{z} ij; Ammon. muriatis, \mathfrak{D} ss; Extr. taraxaci, \mathfrak{z} j; M. Sum. coch. j max. 2 horâ.

If the case is complicated with visceral engorgemens, he uses frictions with equal parts of ung. nervinum, and mercurial ointment.

NEUROSES.—*Convulsions of new-born Children.*—These convulsions are usually caused by cerebral irritation; and Dr. Gölis always opposes the use of stimulating antispasmodics, which, he says, only aggravate the disease. Antiphlogistics alone are suitable, namely, calomel in small doses, baths, and emollient clysters.

Catalepsy.—The author of this article saw but one case of catalepsy while attending Dr. Gölis's practice, and this case was complicated with worms. After a mild aperient, calomel was administered in combination with valerian.

Epilepsy.—In a case of epilepsy, Dr. Gölis prescribed as follows: *Rx.* Test. præp. pulv. \mathfrak{z} ss; Valer. rad. pulv.; Ferri limaturæ, aa \mathfrak{z} ss; Sacchari albi, \mathfrak{z} iij. The dose to be two or three pinches a day.

Trismus.—Dr. Gölis has never been able to save a new-born infant attacked with this disease.

DISEASES OF THE SKIN.—*Scarlatina.*—Dr. Gölis's treatment changes according to the character of the fever. When the eruption comes out but imperfectly, the body is ordered to be washed with tepid water. Dr. Gölis extols this proceeding extremely, and never substitutes diaphoretics for it in the beginning, as they might prove injurious.

Measles.—When scrofulous children are attacked with this disease, it is apt to give rise to hectic fever. Measles, like scarlatina, must be treated according to the character of the fever and other circumstances, sometimes by antiphlogistics, and sometimes diaphoretics. The following is Dr. Gölis's diapho-

retic prescription in this case: *Rx.* Aq. tilis flor. \mathfrak{z} iij; Liq. ammon. acet. \mathfrak{z} j; Syr althææ, \mathfrak{z} ss.

Tinea Capitis (Porrigo).—Tinea, like the crusta lactea and herpes, is frequently of a scrofulous origin; for as the scrofulous virus produces the crusta lactea on the face, so it causes tinea on the head, and herpes on the body. It is worthy of remark, that if a well-dried porriginous crust is powdered, and another person is rubbed with this powder on any part of his body, the spot thus rubbed becomes covered with an eruption.

The internal treatment of porrigo is that which is suited to the scrofulous affection. A decoction of wild tansy in milk is given for drink, and an ointment is rubbed on the dry crusts, consisting of fifteen grains of red precipitate to half an ounce of fresh butter. Emollient fomentations are used to soften the crusts, and make them fall off.

In a case of affection of the chest, arising from a suppressed porrigo, Dr. Gölis prescribed as follows: *Rx.* Test. præp. \mathfrak{z} ss; Gaiiaci resin. \mathfrak{z} ss.; Hydr. and antim. sulphureti, \mathfrak{D} j; Sacchari albi, \mathfrak{z} iij. A pinch to be taken morning and evening.

Crusta Lactea (Porrigo larvata).—In this eruption, Dr. Gölis always employs an anti-scrofulous treatment. In this, as in all other eruptions of a scrofulous nature, coltsfoot is to be preferred to the wild tansy. The crusta lactea sometimes changes to a serpiginous crust; but in such cases a syphilitic taint is always to be suspected.

Chronic Pemphigus.—An anti-scrofulous treatment is proper in this disease likewise.

Itch.—There is a species of itch, or rather of psoric disease, which is not contagious; it is often observed after vaccination. Scrofulous itch too is not infectious.

The antipsoric treatment of Dr. Gölis is as follows: internally he prescribes—*Rx.* Magnes. muriatis; Sacchari albi, aa \mathfrak{z} ij; Sulph. sublim. \mathfrak{z} j. Half a teaspoonful, or more, to be taken three times a day.

Coltsfoot tea is to be given as drink, and a mixture of sulphur ointment and soap is to be rubbed on externally. These frictions are to be performed twice a day, on the parts where there are no psoric pustules.

Intertrigo (Chafing).—The following is Dr. Gölis's method of treating this erythema, which occurs in children between the thighs and around the genitals. He foment the affected parts with the following mixture: *Rx.* Aq. calcis, lbss; Plumbi acet. gr. xv. At the same time, he endeavours to excite an eruption on the head by means of Garot's ointment. Internally, he administers calomel in the dose of a quarter or half of a grain, and gives wild tansy tea.

If the intertrigo is of a syphilitic nature, the fomentations are made with the yellow wash, consisting of a grain of corrosive sublimate to four ounces of lime water.

Aphthæ.—In this disease he prescribes

R. Mellis rosæ, ʒj; Boracis, gr. xv. M. This is to be applied to the affected parts four times a day.

The following formula is also used: **R.** Mellis rosæ, ʒj; Syr. mori, ʒss; Boracis, ʒss. When there is much inflammation of the mouth the borax is too irritating, and the honey alone should be used. We must never lose sight of the fever by which aphthæ may be accompanied. The salivation induced by the disease often causes dyspepsia, which is remedied by extract of dandelion dissolved in an aromatic water.

—o—

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

Epidermis.—The epidermis has a marked tendency to decomposition. At an early period it becomes thinner and softer, and adheres to the winding sheet, or to the earth, if the body has been interred naked. On the parts where it has not peeled off it is in folds, and is easily detached in thin translucent layers of a greyish white colour, even on the abdomen, where the cutis is of a green tinge; on the palms of the hands and soles of the feet it is drier, denser, white slightly tinged with yellow, rugose, much folded, and presents an appearance similar to that produced by the long application of an emollient poultice to the same part; occasionally its internal surface acquires a partial tinge of red or green, from the presence of a serous fluid, which may be removed by washing with water, and the white colour of the texture restored. There seems to be no regular succession in which the different parts of the body become denuded of their cuticle.

At a stage somewhat more advanced, the portions of epidermis not yet separated begin to undergo a remarkable alteration; they frequently become greasy, and still more adherent to the linen or the earth which covers them; they then form layers of a reddish yellow or brown colour, composed of numerous small lenticular and confluent elevations; sometimes instead of these layers we find a viscid fatty mucosity, by which certain parts become agglutinated with others—as for example, the inner part of the superior extremities with the thorax. Instead of this gluey cement, a dry substance, like the rind of stale cheese occasionally presents itself. These substances are sometimes covered with a white flocculent mould, in some instances resembling hoar frost. At last the cuticle altogether disappears; if, however, it has been elevated during life by serum effused beneath it, it may resist putrefaction and present its natural characters at the end of many months.

The Nails.—The nails are softened, lose their elasticity, and acquire a greyish hue; they become less and less translucent, and they may be easily plucked out even when the body has been buried only twenty or thirty days. At this period the cutis beneath them is smooth, humid, and of a vivid red; finally the nails dry up and fall off.

The Hair.—This strongly resists putrefaction; we have always found that it preserved its natural appearance, even several years after inhumation.

The Cutis.—After having separately noticed the epidermis, we proceed to examine the changes produced in the true skin, which we will suppose not to have been as yet deprived of its cuticle. At an early period it is of a yellowish colour, with a tinge of rose, presenting here and there tints of green, red, and violet; it is little softened, not at all corroded, and altogether nearly in its natural state. It is always moister at the posterior part of the trunk than anywhere else. Later than this, it is sometimes covered in certain portions of its surface with small sandy granulations, consisting of phosphate of lime. By the effect of putrefaction it is nearly detached at the back, where it forms a sort of pouch, as the skin of the toad does round the body of the animal; its thickness is not yet sensibly diminished, except in the eyelids, where it is easily torn; its structure is still perfectly recognised, and no part of it is transformed into fat. Later still, it begins to dry up, becomes thinner, and assumes a colour varying from a pale yellow to an orange, and sometimes a deep brown; it is covered with the cement we have already described when speaking of the epidermis, and at certain points with mould; the latter is scarcely to be found in the more humid parts, as the back, but is abundant in those which are dryer. Desiccation now makes daily progress; the integuments appear as if they were tanned, and when any part of the body is struck with the handle of a scalpel, it sounds like a band-box. When cut into, the skin resembles that of a piece of bacon, and an evident tendency to saponification is observed, especially where the subcutaneous cellular tissue is charged with fat; in parts where this is the case, the skin is generally best preserved, except around the anus, where it is easily accessible to worms. The adhesion of the skin to the subjacent parts varies; when it lies close to bones, the cellular membrane is dry and easily torn, but when it covers parts furnished with a fatty cellular tissue, or is attached to muscles, it adheres very firmly. In a still more advanced stage, the desiccation and attenuation of the skin increase in those parts where it has not been saponified, and, as formerly, the anterior parts are dryest; sometimes, indeed, the skin over these is very much dried, while on the posterior aspect of the body it is very moist, much attenuated, and partly destroyed by

worms. It assumes more and more of a brown colour, but generally preserves a moderately firm consistence, though corroded and destroyed at many points. The tissue becomes thinner and thinner, and at last gradually disappears. It is unnecessary to add, that its destruction is much more rapid in those parts which have neither been dried up nor converted into fat. It will doubtless be remarked that we have not included *cadaveric lividities*, *vergetures*, or *ecchymoses*, among the changes which the skin undergoes after inhumation. The cadaveric lividities generally appear when the body begins to grow cold, consequently long prior to inhumation; they have moreover been very fully described in our *Leçons de Médecine Légale*. Again, the *vergetures* are nothing but cadaveric lividities of the skin, traversed by lines, wrinkles, or white patches, evidently resulting from the pressure of the clothes, bandages, &c., on the livid parts; we have, therefore, not commented upon them; we have made no mention of *subcutaneous ecchymoses*, because we have never observed them in the bodies we have subjected to putrefaction; we do not, however, doubt their occasional occurrence in dead bodies after interment; on the contrary, every thing would lead us to expect their appearance in young persons who are fat, and abounding in moisture, who have died of an acute disease, and have been buried during the summer. These *ecchymoses* are most frequently seen in the most dependent parts, as the occiput and loins, or in the eye-lids and scrotum, where the subcutaneous tissue is lax and easily distended; they never present the different shades of yellow, reddish brown, and black, which are often observed in *ecchymoses* during life; their colour is generally uniform.

Subcutaneous Cellular Tissue.—This texture is little changed at an early period; nevertheless, a difference is soon observable between that on the anterior, and that on the posterior part of the body, and according to the thickness of the muscular layers with which it is connected. Thus, on the fore part of the trunk, and especially where the muscles are thin, as on the abdomen and middle of the thorax, it is not infiltrated, but dry, and of firm consistence, while on the back part it is infiltrated, soft, and easily lacerable: this infiltration may be simply sanguineous, or sanguineous and oily; in the latter case, little yellowish fatty drops are mixed with a red fluid. At the posterior part of the head and neck, and over the whole extent of the back and loins, the infiltration is more or less of a violet colour, and has a gelatinous appearance, resembling that of the epicranial cellular membrane in some new born children; the tissue is here tumid and easily torn. In the nates and back part of the limbs, the fluid is scarcely gelatinous, but flows much more readily from the cellular tissue; in the la-

teral regions of the thorax and abdomen, the infiltration is of a character intermediate between that on the anterior and posterior part of the trunk. On the fore part and sides of the thighs and arms, where the muscles are thick, the cellular membrane is moist, though not infiltrated, and easily torn, owing to the progress of putrefaction, which is more rapid here than in parts where the muscles are thinner.

Of course the infiltration will be greatest in the bodies of those affected with anasarca. In a more advanced stage, especially in fat subjects, the adipose membrane has a tendency to be transformed into a soap; it acquires a whitish or yellowish grey colour, is of the consistence of suet, and unctuous to the touch: wherever it is abundant, it presents, on being cut into, a porous and puffy appearance, occasioned by a number of small, empty pouches, the result of desiccation, or the disengagement of gas. Still later we have observed it dry, dense, white, or greyish, filamentous, and easily lacerable in parts where it contains little fat; but yellowish, offering little resistance, moist, and resembling lard that has been boiled and suffered to cool, in parts where it contains more fat: lastly, in the fattest parts it was of an orange colour, of a globular texture, and evidently saponified. The conversion of the adipose membrane into soap is by no means a constant phenomenon; we have found this tissue in its natural state in a thin person who had been buried six months, while in a fat woman who had been buried nearly the same time, and in the same soil, it was saponified in several parts. At a more advanced period, the cellular tissue which has not been saponified, assumes a brown hue, dries up, and disappears.

Muscular Tissue.—The changes in the muscles commence with softening; in general their red colour becomes paler where they are not much infiltrated, some, however, are of a violet hue, and those of the abdomen are often green: for some time their texture is easily to be recognized; they are not transformed into fat, unless it be in the orbits, where saponification appears to take place more readily than in other parts. Their colour is then green, or that of wine-lees; the first of these colours is much commoner than the second, which seldom exists, except when there is a sanguineous infiltration. The muscular tissue is throughout humid, except in the orbits, and in many parts it is infiltrated with a sero-sanguineous fluid, similar in colour to that found in the cellular membrane, and which is so abundant in certain regions, particularly in the back, that a large quantity escapes on pressure, and even on simple incision. Some of the muscles resemble a jelly, in the midst of which fleshy fibres appear, still so united as to preserve the form of the part; notwithstanding this infiltration, the muscles are diminished in vo-

lume, and their fibres dissolved as it were, in the liquid. At the anterior part of the limbs, the muscular substance forms a very thin layer on the bone which it covers; its consistence is generally considerably diminished, and it is lacerable in proportion to the degree of infiltration; as this is greatest at the posterior part of the trunk, and where the muscular layers are thickest, it is in these parts that the fibres are most easily torn. The muscular tissue, having been softened, and undergone the changes of colour above mentioned, is either saponified or destroyed. Saponification takes place especially in fat persons; the fibres become more and more blanched, and some are converted into a whitish soap, while the rest retain their rosy colour. We have never seen a muscle entirely transformed into fat; the other kind of alteration which leads to the destruction of the muscle is much more common: it happens in the following manner. After being softened, the muscular tissue gradually dries and diminishes in volume, till the masses it forms become flat; as the desiccation proceeds, the colour deepens, till it becomes quite brown; but notwithstanding these changes, the tendons and the aponeurosis, with their fibrous structure, may still be recognised. Desiccation, however, does not always attend the destruction of the muscles, and those which remain moist are always of a deep colour—green, or that of wine-lees. The dried muscular fibres are ultimately destroyed, and nothing remains in their place but membranous layers of a gray or brownish yellow colour, in which no fibres can be detected; sometimes these layers are moist and brown, and resemble tobacco leaves which have been soaked after having been dried: in some parts of the body we only find, in place of the muscles, areolar masses, brown, and even black, bearing a resemblance to some of the polypiferous animals. At the posterior part of the limbs, the desiccation of which we speak is never so complete, nor does it take place in the back and loins, where the muscles are constantly immersed in liquids; in these parts the muscles are destroyed by a kind of maceration.

Aponeurotic and Tendinous Tissue.—The aponeuroses enveloping the muscles retain for a long time their shining appearance and their consistence, but they have generally a bluish colour where they are thin: the tendons are whiter and more shining, owing to their greater thickness; where, however, they assume an aponeurotic form, they have the same colour as the aponeuroses.

At an advanced period the aponeuroses and tendons become opaline and yellowish, then of a clear and deep brown; they dry more or less completely, and lose their natural pearly aspect, which, however, they recover if they be moistened for some time

with water. The tendons and aponeuroses, with the cellular tissue, constitute nearly the whole of those foliated masses which are the sole residue of the soft textures in these parts of the body, and they finally perish, leaving nothing but the skeleton.

The tendinous tissue is one of those which most strongly resists putrefaction.

Ligamentous Tissue.—For some months the parts forming the joints preserve their relative position, and their ligaments undergo little change in their appearance or consistence. At a later period the ligamentous texture softens and turns yellow, and after a considerable time is entirely destroyed; it resists decomposition much less powerfully than the tendons. The crucial ligaments retain their form longest, the rest are in a few months so blended with the soft parts surrounding the joints, that it is impossible to distinguish them.

Cartilaginous Tissue.—The articular cartilages preserve for a long time their natural appearance and texture, except that they become slightly tinged with a rose colour. At a later period they grow yellow and begin to shrivel; their consistence becomes less and less, they are finally destroyed, and nothing remains in their place on the articular surfaces but a very thin and moist covering, slightly fatty, and of a bistre colour. The cartilages of the ribs also become brown and lose their elasticity; but before their disappearance they become quite black, brittle, and appear as if worm-eaten.

Osseous Tissue.—The bones undergo scarcely any alteration, even after the lapse of several hundred years. Those of King Dagobert, who died nearly twelve hundred years ago, have been discovered at St. Denis; they were in a wooden chest, contained within a tomb of stone. Haller observes, at the commencement of his *Elements of Physiology*, that the gelatine of the bones has been preserved for two thousand years in mummies, while by exposure to the air or a humid soil it is destroyed in a few centuries; the bones then crumble into dust and disappear. The teeth long resist decomposition, and the enamel is nearly indestructible.

Serous Tissue.—The pleuræ, peritoneum, &c., at first become gray and soft, they then become thinner, are disposed to dry, and are easily torn; still later, their colour deepens and turns blueish, olive brown, or blueish black; occasionally also their surface is covered with a layer of black fatty matter; finally they disappear. We were able to recognise the pleura in a subject buried in a thick coffin, and opened fourteen months after death.

Encephalon.—The brain, which putrefies so readily when removed from the cranium, offers greater resistance to this process when shut up within its bony case. Before inhumation it is sometimes gorged

with blood, as the effect of death, the stomach being distended with gas, the diaphragm drawn up, and the blood in the right side of the heart flowing towards the head. For several weeks, if the temperature be not very high, the brain retains its natural appearance sufficiently to enable us to recognise its different parts, and to detect morbid effusions and softenings; it soon, however, acquires a clear olive gray colour. In a short time after, it softens, this process commencing in the gray substance; it diminishes in volume, and no longer exactly fills the cavity of the cranium: at this period a great part, if not the whole, of the convolutions may be distinguished, as well as the two substances, of which the white has become gray, and the other of an olive green. In a case of death from severe apoplexy, the brain was found in a short time to have been reduced to a very soft pulp of the colour of wine-lees. At a later period it becomes softened to a pulp, and emits an exceedingly fetid odour; the two substances are no longer distinguishable, but are both greenish or the colour of wine-lees, and the form of the parts in the different ventricles is lost: here and there, throughout the mass, filaments are observed surrounded by fatty granulations; these appear to be the remains of vessels. At a still more advanced stage of decay the brain becomes less fetid, and its consistence is firmer; it then forms a mass of a greenish gray colour, similar to that of potters' clay, distempered or azured; sometimes the surface of this mass is yellowish, at others it is pierced by worms. In all cases the brain gradually diminishes in volume, and at last only occupies a tenth or twelfth part of the cavity of the cranium; at this time it is frequently saponified. In our numerous dissections we have always found more or less of this organ remaining, when there was no vestige of any of the other viscera; in one instance only the cranium was empty, because its contents had been devoured by worms. The cerebellum and spinal marrow present the same changes of colour and consistence as the brain; they are however usually more softened.

The pia mater and arachnoid follow nearly the same course as other serous membranes. The dura mater strongly resists putrefaction, and for some time suffers hardly any change; eventually, however, it almost always becomes greenish and soft, and often splits into layers, which have a strong slaty smell*. The nerves remain

entire for some months after interment, and undergo no change except in their solidity, which is diminished, and their colour, which becomes slightly rosy.

Globe of the Eye.—A few days after inhumation the cornea has shrunk and lost its transparency, and the vitreous and aqueous humours acquire a slight bistre or a reddish colour. Some weeks after, the eyes are so much collapsed that the sockets at first sight seem empty; the opacity of the cornea, and the coloration of the humours, have increased; the humours have assumed the consistence of a thin fluid, of a bistre colour, which appears to be derived from the choroid: the crystalline lens and the membranes of the eye preserve their characters. In general we have found the eyes entire till the second month; later than this their contents are evacuated, the crystalline and the membranes alone remaining; still later, only the debris of the sclerotic is found; and, finally, the orbits contain nothing but a mass of adipocere in

animals and the dead bodies of persons who had suffered under no derangement of the nervous functions, have established—

1. That the space between the spinal cord and its dura mater is naturally filled with a colourless fluid, which exerts on the cord a certain degree of compression necessary to the exercise of its functions, while it also protects the organ from violent shocks.

2. That the escape of this fluid produces, in the living animal, severe symptoms, which soon cease on the regeneration of the fluid.

3. That a similar fluid is infiltrated in the areolæ of the pia mater, and moderately distends the ventricles of the brain.

4. That the position of this fluid is remarkable, as Cotugno formerly observed, being between the visceral fold of the arachnoid, and the viscus itself, invested with the pia mater.

5. That the cavity between the contiguous surfaces of the arachnoid is lubricated merely by a halitus, and that when any serosity is found there, it is in small quantity, and of a reddish colour, and is generally to be attributed to transudation after death—rarely to irritation of the membranes.

6. That the cerebro-spinal fluid passes easily from the spinal canal into the ventricles, and vice versa, through an aperture situated between the posterior surface of the medulla oblongata and the cerebellum (this appears, however, to be closed by a membrane in sheep). It can easily pass, also, from the spinal canal into the areolæ of the cerebral pia-mater, since it is in both under the arachnoid. These remarks render it evident that the position in which the body is placed during the examination may favour the accumulation of the fluid either in the cranium or spinal canal.

* The presence of a serous fluid in the ventricles of the brain, the spinal canal, or the areolæ of the cerebral pia mater, is not to be referred to the changes in the dead body, nor is it to be considered as a morbid appearance, except when the fluid differs much from its natural quantity or quality. The researches of M. Magendie on living

place of the eye-balls, muscles, and fat. Few organs disappear so speedily as the eyes: in the exhumations made at the Bicêtre we have never found any vestiges of them four months after death.

(To be continued).

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 691.)

It is important to state that simple gonorrhœa or urethritis may be induced by excessive sexual commerce between healthy individuals, and both may be affected, and it may also be excited during menstruation or the child-bed (lochia) discharge. It is for this reason that conjugal intercourse was interdicted by Moses, during the two last states of health. There is another cause of the disease, and that is, purulent leucorrhœa. But it is always to be recollected that urethritis or urethral discharge from the male arising from these causes, is exceedingly mild, and usually disappears without the use of medicine. The young practitioner ought, however, to be aware of these causes, lest he pronounce the disease virulent or contagious gonorrhœa, and ruin the reputation of the woman. He should also bear in mind that gout, rheumatism, diseases of the skin, and of the mucous membrane in any part, in the mouth, throat, lungs, bowels, &c. may cause urethritis, or inflammation of that portion of the membrane which lines the urethra. Various articles of diet and of medicine may produce a similar result. It is therefore obvious, from the preceding statements, that there are two forms of urethritis; one a simple inflammation of the mucous membrane; the other a specific inflammation caused by a contagion. This is the opinion of nearly all medical authorities, both national and foreign; with one or two exceptions. Thus, Mr. Travers, the eminent surgeon to St. Thomas's Hospital, maintains the opposite opinion. He holds that gonorrhœa and syphilis are the same disease; and that simple gonorrhœa caused by purulent leucorrhœa is virulent and contagious*. It is on this account that patients affected with gonorrhœa were salivated with mercury a few years since, in the Borough Hospital, which led to the public condemnation of the practice by Sir Astley Cooper, the consulting surgeon of the above-mentioned hospital. The profession in this, and every civilized country agree with Sir Astley, in denouncing this practice, on the grounds of the dissimilarity of gonorrhœa and syphilis. It is almost incredible to suppose it possible, that any scientific surgeon of modern times could entertain the opposite opinion.

* Anniversary Oration, delivered before the Hunterian Society of London, 1830.

Treatment.—It is now almost universally agreed that the antiphlogistic treatment is the most proper for urethritis. When the patient is of a full habit and in the prime of life, one or two bleedings from the arm, with leeches to the perinæum and groins will be the best remedies. It has been repeatedly observed, that leeches to the penis cause ecchymosis and inflammation, and are often succeeded by gangrene. This arises from the vascularity of the cells of the corpora cavernosa. A free use of cold water, linseed tea, or barley water, will act as a diuretic, and render the urine less irritating to the inflamed mucous membrane. Carbonate of soda in the proportion of three or four drachms to two quarts of any of these drinks properly sweetened, will decompose the urine and prevent it from causing the severe scalding or ardor urinæ. The hip-bath is a valuable adjuvant, and generally diminishes all the symptoms. Warm fomentations are also of essential service. Perfect repose and low diet are indispensable to the cure. Walking, riding, or any thing that excites the affected organs will aggravate the disease. It is for this reason that sexual intercourse ought to be avoided. When the inflammation is acute, it will be necessary to exhibit opium, camphor, and hyoscyamus, to allay urgent symptoms, as painful erections, chordee, &c.

The two last are much lauded in free doses every second or third hour. Thus, great benefit will be derived from the use of three grains of camphor and two of extract of hyoscyamus. The piper cubeba will often arrest gonorrhœa on its first appearance; but this medicine must be continued after all symptoms have apparently disappeared, for at least ten days or a fortnight. In first cases, which are in general very severe, all remedies usually fail; though the same will rapidly relieve any future attack.

It is an old and common error to allow gonorrhœa to be fully established, before any treatment is employed. It is clear, however, that as the disease is an inflammation from the commencement, it ought to be treated as such, more especially in those who are affected with it for the first time.

Some practitioners advise stimulating injections, caustic solutions, and bougies on the appearance of this disease; but these are seldom employed by scientific practitioners in this country. They are commonly used in Spain and Portugal, where science is still in its infancy.

Such I conceive to be an outline of the most rational and scientific treatment of acute urethritis, though other remedies are more generally employed; among which are cubebs, capsicum, iodine, balsam of copaiba, lytta, resins, turpentine, &c., stimulating injections, bougies, and cauterization. Most of these remedies may prove

effectual when employed previously to the development of the inflammation, or after it has been very much diminished by treatment, or continued for three or four weeks. It is well attested by surgeons of the highest authority, that a few doses of cubebs administered, on the first appearance of urethritis, will completely prevent its further development; but all the other remedies are improper until the acute symptoms have been abated. It is also on record, that an irritating, astringent, or caustic injection, or the application of cauterization to the fossa navicularis, will arrest and often remove urethritis if employed at the moment of its manifestation; but we are seldom consulted until the disease is developed; when this is the case such a practice is highly injurious, and generally lays the foundation of stricture.

After the antiphlogistic regimen has been fully employed, and the discharge continues copious, unattended with ardor urinæ or scalding, the internal medicines already mentioned may be tried with advantage. They succeed in general in diminishing and finally suppressing the discharge, and are much preferable to the application of local remedies. Some surgeons, however, have advised metallic and astringent injections, such as those of acetate of lead, sulphate of zinc, oxymuriate of mercury; but the majority of the profession are at present opposed to this practice, until the inflammation has abated for some time, and until the ardor urinæ is removed. It is now agreed on all sides, that stimulating injections in the acute state of urethritis aggravate the disease, and lay the foundation of stricture. When the discharge is chronic, the balsam of copaiba and other resins generally succeed in arresting it. Some consider their action specific, as they produce their effects without acting on the bowels or kidneys. Should copaiba act as an aperient, proper doses of opium should be added, and the medicine should not only be continued until the discharge disappears, but for some days afterwards. According to recent French writers, MM. Ribes, Delpech, and Ansiaux, the dose of copaiba may be from one to three drachms twice a day; and this medicine may be given during the acute stage of the disease. In this country the balsam is not given in first cases of urethritis, until after the acute stage has ceased, which is generally about the tenth day. When the disease has frequently occurred, Sir A. Cooper prescribes copaiba and cubebs on its appearance, and speedily suppresses it.

Another mode of treatment consists in the repeated introduction of bougies, during the chronic stage, but this plan is not generally practised by British surgeons, though it is advisable in some obstinate cases. M. Lisfranc, of Paris, has lately recommended the employment of powerful astringent injections, but these are considered objection-

able by most practitioners. Some of our countrymen have, however, long since proposed strong injections of nitrate of silver, but these have very seldom been employed. It is scarcely necessary to observe, that the old practice of purgation is entirely abandoned at present. It has, however, happened that gonorrhœa has suddenly ceased after the operation of a purgative; as it has after the copious libation of ardent liquors diluted, such as brandy, whiskey, gin, rum and water; but this would not justify the administration of either the one or the other in the treatment of acute urethritis. It is well known to every observant practitioner, that those persons who have had repeated gonorrhœa, very often cure themselves by the copious use of diluent fluids. It sometimes happens that the urethral discharge proves extremely obstinate, and defies the ordinary mode of treatment. In such cases M. Lallemand has cauterized a certain portion of the urethra with the nitrate of silver, and states that he has cured a great majority of his patients. He sometimes applied the caustic to the fossa navicularis, but sometimes he passed it along the urethra towards the neck of the bladder. It is generally known to surgeons, that the gonorrhœa usually takes this course, and that in obstinate cases, the neck of the bladder becomes diseased; in the first instance giving rise to the incipient symptoms of stricture, and causing considerable difficulty of voiding the urine. Sir A. Cooper very strongly recommends, as soon as the acute inflammation has subsided, an injection composed of liq. plumbi acetat. dilut. \mathfrak{z} iv; sulph. zinc. gr. vi; and a mixture composed of balsam copaiba, mucilage acacia ana. \mathfrak{z} i; camphor mixt. \mathfrak{z} iv a—table spoonful morning and evening. He employs this mixture and injection, ten days after the commencement of a first gonorrhœa, so soon as the inflammatory stage is over. When the patient has had the disease two or more times, the inflammation is comparatively slight, and Sir Astley administers the balsamic mixture at once. When a discharge becomes chronic, he employs bougies and an injection of the sulphate of zinc, which should be used three or four times a day. He has found a combination of balsam of copaiba with cubebs very generally successful.

I have now described the symptoms and treatment of gonorrhœa or urethritis, and shall conclude this part of my subject, by considering the sequelæ or consequences of this disease.

Swelled Testicle—Orchitis—Hernia Humoralis.—Inflammation of the testicle was at one time supposed to arise from the sudden suppression of the urethral discharge, its absorption into the system, and its ultimate deposition in the testicle; hence it was called hernia humoralis, in consequence of a belief that it arose from a fluxion of humours

to the part. According to modern pathology, it is a sympathetic affection produced by irritation in the urethra. It seldom happens when urethritis is very acute. It generally occurs in slight cases, may come on suddenly without any evident cause, and usually appears about ten days after the commencement of urethritis. It may be induced by a variety of causes, such as purgation, the use of astringent injections, the sudden application of cold to the genitals, much standing or walking, prolonged erection or venereal excesses. The first symptom of this disease is a sensation as if a drop of urine was in the perinæum, accompanied by a sense of heavy pain in the testicle, rapidly succeeded by enlargement of the organ, which, in a few hours, acquires three or four times its ordinary size. The disease extends to the spermatic cord, and this enlarges so considerably that it is sometimes found constricted and almost strangulated by the inguinal ring. The urethral discharge now diminishes, but seldom ceases entirely. This may be easily accounted for on the principle of counter-irritation. If we inquire into the history of the case minutely, we then find that before orchitis commences, the inflammation proceeds down along the urethra, affects the verumontanum, prostate gland, vasa deferentia, proceeding up the cord to the inguinal ring, then to the epididymis, and finally the cord itself. The closest sympathy exists between the urethra and the other parts of the genito-urinary apparatus. The painful erections during urethritis affect the testicles and spermatic cords, as well as the whole tract of the urethra, extend to the parts about the neck of the bladder, and sometimes to this last organ, to the ureters, and even to the kidneys. This sympathy might be proved by the fact that the irritation caused by a bougie in the urethra, will very frequently produce orchitis, and that seminal emissions considerably diminish the pains in the urethra. While the inflammation is confined to the epididymis, the pain is very slight, but becomes acute when the testicle is implicated. It has been often remarked that the right testicle is more commonly affected than the left. Orchitis usually continues for ten, twenty, or thirty days; but may be removed in a much shorter period by judicious treatment. It usually terminates by resolution, but the epididymis remains affected for weeks or months, or even during the remainder of life. In some instances the disease terminates in scirrhous or scrofulous enlargement.

There is much diversity of opinion with regard to the *treatment* of this disease. Some very strongly recommend antiphlogistic measures, others advise the use of calomel and colocynth pills, which, like many other purgatives, often induce the disease. Sir A. Cooper, however, recommends such pills, with inf. sen. and sulph. mag. He then employs an evaporating lotion composed of $\frac{3}{4}$ j sp. wine, and $\frac{3}{4}$ v of water, or one consisting of mur. ammonia water and spirit. In all cases he orders a suspensory bandage, and advises opening three or four veins on the scrotum with a lancet, in preference to leeching. He strongly recommends the compound ipecacuanha powder in irritable constitutions. He states that all the measures sometimes fail, and abscesses in the testicles form, which are to be encouraged with warm fomentations. Should these open and fistulæ form, he advises an injection composed of two grains of sulph. copper in an ounce of water. When fungi appear, he recommends them to be pared off at their roots, and the edges of the wound to be brought into contact. He observes that these fungi are seldom malignant. He finally states, that wasting or atrophy of the testicles frequently occurs in young persons about 15 or 16 years of age, who are affected with gonorrhœa, and the same thing may happen from external injuries.

A recent writer advises a different mode of treatment. Mr. Philips has found balsam of copaiba, in the dose of a drachm three times a day, combined with opium, to prevent violent purgation—the best remedy in the acute and chronic forms of this disease. The general practice, however, is to confine the patient to the horizontal posture, which will obviate the pain produced by the pendency of the testicle; to apply leeches, encourage the bleeding by warm fomentations or poultices, and then to use cold lotions freely—the affected organ being constantly supported with a suspensory bandage. This plan generally arrests acute orchitis, but when the disease becomes chronic, frictions with mercury or iodine generally succeed in removing it. The ioduret of lead and protoioduret have been lately employed with decided success in such cases. In some cases a blister will very speedily produce the same effect. In the acute form, an emetic has effected a rapid cure; and the same result is said to have followed the repeated introduction of a bougie, when the disease has arisen from the suppression of the urethral discharge.

AN HARVEIAN ORATION.

"I had a dream which was not all a dream."—BYRON.

WE did not attend the late Harveian Oration, but our imagination was so impressed by the recollection of that affecting solemnity, as witnessed by us on former occasions, that our nocturnal couch was visited by a dream, wherein we beheld the College of Physicians assembled, and heard the learned president deliver a discourse in the purest Latin, which we shall translate for the benefit of some of our readers to whom English may possibly be more familiar.

Gentlemen!

The veneration entertained by this College for the memory of Harvey, is sufficiently evinced by our zeal in promoting all those objects to which he devoted his life. Can it be wondered at that we are proud of Harvey? The illustrious discoverer of the circulation was a fellow of our own body, and in his person almost all the genius of our order was concentrated, as is evident from the fact that so few of the succeeding fellows have manifested any!

But, gentlemen, how nearly was Harvey lost to us, and his discovery to the world! Having studied four years at Cambridge, it occurred to him that the medical degree of that university, *intrinsically* valuable as we know it to be, was thought very little of among the nations of the earth; and accordingly he went to Padua, and graduated there. Any surprise that might be excited in our minds by this injudicious preference of Harvey's is at once removed by the consideration of his youth; at the time alluded to he was only nineteen years of age, and had not yet attained sufficient moral elevation to appreciate the value of a medical degree from an

university where nobody knows anything about medicine. On his return to England he providentially repeated his graduation at Cambridge; had he not done so, he never could have become a fellow of the Royal College of Physicians—need I add, that he never could have discovered the circulation of the blood?

Gentlemen, I have asserted our zeal for those studies to which Harvey devoted his life. Our addiction to anatomy and physiology is well known—to *ourselves*; the magnificent works on these subjects produced by the modern fellows of the College have, I assure you, been *privately* printed, and adorn in secret the shelves of our library: only one of our present number has so far lost sight of his professional dignity as to allow his anatomical acquirements to be at all known to the world.

Harvey, fully aware of the folly of the monkish distinction between physic and surgery, diligently cultivated both branches of the healing art: he presented to this College a curious collection of surgical instruments, and delivered lectures on surgery within its walls. Succeeding fellows have followed his example with so much ardour, that it has latterly even become necessary to put a check upon their enthusiasm, by enacting that no person possessed of a surgical diploma shall become a member of our body.

The researches of Harvey on the generation of animals we have endeavoured to follow up, to the best of our ability, by contemning and proscribing the study of obstetrics—of course including embryology.

Gentlemen! In paying a merited tribute of respect and veneration to departed worth, is it not gratifying to men of high moral feeling to find that they have thus scrupulously fulfilled what may be regarded as a sacred trust? When we look on the marble bust which the gratitude of our predecessors has erected to the greatest of the physiologists, is it not pleasing to fancy a smile

of approbation playing around its features, and encouraging us not only to pronounce annual orations in praise of Harvey, but resolutely to maintain science exactly as it stood in his days—that is, *two hundred years ago!*

You are aware, gentlemen, that the oration which I have now the honour of delivering was instituted by Harvey himself, in commemoration of the benefactors of the College; but the truth is, all the old worthies have long since been praised to satiety, and of late years the College has had no benefactors—with sorrow do I say it, gentlemen, our friends are daily falling off; we have now no legacies left us, and the College is only kept in existence by repeated and painful applications to our own breeches pockets. So deplorable, indeed, is the state of our temporalities, that if it were not for the profane jeering which wicked men would institute thereon, I would request my very esteemed friend, the Right Reverend Father in God the Lord Archbishop of Canterbury, to preach a charity sermon in aid of the funds of this institution.

But to return from this digression.—In default of benefactors, who have become exceeding scarce, it has been usual of late years to pronounce a few words of eulogy on those who have most eminently contributed to the honour and prosperity of our profession—and especially those who have been removed by death from the sphere of public utility; many reasons will at once suggest themselves to you why the *defunct* are the best subjects of laudation. (The learned president here made honourable mention of several respectable physicians lately deceased, and continued as follows). Some among you may feel surprised at my omitting the name of Hooper; but I am convinced that none who now hear me in the *moral* spirit in which all orations delivered within these walls should be heard, will misconstrue my silence: it is indeed true that Dr. Hooper did more for medical science than all his contemporaries

whom I have eulogised put together—but, gentlemen, Dr. Hooper was not a *fellow!*

Permit me, in conclusion, to impress on your minds the necessity of rigidly observing the important distinction at which I have just hinted. When I presume to call the particular attention of the *junior* fellows to this momentous subject, I must plead, as my excuse, the paternal solicitude which I feel for their welfare, and for the dignity of our august order. May no mistaken liberality induce even the most inexperienced among us to break down the barrier which separates them from the common herd of physicians; may they never descend from their proud and enviable height of professional aristocracy, to become simple members of the commonwealth of science!

—o—

PURE SURGERY—ODD SUPPOSITIONS.

IN our last number we started a question with reference to a supposed transaction at a metropolitan hospital. We did so in order to elicit information on the subject of a rumour which reached us; but being ourselves at that time ignorant of the names of the parties, we merely put the case precisely as we had it, in an hypothetical form. If all were right, no harm could arise from investigation, while if suspicions were just, the affair was deserving of exposure. We have since become fully acquainted with all the particulars, and are bound to state most explicitly that everything reflecting on the skill or conduct of the hospital surgeon is *utterly false*. The costs were *not* paid by the operator; and we have seen a letter in the hand-writing of the eminent surgeon supposed to have been referred to by the general practitioner, declaring that his examination of the case never induced him for a moment to call in question either the existence of the aneurism or the fact of the brachial artery having been secured by the hospital surgeon. There was a prosecution, and it was hushed up. That the

attorney for the prosecution was purposefully misled by the false statement of some injudicious friends of the general practitioner, as to the real facts of the case; and that some such infamous proceeding was the origin of the report, we have every reason to believe; but there can be no doubt that the conduct of the eminent surgeons alluded to originated from motives highly honourable to them.

—o—

DUPUYTREN'S CLINIC.

—

Hydatids.

IN a recent number*, we dwelt at length on the subject of cysts with osseous walls, developed in the substance of the bones; and of which, we observed, the chief pathognomonic sign is a crepitation like that produced on crushing paper, or better still, very dry parchment, between the fingers. We also compared the sound to that of the tumours at the wrist, divided into two parts by the the anterior carpal ligament, when we endeavour by pressure to force the fluid out of one division into the other. The day after the article in question appeared, it happened that a man of about thirty years of age came to the Hotel Dieu, with a tumour on each side of the carpal ligament. M. Dupuytren invited those present to assure themselves of the crepitation, which was apparent both to the touch and to the ear, and which might be compared to the noise produced by a chain of little rings, inclosed in a skin-purse, when we press the links one against another, through the sides of the bag. The surgeon thought it a favourable opportunity for explaining the opinions with which the experience of twenty years has furnished him. His observations were to the following purport.

Tumours of the nature of that before us, are not *exclusively* developed in the situation of the anterior carpal ligaments. They are sometimes found among other places, at the ankle-joint; but, nevertheless their most frequent situation is the anterior surface of the wrist. Their seat is the fibro-cellular tissue near the joint. Wherever they may be placed, they are always divided, more or less equally, into two parts. This remark is important; for we might have been led to believe that the division was owing to the presence of the carpal ligament, were it not that the division exists where no ligament passes over the tumour. Generally free from pain, and without change of colour in the skin (unless the

latter from some cause or other, should take on secondary inflammation), these tumours may, and frequently do acquire a volume sufficient to obstruct the free motion of the neighbouring articulation. Sometimes they put a stop to its motion entirely, prevent the patient from continuing his occupation, and obliges him to seek a cure. If we press alternately on the one and on the other half of these tumours, endeavouring to make the fluid pass from one division to the other, we perceive the sound—the crepitation such as we have described it. In the first case of the kind which M. Dupuytren met with, it was in endeavouring to ascertain fluctuation, that he produced and observed these sounds. The frequent examples which have since come under his notice, have led him to look on this as a truly pathognomonic symptom. At any rate, this sign has never led him into error respecting the nature of the tumours in which it occurred. When the diagnosis, then, is established, what are the curative means to be employed? It is from pathological anatomy, as much at least as from experience, that the surgeon has drawn the rules of treatment we are about to lay down. On opening the first tumour he met with, M. Dupuytren, who had already made up his mind it was encysted, was surprised at seeing escape from it a serous and straw-coloured liquid, in the middle of which were floating some white semi-transparent bodies. Their sides were puckered, and they formed a kind of bag, one extremity of which was terminated by a large rounded *cul-de-sac*, while the other resembled the neck of a bottle. The analogy of these bodies with the hydatids which are met with in other parts of the human subject, the peculiarity of being like them inclosed in a cyst, and immersed in a fluid of which the appearance is similar, immediately led M. Dupuytren to conclude, that they were really hydatids. Having collected several, he submitted them to the examination of M. Bosc, professor of Natural History in the Garden of Plants, a gentleman well versed in the study of Helminthology, and of whom science has had to deplore the recent loss. This professor examined them with the greatest attention, submitting them to the action of the compressor, an instrument in which two parallel plates of glass are gradually brought nearer and nearer to each other, and thus compress, on opposite sides, any body placed between them. This pressure, by making the sides of these bodies tense, rendered the examination more exact and conclusive; but M. Bosc could not by any means assure himself of their vitality; and he therefore concluded they were not hydatids, but probably the *debris* of fatty cellular tissue, floating in the serous liquids.

M. Dupuytren could not by any means subscribe to this opinion. No fatty cellular tissue exists in the regions where they are

* See London Medical and Surgical Journal, No. 176, p. 626.

found; nor does the conformation of these bodies permit us, in his opinion, to suppose they are formed in this manner. Although M. Dumeril, to whom they were likewise submitted, could not, any more than M. Bosc, discover vitality, yet these two naturalists were forced to admit in them an individual existence, apparently independent of the surrounding parts. M. Dupuytren assumed this individuality as at least probable; and along with this individuality, a life altogether independent of that of the body in which they may be developed. In a word he believed, and did believe still, that they are real hydatids. As to the causes of their production, we must refer them to those under the influence of which hydatids are developed in other regions of the body; and they must therefore be sought in the mode in which patients live, or in the dampness of their dwellings, or in a lymphatic and scrofulous constitution. It might have been difficult to believe that any *external* cause, such as a blow or other contusion, could have given birth to them, had not M. Dupuytren seen an instance several years ago, in the case of a young female at the Hotel Dieu. She received on the forehead a blow of a whip, which gave origin to an encysted tumour; and on its being opened there issued a true hydatid, which had completely filled it.

Experience, again, has proved to M. Dupuytren the inutility of all external means, such as *douche*, baths, frictions, &c. in the treatment of these affections. These means, frequently so useful in tumours *not* encysted, have always appeared to him completely inefficacious, when applied to *encysted* tumours. The opening of the cyst, and the suppuration of its internal surface, then, are the only means of effecting a cure. But in tumours of this description, however little developed they may be, the opening and consecutive suppuration of the cyst are not always unattended with danger. Several patients in whose cases M. Dupuytren has opened and brought on suppuration in these tumours, have met with very serious consequences. Some had even fallen victims to an inflammation propagated from the hand to the fore-arm. Experience in the first place, and reasoning in the second, have convinced this surgeon, that when we decide on opening a cyst of this nature, we ought to make a large incision into both halves of the tumour. The propriety of this will be evident from a consideration of the anatomical relations of the parts concerned. At the instep, but especially at the palmar surface of the wrist, these cysts are developed beneath aponeuroses, and in the midst of tendons, vessels, and numerous nerves, bound together by fibrous cellular tissue. Hence, if we have made but a small opening, the swelling produced by suppurative inflammation of the cyst, almost always shuts it up again. The inflammation

is then propagated, more or less, to the surrounding parts, along the sheaths of the cellular tissue which embrace the vessels and nerves, either in the palm of the hand, or the fore-arm and arm; giving rise to numerous collections of pus, to numerous sinuses, sometimes to phlegmonous inflammation of the whole limb, and even to the death of the patient. On the contrary, we are certain to avoid the most frequent cause of all this mischief, by taking care to open at once, and by a large incision, the two divisions of the cyst. No confinement of matter can then take place, and the suppurative inflammation generally commences and terminates favourably.

When once the incisions are made, the liquid has escaped, and the cyst is freed from these semitransparent bodies, which are sometimes tolerably numerous, a piece of lint ought to be introduced between the lips of the wound. M. Dupuytren has sometimes passed a seton from the opening in one half of the tumour to that in the other; but he had now ceased to employ that method, which he considered not only useless but dangerous. It is quite sufficient that the edges of the wound should be kept asunder, and their adhesion thus prevented, in order that the walls of the cyst may inflame and suppurate; and the seton introduced into the cavity appears to excite an inflammation which is too severe, and which may also propagate itself to a distance with greater facility. The inflammation may likewise extend to the interior of the articulation, and give rise to an ankylosed joint. The seton at any rate is useless, and that would be a sufficient reason for not employing it; but further than that, it is dangerous, which is a still more urgent reason for abandoning it.

Incision, then, and the suppuration of the cyst, are the only means of curing these tumours; for we take it for granted, no one would think of extirpating them without opening. It may suffice in reference to that subject, to remark that these tumours adhere strongly by their external surface, throughout all their circumference, to the surrounding parts; so that the idea of extirpating them altogether is inadmissible. With respect, however, to the question of operating at all, we should remember that the suppuration of the cyst is not always without danger; and that notwithstanding the valuable directions of M. Dupuytren, as to the extent of the incisions, and the means of avoiding mischief, there is still room for dreading unfavourable consequences, which may bring the life of the patient into jeopardy. We should also bear in mind that these tumours are never attended with pain, nor do they occasion any other inconvenience than that of obstructing, by their bulk, the motion of the joint. We ought not, therefore, to resort to an operation, unless the tumour has at-

quired a volume so considerable as to fatigue the patient, and prevent the free exercise of his profession; or at any rate unless the patient be very urgent for its performance. In all other cases prudence directs us not to interfere with tumours, which occasion no pain, and are attended with no danger.

Hospital Reports.

WESTMINSTER HOSPITAL.

Dreadful Accident from Machinery—Diastysis of the Head of the Os Humeri, &c. &c.—Death.

A FINE stout boy, aged 15, was received May 12th, into the Northumberland ward, under the care of Mr. White.

We were not able to obtain a very precise account of the way in which this dreadful accident occurred, but it appears that the boy was employed in some capacity or other in a veneering mill, worked by steam, and that on the day of his admission, he had come in contact with the spindle of one of the wheels of the machinery, and that in this way the fractures and other injuries of the extremities were produced.

There were compound fractures of the tibia and fibula of the right side, in more than one situation. On the left side there was only a severe contused wound. The os humeri on the right side was fractured, as were also thought to be the radius and ulna; there was at least very severe injuries of this extremity in several situations.

The more remarkable part of the accident, however, was seated in the left upper extremity, which had been completely torn from the body at the shoulder, where it was merely connected with the trunk by a narrow ribband of skin. It was not ascertained that any of the ribs had been fractured, though the chest had evidently been severely bruised. Blood was effused between the conjunctiva oculi and the sclerotica.

Mr. White arrived at the hospital speedily after the admission of the patient, and the following means were employed for his relief.

Some brandy was administered, the right leg was put up in splints, &c.; whilst the arm of the same side was merely laid on a cushion. Mr. White then removed the left extremity from the body, by merely dividing the ribband of skin before described. It was now found, on inspecting the removed extremity, that neither had a dislocation of the humerus from the glenoid cavity of the scapula taken place, nor yet even a fracture of the bone itself, in the proper sense of the word, but that the accident, known to the older writers by the name of diastysis*,

* The diagnosis of this case from one of simple ordinary fracture, is effected by taking

had occurred, the shaft of the bone having been disrupted from its superior epiphysis, or the head of the bone (which remained in its articular cavity), in the plane of the anatomical neck of the bone, in which situation till about the period of puberty, or process, when the epiphysis becomes an apophysis, a lamina of cartilage exists.

After the extremity had been removed, a piece of linen rag, dipped in cold lotion, was simply placed over the stump.

Every thing calculated in the least degree to add to the shock which the system had received from the accident, was avoided, whether in the way of minute examination, or changing the dressings, &c., and the greatest stillness was enjoined.

13th. Dosed at intervals only during the night. Complains of great pain and soreness over the body generally; tongue dry and glazed; great thirst; respiration laborious; respiratory murmur abnormally puerile over the front of the chest; pulse feeble and frequent; he takes toast-water repeatedly.

15th. Countenance anxious; appears worse; he does not answer questions unless addressed in a loud voice; increased oppression of breathing, from an accumulation of mucus in the bronchi, which he has not power to expectorate.

Habeat Mist. effervescens, ad libitum. Appr. cucurb. cruent, c ferro regioni sternali, et detrach. sanguinis, ʒ xij.

16th. Was cupped yesterday as directed. Countenance is sunken and anxious, though perhaps less so than yesterday; tongue dry and glazed; lips covered with rhagades; pulse 170, sharp and irritable; he answers questions distinctly, though in a low tone of voice; says he is in no pain; takes drink freely to allay the thirst of which he complains. When Mr. White saw him he thought him somewhat better, and observed that it was extraordinary to see how long he continued after such an injury, which, could the chest be relieved of its load, would almost warrant us in anticipating a favourable termination. He ventured to allow him a little nourishment, in the form of an ounce or two of beef tea, which he took with a relish, and which was to be repeated at the discretion of the house surgeon.

17th. The patient died to-day, having sank gradually through the night.

Tumour of the Tongue.

John Richardson, aged 16, was admitted into Northumberland ward, March 17th, 1835, under the care of Mr. W. B. Lynn. The lad is of a pale delicate looking strumous

into consideration the situation of the lesion, the age of the patient in such cases, as upon a careful *auscultatory* exploration, present no traces of crepitus, which it is obvious can never occur in any case of diastysis.—REPORT—*Am. London Medical and Surgical Journal.*

habit, and apparently of a stunted growth. During the last fifteen months, he has been employed at the gas-works in Westminster. During the late winter, and likewise the preceding one, he had several attacks of *cyananche anginosa*. Five or six months ago, he first noticed an alteration in his voice, and a difficulty in performing the act of deglutition, which were the first symptoms of his present affection. These have gone on progressing regularly, to the time of his admission, prior to which they proved so seriously annoying, as to lead him to seek relief at the hospital. On examining his mouth, and causing him to protrude his tongue, a small roundish tumour was seen about the centre of the dorsum of this organ, situate immediately under the mucous membrane. Upon introducing the finger, it was found that this formed but the anterior border of a large tumour, involving the general substance of the root of the tongue. The boundaries of this tumour could be pretty distinctly ascertained by examining the under surface of the organ where it lies in the floor of the mouth. The superior surface of the tumour was found to be fissured and ulcerated from the round elevated tumour before mentioned, in and around the median line, as far back as the epiglottis and os hyoides, or very nearly.

The surface of this ulcer was very irregular to the touch, and secreted a glairy and imperfect pus, very disagreeable to the taste. The soft palate, with its arches, and the tonsils appear to be implicated in the affection, there being a rather large tumour in the situation of the left tonsil. The anterior arch of the palate of the same side, likewise, appears to have gained a preternatural adhesion to the base of the tongue, from the extension, most probably, of a chronic inflammation from that organ. There is little or no pain except on deglutition, when it is of a dull but shooting kind: the voice is nasal, and very indistinct. The general health of the boy appears to be unaffected by the local affections, though, as before stated, he appears to be only of a weakly character.

Mr. Lynn at first thought that the adhesion between the arch of the palate and the tongue, was the primary affection, and that considerable benefit would be likely to accrue from its division with the scalpel; but Mr. Guthrie, whose opinion he asked, considered the adhesion to be altogether of a secondary and symptomatic character, depending upon the disease in the tongue; the best treatment of which he should regard to be one consisting of iodine and mercury, with attention to the state of the general health. He thought that the best form of employing these remedies, would be that of taking the iodine internally; and in addition, of employing friction, with an ointment of iodine and mercury; to which Mr. Lynn assented.

25th. The following have been ordered for him, and he has commenced the use of the

remedies, with the exception of the iodine, which he has not had yet. *Rx.* Tinct. iodini, \mathfrak{z} j; Capt. æger gtt. x (dosi gradatim aucturâ), ter quotidie. *Rx.* Ung. hydrarg. \mathfrak{z} j; Circa coll. omni nocte infriciend. *Rx.* Magnes. sulph. \mathfrak{z} j; Magnes. carb. \mathfrak{z} ii; Tinct. sennæ, \mathfrak{z} ss; Inf. sennæ, \mathfrak{z} vj; M. capt. \mathfrak{z} ij; P. Rn.

28th. He has employed the ointment three times, and the mouth has become slightly affected; the tumour on the tongue looks less irritable: he has been ordered fish diet.

31st. Since he has been taking the iodine, as well as employing the other remedies, he thinks that deglutition has been easier than before.

April 2nd. The tincture has been superseded by the following form of aqueous solution of iodine: *Rx.* Iodini gr. v; Potassæ hydriodatis, gr. x; Aquæ destillat. \mathfrak{z} ss; M. ft. solutio, capt. gt. v, ter die ex aquæ unciam.

He has likewise had fourteen leeches applied to the neck (the ointment having been discontinued), but at present he remains much the same.

4th. The tumour in the tongue appears to be sensibly diminishing, and as a consequence, the various symptoms arising from it are all somewhat relieved.

8th. Considerable amendment has taken place; the tumour is much less than at last report; and the ulcerated surface on the dorsum appears to be healing. He has, ever since his admission into the hospital, been troubled with otorrhœa on the left side, which has been attended with a considerable degree of deafness, but the discharge from the ear is much less than it has been, and the deafness is not so marked. His general health appears somewhat better than when admitted. He takes the iodine, &c. and no unpleasant symptom has arisen from its use.

18th. Much better—the deglutition and articulation are both improved by the diminished size of the tumour.

22nd. Continues to improve, and is still taking the iodine drops in increased doses.

May 9th. Little tumefaction is now perceptible in the tongue; but there is still an excavated surface on its dorsum, particularly near the root, which though less fissured, and not so deep, has not yet cicatrized.

June 6th. During the last month, the disease appears to have been very much stationary, and the appearances do not seem to warrant at all a more favourable report than at that period. The quantity of the iodine drops has now been increased to thirty drops at the dose, without producing any unpleasant effect; during the last week it has been totally suspended. A few days ago a piece of caseous substance, about the size of a bean, came away with his saliva, which is supposed to have been contained in a tubercular cyst, forming the basis of the lingual tumour. The deafness of the left ear is now nearly gone.

9th. Discharged the hospital this day, having been made an out-patient.

—o—

Chronic Orchitis—Hydrocele treated with Iodine.

Samuel Gimbert, aged 36, was admitted April 4th, 1835, into Northumberland ward, under the care of Mr. Guthrie, who being an invalid at this time, the man became a patient of Mr. Hale Thomson, Assistant-surgeon to the Hospital.

He has suffered from an enlarged testicle (of the right side) during the last four months, which was both insidious in its origin and tedious in its progress, making its appearance without any assignable cause having been present, or at least known, with the exception of a slight strain in the loins; and having gradually increased in size until it attained its present magnitude, which is about that of a goose's egg, or even larger. Part of the tumour is however evidently to be ascribed to the presence of a hydrocele of the tunica vaginalis, which appears to have been forming during the same period. Above and behind the hydrocele the enlarged testicle may be distinguished, which is of a cartilaginous hardness, more particularly at its external border, but disappearing towards its anterior and internal margin. Little or no pain is produced by handling it, nor has he pain at other times, except of a very obscure kind. The epididymis appears to participate in the enlargement, but it is with difficulty distinguished from the general swelling. The left testicle is quite healthy.

He is a married man with a family of five children. His general health appears to be unimpaired; his appetite is good and bowels regular.

6th. Mr. Thomson performed paracentesis scroti, and drew off nearly a pint of fluid.

8th. A hard swelling has appeared on the internal surface of the head of the left tibia, of which he complains as being very painful, which on examination appears to depend upon inflammation with thickening of the periosteum. Mr. Snowden, the house-surgeon, has directed the application of leeches over the tumour, and subsequently, common emollient cataplasms.

10th. The leeches and poultices have given him great relief; but he still complains of nocturnal pains, especially in the superficial part of the bone. Although he has occasionally had a sore throat, there does not appear to be sufficient ground to ascribe either that or the affection of the bones to a syphilitic taint; and as he altogether disclaims having ever been the subject of any primary symptoms, it seems reasonable to regard the present affection as being of an arthritic nature.

The following remedies have been directed for him.

Rx. Pilul. hydrarg. gr. v. ft. pil. omni nocte, maneque sumend.

Rx. Decocti sarsaparillæ Oss, quotidie libend.

14th. The tumefaction of the head of the tibia has become much diminished, but the nocturnal pains are still very troublesome.

15th. Remains much the same. A little tenderness of the gums has manifested itself.

Rx. Emp. carthar. genu appl.

18th. Much as before; slight pyalism is present.

Habeat statim ol ricini, ʒ ss, sumat; pilul. hydrarg. quotidie.

25th. He was ordered the following on the 23rd.

Rx. Tinct. iodine, ʒ ss; Potassæ hydriod. gr. ij; aquæ, ʒ viij. M. ft. Mist. capt. cochl. ampl. j, bis die.

After taking the first dose of medicine, a rather severe diarrhœa made its appearance, which however ceased on his omitting the sarsaparilla, which he had been taking at the same time. The testicle is somewhat less swollen and hard. There is still a good degree of pyalism, and he has not yet omitted taking the mercurial pill once daily.

30th. The testicle remains much as before; the general tumefaction, however, is increased, by a fresh accumulation of fluid in the tunica vaginalis.

May 9th. Mr. Thomson again evacuated the contents of the hydrocele, which amounted to four or five ounces of a yellowish serum. He performed the operation with a lancet, and did not employ a trocar. The testicle was now found to have undergone considerable reduction of size and hardness. He continues to take the iodine mixture.

18th. He continues better, and only a slight secretion of fluid appears to have been going on in the tunica vaginalis.

June 9th. During the last three weeks the testicle has gradually grown less, and all the symptoms have by degrees left him. He was considered sufficiently relieved to be able to leave the hospital, though he is to continue as an out-patient.

15th. When he was at the hospital to-day, he stated that very little enlargement of the organ is now remaining.

POLICY OF SMALL FEES TO JUNIOR MEDICAL PRACTITIONERS.

To the Editor of the London Medical and Surgical Journal.

SIR—Being an anti-monopolist I feel confident you will oblige me by inserting the following statement.

Graduated Fees in Dublin.

"Et les hommes en place répètent à ceux qu'on dépouille paix paix c'est pour votre bien."—PASCAL.

Although much has been said on the subject of graduated fees, the junior members

have not yet risen en masse, to shake of the incubus of an overgrown monopoly in Dublin. In the present crowded state of the profession some change is indispensable with respect to fees, to save the majority from penury; those in power exclaim, that a silver fee would degrade their honourable profession. None could advocate a strict adherence to the laws of honour more than I do, but, there is a pseudo-honour invented by self interest, and preached to the wild imagination of the boy, for the exclusive benefit of the former, which I am decidedly hostile to. When the junior member is qualified to practise, he finds the public, ignorant of his attainments, will only give the guinea to one of his eminent brethren; and as he has been taught to despise a less remuneration, he is obliged to pass through years of obscurity, depending on the fallacious promises of his former masters. What is the consequence of this system? The dupe of to-morrow finds himself deceived "like the first inhabitants of Arcadia, who chased the sun." Year glides after year, until the season of energy is past; the victim of this vaunted honour finds, after attending patients gratuitously for years, that like the squirrel in the cage he has been labouring without advancing; and with embittered feelings accepts some poor Dispensary, where he can bury his disappointment far from the scene of his youthful ambition. This is unfortunately not an exaggerated picture of our present condition. What then is the remedy? Graduated fees. In the army, does the lieutenant expect the same pay as the captain, or the major as the colonel? No; does not the established man in trade demand a higher price than the beginner? Certainly; this is just. Why should our profession differ? The guinea fee is a relic of the age of the buckled wig, and gold-headed cane; in that day a medical man was a demi-god, who never touched silver; but at present that veil of mystery is removed, and hundreds of struggling members, if once this subject were publicly discussed, would come forward in defiance of the monopolists. At present the public cannot offer less than gold or paper, which they regard as too much for a tyro practitioner, consequently it is added to the colossal fortune of some head man. Let us now look to the Parisian medical men, who have certainly advanced with more rapid strides in the pursuit of science than we have. I do not presume to be able to analyse the causes of this superiority; one I am convinced is, that the young man has some inducement to bring his energies into play; the lowest fee is certainly small, but it is something tangible leading to greater benefits. We may point to hope in the distant prospect in vain, while immediate reward spurs on the mind to enervated action. In youth reward is not our only object, fame and notoriety are equally in view; but I insist that without

some remuneration, notoriety is but a bubble. Were the same system followed in Dublin, many a junior member who now parades the sunny side of Grafton-street, would be found in the eager pursuit of his profession. Some nominal supporters of the honourable fee actually take five shillings, by paying four visits for a pound; this will not do, it is coquetting, but does not arrive at what we seek; the patient, perhaps a struggling tradesman, is still obliged to give the pound, where the case required but one visit. I may now ask how can we best effect our purpose? I leave this point for consultation, recommending active treatment.

A Crown Solicitor.

Dublin, June 30th, 1835.

BOOKS.

Observations on the Climate and Productions of British Guiana, and on the Advantages of Emigration to, and Colonizing the interior of that Country; together with incidental remarks on the Diseases, their treatment, founded upon a long experience within the Tropics. By John Hancock, M.D., &c. 8vo. pp. 89. London. 1835. Frazer.

An interesting essay to the general and medical reader.

The Medical Quarterly Review, No. VIII. July 1. J. Souter.—This journal is discontinued. It was conducted on fair and honourable terms, and its editor is entitled to much praise for the manner in which the work was executed. We perceive that another quarterly journal is announced for the beginning of next year; but we are not very certain that there is room for it, while our contemporary, the Medico-Chirurgical Review, deserves and obtains so much patronage. We are disposed to think the time for quarterlies has almost gone by.

Dr. Ryan's Formulary is published this day, and may be had of his publisher and all booksellers.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXIV.

*Various Doctrines of Sympathy considered—Evidences of the Passage of Sympathies by the
Respiratory System of Nerves.*

ANOTHER doctrine, and still a somewhat prevalent one, with regard to the nature of sympathetic irritations is, that they take place through the brain, the direct and primary irritation exciting first, by some unknown means, sensation, while sensation further excites, by means equally unknown, indirect and secondary irritations in distant parts (a). And the proof of this, say the advocates of this doctrine, is that the *same* sensation—for example, that which gives rise to a desire for venery—excited by primary irritations of two different organs, gives rise to secondary irritations of the *same* distant part; whereas *different* sensations—for example, those producing gratification and annoyance—excited by primary irritations of the same organ, give rise to secondary irritations of *different* distant parts: such sympathetic irritation, therefore, they contend, cannot depend on the character of the irritation primarily excited, but must arise from that of the sensation thence resulting. But all this applies only to passion or instinct—not to sympathy properly so called—and in as far as it does even this, it only tells us what we do not require to be informed of, namely, that every form of passion must be preceded by sensation, as the latter must by irritation, while it gives us no sort of clue to what alone we want to know, to wit, by what means passion—no matter how excited—acts as a stimulus on the irritability of distant organs. And that it cannot apply to sympathy, properly so called, is manifest from this, that sympathetic irritations are not less observable when the primary irritation is seated in an organ apparently destitute of sensiferous nerves—the lungs or stomach for instance—than to one furnished with them; that even the division of these nerves, when they exist, makes no material difference in the certainty with which such secondary irritations are excited in distant parts, as in the case of sneezing from volatiles to the nostrils, after the destruction of both the olfactory and trigeminus nerves (b),

(a) The principal authors who have maintained this opinion are, Whytt (Physiol. Ep. 1755), Haller (El. Physiol. 1757), and Monro (On the Struct. and Funct. of the Nerv. Syst. 1783); and with respect, at least to some cases of sympathy, Blumenbach (Inst. Physiol. 1786). It has been recently advocated also by Professor Alison; who has, apparently rather too hastily, concluded that, because Whytt, Haller, and Monro could not, half a century ago, explain the communication of sympathetic irritations upon the principle of any association of nerves, such an explanation must be still

impossible. (Ed. Med. and Surg. Journ. 1826). There are probably many more things, however, in heaven and earth than were dreamt of in their philosophy. Similar doctrines are maintained likewise by Broussais, Georget, and Roux.

(b) Magendie has shown this with respect to the olfactory nerve—and it is his principal argument, although a very fallacious one, to prove that this is not the nerve of smell—and Sir Charles Bell with respect to the trigeminus, a palsy of this nerve on the right side having been found quite compatible with the usual effect of volatiles, ap-

that some of the most striking examples of sympathetic irritation—for example, the act of respiration—are not interrupted during sleep, or in comatose diseases, and are compatible with the congenital defect of the greater part of the brain; and that even the artificial removal of the greater part of this organ does not obviate the occurrence of convulsions, in almost all the voluntary muscles of the body, from a primary irritation of one part of the surface. How is all this reconcileable with the doctrine that it is only through sensation that sympathy operates on distant organs, and that it always takes the brain as a kind of half-way house on its journey? It is true the advocates for the hypothesis in question take no account of the nerves—sensiferous or any other—assuming it is a fundamental axiom that no anatomical principles are at all adequate to explain the route which sympathetic irritations are frequently observed to follow. If, say they, the nerves were the vehicles of the primary irritation, becoming always, as they imagine, sensation, which excites sympathetic action, since different primary irritations of any one part, in journeying to different parts, must each travel by a different road, it follows that every one which is adapted to excite a distinct sympathetic action, must have a distinct nerve to convey it to and from the brain. Among the examples of sympathetic action already enumerated, we find that of sneezing, from acrid substances applied to the nostrils, and, among those of the operation of passion as a stimulus to irritability, that of syncope from depression, such as is excited by mawkish odours, that of a flow of saliva from desire, such as is excited by savoury odours, and that of vomiting from disgust, such as is excited by nauseous odours. Now admitting for a moment that all had to pass through the brain, if we presume, say those who attempt to explain sympathetic action by affirming that it is inexplicable, that such primary irritation is translated by nerves, we must conceive that these are bound up in the sensiferous nerves leading from the nose to the brain, and again from the brain elsewhere—one filament for acrid, a second for mawkish, a third for savoury, and a fourth for nauseous odours, since each has to be conveyed to a different distant part (a). But even continuing to admit that it is through the medium of sensation that all such irritations operate—and such is certainly the case with those which give rise to passion—it seems perfectly easy to understand that the character of the sensation will vary in every case, although conducted by the same nerve, according to that of the exciting cause of the irritation where it arises. It is true, the olfactory nerve takes cognizance only of that produced by odoriferous particles, the optic of that produced by light, and the auditory of that produced by the vibrations whence sound arises; but each is susceptible of very different impressions from different modifications of these respective irritations; and when such impressions, or their consequences, are to be again conducted from the sensorium or brain, so as to act as stimuli on the irritability of distant organs, it is equally easy to conceive, either that they may travel by this or that nerve, according to circumstances, or that, travelling equally by all the nerves belonging to a certain system, they still display their effects only or chiefly on those parts to the specific irritability of which they are respectively adapted—in the same manner as the primary irritation on which expiration depends is conveyed, probably, by the same nerves as that on which inspiration depends, but, being of a different character, it acts on a totally different set of muscles. But with cases of sympathy properly so called, it is probable, for reasons already assigned, that sensation has nothing whatever to do; nor is its instrumentality in exciting the irritation of the brain, in which passion or instinct consist, at all connected with the present inquiry, since, in regarding this agent as a stimulus to irritability, we start directly from the irritation of the brain, however produced, and it is the translation of this to other parts which alone requires to be explained. We may conclude then that the doctrine of intermediate sensation, as applied to sympathetic irritation generally, is erroneous—and as applied to that excited by passion or instinct, is superfluous; and that that which assumes that any association of terms must be incompetent to explain the translation of the primary irritation in which both originate, has not been established by any argument *ad absurdum*.

There still remain two other opinions respecting the communication of sympathetic irritations—one, that it depends on either the contiguity or continuity of the sympathising organs, the other, that it hinges on their similarity in either structure or function (b). But with respect to contiguity or continuity as a means of explaining the simultaneous irritation of any two organs, upon a stimulus being applied to one of them, it is sufficient to

plied to the right nostril, in exciting sneezing. It is fair to acknowledge, however, that the latter fact is denied by Belingeri.

(a) Alison.

(b) These complete the number of the six modes, enumerated by Haller, in which sympathetic actions have been presumed to

be effected, 1, by blood vessels; 2, by nerves; 3, through the sensorium; 4, by contiguity of cellular tissue; 5, by continuity of membranes; and 6, by similarity of structure or function. the contiguous doctrine found an advocate in Bordeu: the continuous in John Hunter; the analogous, at least in some cases, in Blumenbach.

refer to the above enumerated instances of proper sympathetic irritations—and to those excited by passion or instinct the doctrine is obviously quite inapplicable—in order to show that, while frequently little or no sympathy exists between organs the most favourably situated in these respects, some of the most remarkable of these sympathetic irritations take place between organs neither contiguous to, nor continuous with, each other, and consequently that such conditions, when they present themselves, are quite accidental. What contiguity or continuity, for example, is there in the case of the lungs and respiratory muscles, the female genitals and mammæ, the diaphragm and muscles which depress the jaw, the nostrils or larynx, and abdominal muscles? and even where one or other of these conditions exist, as between the fauces and stomach, it has been found that this connexion may be severed without impairing the sympathy between them (a). Moreover, such contiguous or continuous organs cannot, any more than blood-vessels or lymphiferous vessels, convey vital impressions otherwise than by their nerves; so that, although this explanation of sympathetic irritations were true, it would be so only at one remove. And similar objections apply to the hypothesis of a similarity in structure or function as a means of explaining such irritations, no very obvious consent being met with between many parts the most nearly allied in these respects, while such consent is most striking in others without either of these conditions. Besides, a correspondence of tissue can do no more than produce a correspondence of susceptibility—and it is by no means a necessary consequence that it should do even this—so that, from the same stimulus directly applied to two several organs, similar effects should arise—it cannot certainly afford any explanation of the fact that a stimulus applied to the one should be extended to the other, which is what is understood by sympathy; and to bring in analogy in function, when such is observable, as a means of explaining sympathetic irritations, is obviously to confound an effect with a cause, since it is not because the functions are connected, that the parts sympathise, but because the parts sympathise, that the functions are connected.

Upon the whole, it appears that we must return to the nervous system as the vehicle of sympathy and passion or instinct, considered as stimuli to irritability, but not to that department of it which was lately mentioned. That the direct and primary irritation, of whatever nature it be, by which the voluntary movements of the body are excited, is conveyed to the requisite muscles by proper nerves adapted to the purpose, is unquestionable; and, for the same reason that the established residence of sensibility in one department of the nervous system was allowed to furnish an argument *à priori* for referring the analogous property of irritability to another, the established conveyance of the stimulus to voluntary motion by one department of this system may be taken as presumptive evidence that it is by another that the analogous stimulus of sympathy and passion or instinct is translated; nor do the objections which have been stated against regarding the ganglionic system as instrumental in this way, apply equally to every other.

But if this doctrine be maintained, we must be prepared to show, 1st, that there is a system of nerves which, unlike that by which the stimulus to the voluntary movements is conveyed, is very extensively distributed; since the influence of sympathy and passion or instinct manifestly extends to almost every organ of the body; 2ndly, that this system of nerves is quite independent of the sensiferous department; and 3rdly, that its action is not interrupted by sleep or coma, nor even by the want of the greater part of the brain. Now all this is true of the system of nerves called respiratory. It is admitted that it is equally so of the ganglionic system; but if the respiratory nerves are, 4thly, developed in all animals in the direct ratio, not of their irritability, like the ganglionic, but of the manifestation by them of the stimulus of sympathy and passion or instinct; if, 5thly, they are, unlike the ganglionic, similar in structure to the proper motiferous nerves, which convey the analogous stimulus of volition; if, 6thly, again, unlike the ganglionic, they conduct, in common with the proper motiferous nerves, the stimulus of galvanism; if, 7thly, any stimulus applied to them, unlike which happens with respect to the ganglionic nerves, occasions a display of irritation in the parts on which they are distributed; and lastly, if a lesion of these nerves produces a corresponding failure in the conveyance of the stimulus of sympathy and passion or instinct, while a lesion of the ganglionic nerves has no such effect, we shall perhaps have little hesitation in admitting the respiratory system of nerves as the exclusive vehicles of the stimulus in question, particularly when we remember that not only the ganglionic system, but every department of the cerebro-spinal system except this, as well as the brain—cerebrum and cerebellum—is known to be otherwise appropriated, so that this alone of the whole nervous system is left for the purpose.

But it will be necessary to examine a little more in detail each of the foregoing arguments in favour of the doctrine that it is by means of the respiratory nerves that the direct and primary irritation in question is so translated to distant parts as to become there a new

(a) It was found by Bichat that vomiting was produced by irritating the fauces, as

certainly after dividing the gullet, as when this organ was entire.

stimulus to irritability, and afterwards to mention, and endeavour to obviate some of the chief objections to which this doctrine is amenable (a).

I.—The distribution of the respiratory system of nerves appears, at first sight, very circumscribed, and quite inadequate to explain the almost universal extension of sympathy and passion or instinct over the body. The proper respiratory tract, beginning at the tuber annulare, and descending, on each side of the spinal cord, between the anterior or motiferous, and posterior or sensiferous columns, seems to terminate about the middle of the back, having given off in its course only seven pairs of nerves—the distribution of most of which is apparently by no means general—to which must be added, perhaps, some filaments to the intercostal and lumbar nerves, the course of which, however, is still to all appearance confined to the parietes of the chest and belly. But we must remember that—to say nothing of the numerous other probable ramifications of these nerves—the pneumogastric nerve, throughout the whole neck, chest, belly, and pelvis, is inextricably interwoven with the roots of the ganglionic system; and as this system may be presumed, as already explained, to be universal in its distribution, partly from its everywhere accompanying the blood-vessels, and partly from every cerebro-spinal nerve, the respiratory inclusive, being reinforced by one or other of its several departments, so, whithersoever a ganglionic nerve goes, thither a respiratory filament may be presumed to accompany it. Not to mention, then, any of the other nerves of the respiratory system, the probable distribution of the pneumogastric nerve alone seems sufficient to establish the claim of this system to be regarded as almost universally disseminated. We know that such is the case with the pneumogastric nerve of fishes; and when to this we add, in the superior tribes of animals, the various other nerves belonging to this system, and consider them as all associated

(a) In the tabular view formerly presented of the nerves of the human body, arranged “after their kinds,” the respiratory system comprehended the pathetic, the facial, the glosso-pharyngeal, the pneumogastric, the accessory, the phrenic, and the external respiratory; but the uses formerly, and still by many ascribed to most of the individual nerves of this system—for of the whole collectively nothing was till very lately known—have been extremely various. Thus the pathetic has been commonly regarded as a simply motiferous nerve; the facial, sometimes as a vehicle of sympathy—not however in as far as it appertains to the respiratory, but is supposed to appertain to the ganglionic system, as by Bellingeri—sometimes as a simply motiferous nerve, as by Mayo, and sometimes, besides being a vehicle of sympathy, as a regular nerve, or consisting of both motiferous and sensiferous filaments, likewise by Bellingeri—the glosso-pharyngeal and pneumogastric, at one time—qua ganglionic—as vehicles of sympathy, as by Bellingeri, at another as simply motiferous nerves, at another as sensiferous nerves, as by Brachet, who represents at least the pneumogastric as conveying certain irritations from the viscera to the sensorium, so as to occasion the sensations giving rise to the desire to breathe, to eat, and so forth, and at another, lastly, as regular nerves; and the accessory, phrenic, and external respiratory, either as simply motiferous, or as regular nerves. In the mean time Prochaska seems to have been one of the first explicitly to promulgate the doctrine that at least the pneumogastric nerve was, per se, a vehicle of passion (Comm. de Funct. Syst. Nerv. 1800), and it had for some time been suspected that the function of respiration was more particularly under the influence of the l

ral portions of the spinal cord, which had been described as distinct from the anterior and posterior portions of it by Chaussier (Exp. Sommaire, &c., 1807), especially, as suggested by Le Gallois, of that portion of it which is within the skull (Sur la Principe de la Vie, 1812), whence many of the principal nerves above enumerated arise; but it was reserved for Sir Charles Bell (Phil. Trans. 1821 and 1822), and his coadjutor, Mr. Shaw (Lond. Med. and Phys. Journ. 1822), to establish, at once, the existence of the distinct system of nerves called respiratory, and the uses to which it is subservient. The name is unfortunate, since it alludes only to an indirect, instead of a direct effect of their agency, and what is more, to one effect only out of thousands; but to have called it sympathetic, would have been still more ambiguous, this name having been appropriated, by general consent, to a system of nerves which has pretty certainly nothing whatever to do with sympathy; and perhaps it is of very little importance what it is called, provided we do not allow the name to circumscribe in any degree our ideas of its nature and office.

*“What’s in a name? That which we call a rose,
By any other name would smell as sweet.”*

It is to be observed also that the admission of these nerves as respiratory, is equivalent to the admission of them as vehicles of sympathy, at least in one instance, since it is by sympathy alone, between distant parts, that respiration is effected: and as nature never uses two hands where one will do, we might hence have inferred that they were, in every instance, the vehicle both of sympathy in general, and of that particular sympathy in which passion or instinct, regarded as a stimulus to irritability, consists.

together at their common origin (a), through which an impression made upon any one is communicated, according to its intensity, to more or fewer of the rest, we shall be at no loss, on the score of limitation, either in tracing a respiratory nerve to every organ of the body, or in explaining, by means of such nerve, its sympathy with others. Thus, between the lungs and respiratory muscles the sympathy appears to be maintained by the pneumogastric nerve, with which the former are furnished, being associated at its origin at once with the roots of the intercostal and phrenic nerves, so that, when the primary irritation, calling for the inspiratory process, is moderate, the intercostal muscles and diaphragm alone are excited, with those of the accessory and external respiratory nerves, so that, when this primary irritation is more severe, the muscles on the front of the neck, also, and sides of the chest are called into action, with those of the pathetic, facial, and glosso-pharyngeal nerves, so that, on this primary irritation becoming intense, many of the muscles of the eyes, face, and throat are involved in the general perturbation, and lastly with those of the lumbar nerves, so that the primary irritation, calling for the expiratory

(a) It would be improper to assume that all the nerves above enumerated as respiratory arise from a common tract, without remarking that this fact is by no means universally admitted. Thus, the pathetic nerve has been commonly described, since the time of Vieussens, as arising from the corpora quadrigemina, and considered as a nerve of voluntary motion; the facial is generally represented as arising from the tuber annulare and corpora olivaria, which, according to Bellingeri, is true only of the smaller portion of the nerve—which is described by him as a kind of ganglionic nerve—while the larger portion, he says, arises from the corpora restiformia and sides of the fourth ventricle, and is a compound motiferous and sensiferous nerve; and the glosso-pharyngeal and pneumogastric nerves are described by Vieussens, Santorini, and others, as arising, partly from the corpora olivaria, and partly from the crura cerebelli, and they are again classed with the ganglionic nerves by Bellingeri; so that the only nerves of the above system generally acknowledged as having the origin ascribed to them by Sir Charles Bell are the accessory, the phrenic, and the external respiratory. With respect, however, to the pathetic nerve, its minute size, which so long prevented it from being recognized as a nerve at all, may easily explain the circumstance of its origin, from the summit of the respiratory track having been, till lately, overlooked; and the circumstance of its passing into the orbit—a respiratory nerve in the orbit, so fertile a theme of ridicule to those who allow themselves to be governed in their conceptions by a name—furnishes no objection, but on the contrary, a strong support to the opinion that its origin and office are such as have been above presumed; at any rate, its supposed origin from the corpora quadrigemina is as incompatible with the notion that it is a motiferous, as that it is a respiratory nerve; and, as it is certainly either the one or the other, we seem quite justified in assuming that as its origin which explains its office in the latter capacity, in preference to that which does not explain its office in the former. But still greater ambiguity appears to exist with respect to the sources of the

facial nerve. That a small portion of this nerve arises from the tuber annulare and corpora quadrigemina is unquestionable, but the office of this portion is not and cannot be that of a ganglionic, but of a motiferous nerve—as will be in future more particularly explained, while the bulk of it arises, not from the corpora restiformia and sides of the fourth ventricle, but from the respiratory tract immediately between the corpora olivaria and corpora restiformia; and its office, therefore, is not that of a regular nerve—which it could not be consistently with either its supposed or real origin—but that of a respiratory. Lastly, the glosso-pharyngeal and pneumogastric nerves, while they also in part arise from the corpora olivaria, have their origin principally, not from the crura cerebelli, but, like the facial, from the respiratory tract immediately between the corpora olivaria and these crura, so that their office is no where that of ganglionic nerves—which is incompatible with any view of their origin—but, in as far as they have the former source, that of motiferous nerves, as will be stated more fully in future, and in as far as they have the latter, that of respiratory. It may be observed, moreover, in conclusion, that it is only upon the presumption that the functions of the several cerebro-spinal nerves must be different, as arising from different parts, that any necessity exists for showing that all the nerves above enumerated have a common origin, in order to be justified in regarding them all as vehicles of sympathy and passion or instinct. It has never been proved, although it is no doubt highly probable, that not more than one central portion of the cerebro-spinal system and the nerves immediately connected with it can perform this office; so that if any strong reason exist for regarding any one of these nerves as ministering to this end, such as the circumstance of its being, in certain animals, vicarious of some other nerve which, in other animals, is known to do so, or the effects of direct experiment upon it, it needs not be at once excluded from this office, because it cannot be distinctly traced to the common centre in question. There may be association without unity.

process, excites in like manner the abdominal and lumbar muscles to action, more or less violent in proportion to its intensity (a). Upon the same principle, the sympathy between almost every organ of the body and the heart seems to be maintained by the several respiratory nerves which are supplied to these organs, being associated at their origins with that of the pneumogastric; that between the nostrils and lachrymal gland by a similar association of the facial and pathetic (b); between the mouth and salivary glands, of one portion of the facial, the glosso-pharyngeal and pneumogastric, and between the female genitals and mammae, of the pneumogastric, the intercostal, and perhaps also the phrenic, and external respiratory; between the fauces and stomach, of the glosso-pharyngeal and pneumogastric; and between almost every other part of the body and this organ, of numerous other respiratory nerves and the nerve in question. So also between the choroid coat and iris the sympathy may be presumed to be effected by the association, at their origins, of the different portions of the pathetic nerve (c); between the ear and gums of the different portions of the facial; between the diaphragm and the muscles which depress the lower jaw, of the phrenic and facial nerves; between the stomach and diaphragm, of the pneumogastric and phrenic; and between the former organ and all other parts of the body, of the pneumogastric and various other respiratory nerves. Lastly, the nostrils, larynx, eye, &c. appear to extend a sympathy to the abdominal muscles, by the association, at their origins, respectively of the facial, pneumogastric, and pathetic, and the lumbar nerves; the rectum and urinary bladder to the same muscles by a similar association of the pneumogastric and lumbar; and the integuments of the arm-pit, or sole of the foot, to the expiratory muscles, and indeed to almost all the muscles of the trunk and limbs, by the association of the pneumogastric—connected as it may be presumed everywhere to be with the several ganglionic nerves going to the surface of the body—and the lumbar and numerous other nerves of the same system. With respect, also, to passion or instinct, the primary irritation constituting which is always in the brain, and immediately communicated, we must suppose, to the respiratory tract, we have only to find a nerve tending from this tract to the organ which is to display the secondary irritation, in order to explain its translation by this system of nerves; and that such a nerve may be always either directly or indirectly traced to every organ liable to be so acted on may be easily inferred from what has preceded. We seem quite justified in concluding, then, that the respiratory system of nerves, so far from being circumscribed in its distribution, is almost universally disseminated over the body; and that it is quite adequate, as far as regards this condition, to be the vehicle of the stimuli in question.

11.—It has been said above that sympathy, properly so called, may display its effects without exciting intermediately any sensation, that it takes place where the primary irritation is seated in parts destitute, to all appearance, of sensiferous nerves, and that, when such nerves exist, it is not obstructed by their division; and, with respect to passion or instinct, that although sensation is a necessary prelude to this, regarded as a mode of thought, it constitutes no link in the chain of its translation, regarded as a stimulus to irritability. The nerves, therefore, by which sympathy and passion or instinct are conducted must be such as are quite independent of the sensiferous system; and that this is true of the respiratory nerves, connected as they are with a tract which occupies the lateral part of the spinal cord, while the sensiferous column is on its posterior aspect, is sufficiently obvious. In the case of sympathy, properly so called, the primary irritation may, or may not excite sensation, according as the part, to which the stimulus is applied, have or have not sensiferous nerves; but the sensation of the odour of snuff, for example, contributes nothing to the sympathetic action, on either the lachrymal gland or abdominal muscles, resulting from its application to the schneiderian membrane, and constitutes no part of the specific gratification which, whether it occasion sneezing or not, it habitually produces, and which appears to consist in a general excitement of the respiratory system of nerves throughout all its ramifications. No direct sensation is excited by nitrous oxyd taken into the lungs, nor by alcohol received into the stomach, and yet how strong is, in both these cases, the sympathetic action on the rest of the system!

(a) In these cases the translation of the sympathy is *from* the lungs, through the common centre of the respiratory system of nerves, *to* the muscles in question; and it is obvious that, in every case of sympathy, there must be, in like manner, a starting post and a goal. The organ furnishing the former, is sometimes described as displaying an *active*, and that furnishing the latter, a *passive* sympathy, with respect to the other; but there appears to be very little advantage in retaining these terms, particularly as

such sympathies appear to be in general, as we shall in future find, mutually convertible.

(b) The lachrymal portion of the ophthalmic branch of the trigeminus, by which principally the lachrymal gland appears to be supplied, is described by Amussat and others, as receiving a filament from the pathetic, through its nasal portion.

(c) The ciliary nerves, like the lachrymal portion of the ophthalmic nerve, are furnished with a filament from the pathetic, through the nasal portion.

logy and Treatment—Cases shewing fatality
of Disease—Supervention of Dropsies in
Children and Adults—Treatment of Disease
in Children.*

GENTLEMEN—I have now to direct your attention to a most important class of diseases—namely, to quinsies, or diseases of that portion of the digestive organs, designated the throat. The tonsils are liable to inflammation in young infants. The disease is, however, most common to children that are able to walk; as these very often expose themselves, or are imprudently exposed by mothers and nurses to wet and cold.

Amygdalitis, tonsillitis, cynanche-tonsillaris, or inflammatory sore throat, is most common to children, adolescents, and adults. It sometimes terminates in suppuration, and occasionally in gangrene. These terminations are, however, comparatively rare in new born infants. Cynanche or angina is commonly termed quinsey; and this comprises all the forms now mentioned, as well as cynanche, trachealis, or croup, trachitis, cynanche pharyngea maligna, or ulcerated sore throat.

Cynanche and inflammation of the fauces (throat), considered in a general view, affects infants most frequently; it sometimes prevails, as an epidemic, in spring and autumn—seasons remarkable for the vicissitudes of the atmosphere; and it is also observed in some countries more than others. Infants are most commonly affected when suddenly exposed to the impression of cold air, after having been in a warm temperature, or when they repose in moist situations while in a state of perspiration. The sudden application of cold to the feet, the action of a current of cold air on the nape or front of the neck, cold drinks, while the body is heated, or in a state of perspiration, the deglutition of acrid or stimulating substances, walking in a contrary direction to a cold wind, long and loud cries, or singing; every thing that suddenly suppresses transpiration (insensible perspiration), or habitual evacuations, and every thing which directly irritates the air-

passages, may excite inflammation of the the throat, windpipe, and induce quinsies.

The preceding causes may be divided into two classes—the first comprises all those that directly act on the pharyngo-tracheal mucous membrane, or that which lines the throat; and the other, those whose action is on organs which sympathise with it. In the first class are all mechanical or chemical irritants, whose source is within or without the individual; in the second, are cold and moisture, which applied to the skin, suppresses insensible perspiration, and determines blood from the skin to the internal organs and mucous membranes.

Angina is often preceded by cold chills, followed by heat; the infant is restless—it is deprived of appetite and sleep, and it often rejects the breast milk, or any other food it may have taken.

The symptoms now vary according to the seat of the disease. If the tonsils are affected, there is difficult deglutition and respiration; the infant raises its hand to its throat; there is swelling externally, and on looking into the throat, we observe inflammatory redness of the soft palate, tonsils, and all parts that are visible. The mouth and throat are dry in the first stage of the disease, but soon become covered with a tenacious mucus or phlegm, and the inflammation extends along the mucous membrane into the eustachian tube to the ear, in which organ severe pain is occasionally experienced. This is often but not always the case.

The characteristic symptoms of inflammatory sore throat, or to speak scientifically, of guttural or pharyngeal angina, are unusual redness, frequently covered with white spots on the posterior surface of the throat, great difficulty or impossibility of deglutition, the return of drinks or aliments by the nostrils, heat and dryness of the throat, and after some time, an expectoration of viscid, ropy, whitish or yellowish mucosity (phlegm), and finally, acute pain in the eustachian tube and ear, sometimes alteration of the voice, and at the same time a difficulty of articulating sounds. In some cases the voice is altered or suppressed, and there is a complete hoarseness.

In tracheal angina, or cynanche (croup), the inflammation affects the margins of the glottis, the larynx, trachea, and commencement of the bronchiæ. In such cases the respiration is impeded, or difficult, the cough is hoarse, the voice trembling, the expectoration slight, but after some time abundant; the pulse is small and feeble, the patient is anxious and restless, and in extreme cases, there appear to be danger of immediate suffocation. There is always some degree of fever in this disease, and it is, in general, more intense in the evening or night.

The duration of faucial, or guttural angina (sore throat), is more or less prolonged, according to the seat of the disease; the tonsillar or guttural form continues for five or

seven days, while the tracheal or croupal terminates in one, two, or three days.

The first usually terminates by resolution, though occasionally by suppuration: and in adults there may be ulceration or gangrene. When the tonsils suppurate, the abscess bursts into the mouth in most cases, and it may be opened with a sharp pointed bistoury. It often happens that tonsillitis, or the inflammatory sore throat, may become chronic, the affected parts enlarged and indurated, and this state may persist, in grown persons—especially in those of a scrofulous habit—for weeks or months, unless removed by some of the preparations of iodine. I have seen some cases in which the tonsils were so enlarged as to impede deglutition and respiration, and to require tracheotomy. In one case of this description, for which the operation was proposed, an empiric passed the shank of a table spoon into the throat, lacerated the tonsils, caused profuse hæmorrhage, and relieved the patient so much that tracheotomy was rendered unnecessary. In chronic tonsillitis the use of iodine, in the form of gargle, and ointment applied to the throat, is highly advantageous, and generally removes the enlargement of the affected parts. There is not the slightest danger in using the hydriodate of potass dissolved in *distilled* water, and sweetened at the time of taking each dose, in cases of infants. I have found it a most valuable tonic and absorbent in the treatment of every form of scrofula and glandular enlargement in children. You see it employed almost daily at the Free Hospital.

The pharyngeal or guttural angina usually terminates by resolution; and occasionally by abscess. Sir Astley Cooper mentions an instructive case of this description, in his Lectures on Surgery. He opened the abscess, and the operation, with proper constitutional remedies, speedily restored the patient to health. Suppuration is however of rare occurrence. The tracheal or croupal angina may terminate by resolution, when proper remedies are employed, but there is often a copious secretion of mucosity which the infant cannot expectorate, and which may cause suffocation; or coagulable lymph is thrown out on the inflamed mucous surface: this is converted into a false membrane which may partially or totally cover the whole internal surface of the wind-pipe, or render it completely impervious, and thus cause death from suffocation. I shall give a full account of the pathology and treatment of this form of angina, under the head of croup. In some cases an abscess forms, bursts, and causes suffocation; or the ulcerated surface does not cicatrize, as it is constantly irritated by the passage of air into the lungs, and will produce chronic angina, laryngeal or tracheal phthisis, and death, unless tracheotomy be performed. Several cases of this kind in adults have been cured by Mr. Carmichael of Dublin, by the opera-

tion of tracheotomy, of which there is a full account in the Dublin Medical Journal, 1834, vol. 4, and also in my Journal, 1834, vol. 4.

In fine, tracheal angina may terminate in gangrene, though this is of rare occurrence.

Each of these terminations are characterized by peculiar symptoms. Thus we presume that resolution will take place when the disease is slight and properly treated, when the respiration is not much impeded, and when there is expectoration, but this is not to be expected in young infants. These do not expectorate, for when they bring up mucosities by coughing, into the throat, they immediately swallow them. Suppuration is to be feared when the disease is prolonged and does not yield to remedies, when the local pain is acute and throbbing, or when there are rigors or cold shiverings without any evident cause. An abscess is indicated in tonsillitis, when there is swelling, a sense of fluctuation, on pressure made with the finger, a whiteness of some part of the tumour, and finally by purulent expectoration and a cessation of all the symptoms.

There can be no difficulty in detecting induration; the inconvenience arising from it leads us to its immediate discovery. Ulceration is accompanied by painful deglutition and respiration, and may terminate in pharyngeal, laryngeal, tracheal, and bronchial phthisis, according to the seat which the disease occupies. Gangrene is to be dreaded, if the fever is intense, and the pain extremely violent, without any sign of resolution, suppuration, or metastasis; the countenance is sunken, the extremities cold and covered with a clammy perspiration, the pulse is small, soft, frequent and weak, and there is a foetid odour issuing from the mouth. We often observe this train of symptoms in the worst form of scarlatina.

Infants are much more subject to the different species of cynanche, or quinsey, than adults, and are treated with more difficulty, on account of their want of reason, and terror of leeches, venesection, and their repugnance to medicine. Such is an outline of the pathology of angina; and I shall now make some general observations on the treatment.

The *treatment* of cynanche or angina, ought to be more or less active, according to the severity of the symptoms. When the disease is slight in very young infants, there is scarcely a necessity for using medicine. A moderate diet, a mild aperient, confinement to bed, with warm drinks, are generally sufficient to effect a cure. The diet of the wet nurse ought to be changed, and such as would remove all stimulating qualities from the breast milk.

When the infant is one or two years old, and suffers from pain during deglutition, evinced by its crying and raising its hand to its throat, the respiration laborious or diffi-

are covered with a brownish fur, there is a foetid odour from the throat, and all the symptoms of typhus or putrid fever manifest themselves. On the fifth or sixth day the scarlet eruption disappears, leaving the skin of a brown colour; the cuticle peels off in small scales all over the body, and may even separate from the palms of the hands and soles of the feet in some cases, specimens of which I now show you.

Should the symptoms improve, the patient regains his appetite and strength; but it often happens that the convalescence is tedious, there is languor and debility, stiffness of the limbs, frequent pulse, disturbed sleep, loss of appetite, great thirst, scarcity of urine, which are rapidly succeeded by anasarca alone, or combined with ascites or hydrothorax. I have known some of these dropsies occur so early as the tenth day; and others three and four weeks after convalescence, and even when the appetite was good. The morbid change of the skin, which causes the exfoliation or peeling off of the cuticle, must derange transpiration, prevent or impede the cutaneous function, and throw a great quantity of the serous part of the blood into the cellular and serous tissues, and thus gives rise to dropsy, or a preternatural effusion of such fluid in these tissues. Malignant or putrid sore throat, and malignant scarlatina, are now very generally considered the same disease, and are treated in the same manner. Some writers describe them separately; but it will be found, on due consideration, that the symptomatology, pathology, and treatment of both, are precisely the same. This disease may terminate in health or death. The favourable termination is announced by the moderation of the symptoms, and by their remission on the fourth or fifth day. The fever diminishes, the state of the throat is improved on the appearance of the eruption, the cuticle desquamates to a greater or less extent, in most but not in all cases, the sleep and appetite return.

The unfavourable termination is expected when the throat is of a deep red, ash, or purple colour, speedily succeeded by sloughs and deep ulcerations, accompanied by salivation, or a discharge of a corrosive, offensive fluid, some of which is swallowed, irritates the stomach and bowels, and induces violent diarrhoea. These symptoms are attended by great prostration of strength, delirium or coma, difficulty of deglutition and respiration, great anxiety of the countenance, the eruption of a dark colour, and in patches on the second day; or it does not appear at the usual time, or for several days afterwards, which state is often followed by cerebral congestion, the lips, throat, and genitals becoming gangrenous, or passive hæmorrhages issuing from the nostrils, mouth, bowels, or bladder.

In other cases the fever continues after the desquamation; there are glandular

swellings, discharges of purulent matter from the nostrils or ears, anxious difficulty of respiration, stridulous voice, indicating the extension of the inflammation to the larynx and trachea; acute pain in the ear, with deafness, the saliva tinged with blood, or of a dark colour; the skin continuing dry, and covered with a fresh eruption, and there is also an increase of fever. On dissection the fauces or throat, larynx, or trachea, are found intensely inflamed, ulcerated, or gangrenous; and as the respiration was difficult, preventing the return of blood from the head, and through the lungs, we find the brain or lungs congested or inflamed. This form of the disease is most dangerous, and often destroys several children in schools, and sometimes three out of four in a day or two in the same family. It is erroneously stated in some works on the practice of medicine, that scarlatina maligna is seldom fatal, though every observant practitioner can attest the contrary. Common inflammatory sore throat usually yields to antiphlogistic treatment, such as already described, and terminates by resolution, suppuration, or induration.

Gangrenous or malignant sore throat, on the contrary, is much more intense, has a tendency to terminate by superficial or deep-seated ulcerations, sloughing, and the other symptoms already enumerated. The disease is so sudden in its progress that depletion or leeching can seldom be employed, and, according to most practitioners, are injurious. The indications of treatment are 1, to prevent the tendency to gangrene by supporting the strength of the system; 2, to promote the separation of the sloughs, and preserve the healthy state of the fauces. To fulfil the first indication, the use of wine, bark, quinine, ammonia, and nutritious diet is necessary; in fact the same remedies should be employed as in the last stage of typhous or adynamic fever.

The second indication will be accomplished by the employment of stimulant, tonic, and astringent gargles, such as infusion of capsicum, of roses acidulated, solutions of the chlorides of lime and soda, of muriatic acid, of myrrh, or watery extract of cinchona.

Rx. Capsici contusi, gr. iv;
Aque bullientis, ℥ viij;
Mellis rosæ,
Tinct. myrrhæ, ā ā ʒ iv.

Sit gargarisma sæpe usurpandum.

Rx. Infusi rosæ, ʒ iij;
Tinct. myrrhæ, ʒ iij;
Sacchari pur., ʒ v.

Fiat gargarisma in usum.

Rx. Sol. chlor. calcis, ʒ j—lj;
Mucilag. acaciæ, ʒ j;
Aque fontis, ʒ iss;
Syrupi simplicis, ʒ iv.

Rx. Vini rubri Insitan., ʒ vj;
æ, ʒ j.

Misce

These may be injected into the throat with a small syringe, or applied by means of a piece of sponge or lint securely tied to a piece of wood or whalebone.

When the sloughs are formed they are often removed by the frequent use of some one of these gargles, and I have found the chloride the best; but should these fail, the diseased parts may be touched with the *linimentum æruginis*, a strong solution of *alumen*, or sulphuric or muriatic acid, in the proportion of thirty or forty drops in an ounce of honey, or the muriate or nitrate of mercury. During the whole course of the disease the strength ought to be supported with animal jellies, chicken-broth, beef-tea, and vegetable jellies, such as arrow-root, sago, tapioca, &c., with a due proportion of wine, or spirit of any kind diluted with water.

If diarrhœa supervene, it is treated with astringents combined with opium, as directed in the description of that disease.

Hæmorrhages will, in general, be restrained by the use of acetate of lead in extreme cases. This is the best astringent for internal use, according to my experience, and it will be found effectual in most cases of bleeding from the lungs, stomach, intestinal tube, uterus, or bladder of children and in adults. The following formula may be used in cases of infants under a year old in passive hæmorrhages:—

Rx. Plumbi acetatis, gr. ss;
Acidi acet. dil., *m* iij;
Aque destillatæ, ʒ j;
Liquoris opii sed., *m* iij—vj;
Syrupi simplicis, ʒ j.

Dosis ʒ j secundâ vel tertiâ horâ.

The external application of vinegar and water, or of the compound solution of *alumen* by means of lint, may be applied to the different outlets of the body.

Sinapisms, blisters, and stimulant liniments are useful, though sometimes followed by gangrene. It is highly beneficial to sprinkle the apartment and bed clothes with a weak solution of chloride of lime, in the proportion of one drachm or about a small tea-spoonful of the powder in half a pint of water. This solution is preferable to that of the chloride of soda, which gives out a more unpleasant odour, that impedes the respiration and induces a sense of suffocation. To obviate the inconvenience of this odour there should be free ventilation, or a current of pure air must be occasionally admitted into the apartment. When the heat of the body is intense in the first stage of the disease, it is to be moderated by sponging the body with cold water and vinegar, or affusing cold water over the naked body. Dr. James Home, of Edinburgh, employed this remedy in measles, scarlatina, and small pox, both before and after the appearance of the eruption. If the lower extremities be cold, they ought to be immersed in warm

water during the cold affusion, or dash, as it is now termed. The bowels should be opened moderately; the cold affusion may be repeated for six or eight minutes, provided the temperature of the body is higher than natural. When the patient is of a full habit, we may employ venesection during the first two days; but in some cases there is a well-marked inclination to putrescency, even on the first day, and detraction of blood is totally inadmissible. Some practitioners advise an emetic at first, in preference to all other remedies, and after its operation they order purgatives in divided doses. These last should be prescribed with caution, on account of the tendency to diarrhœa in this disease. A purgative, however, is necessary, and generally useful at the commencement of the disease, but it is dangerous when great debility or sloughing has taken place.

The malignant sore throat is more sudden and dangerous during some seasons than in others, and will require the application of leeches to the throat, which may prevent gangrene. We also observe one child affected with inflammatory sore throat which, if neglected or not, treated with leeches, purgation, &c., will speedily end in the malignant or gangrenous; while we often see another child in the same or in an adjoining house in the same condition as the former; but by leeching, purging, &c., a cure is effected without any appearance of gangrene. When anasarca, ascites, or hydrothorax supervenes, the following remedies will be found effectual in a majority of cases.

It is scarcely necessary to observe that the dose must be increased or diminished, according to the development and strength of constitution.

Rx. Pulv. jalapæ, c. ʒj—3 ss;
Hydrarg. subm. ʒss—ʒj;
Pulveris scillæ,
—— digitalis, ā ā gr. j—ij;
—— cinnam. comp., ʒj;
—— sacchari puri, 3 ss.

Tere in time et divide in chartulas decem, quarum capiat unam mane nocteque nisi alvus nimis soluta sit.

Children from two to four years of age are generally relieved by this medicine. They may take a diuretic mixture at the same time.

Rx. Potassæ acetatis, ʒss—j;
Syrupi simplicis, ʒ iij;
Spiritus æther. nitros. *mxx*—3 ss.

Dosis ʒ j bis vel ter in die.

In extremely bad cases, when the foregoing remedies fail, the following will prove efficacious, but the greatest care is necessary not to allow it to act too powerfully.

Rx. Elaterii extracti, gr. j—jss;
Hydrargyri submur., gr. xij—xx;
Pulv. cinnamom. comp., ʒj—3 ss;
—— sacchari purificati, 3 ss—ʒj.

In pulveris xij vel xvij, partitione ex-

actissimè facta, divide, ex quibus sumatur unus bis vel ter de die, donec alvus copiose responderit.

Malignant sore throat, or scarlatina, is a most fatal disease, both to children and adults, and often destroys a great number of the former in schools. This is well known to all observant physicians, and the ablest acknowledge it. Yet we occasionally hear some practitioners asserting, in our medical societies, that they have never lost a single case of these; but this only proves their limited experience in treating it. It has fallen to my lot to see two and three dead children in one family, on being called in to treat one or two surviving ones; and I have also seen two adults, aged nineteen and twenty, lying dead at the same time, in consequence of scarlatina maligna, while a third, aged eighteen years, was dangerously affected. Another individual, at the adult age, was a month convalescent, his appetite had returned, and he had dined heartily at noon. He became suddenly anasarctous in a few hours afterwards, was seized with convulsions, for which he was bled, cupped, his head shaved and leeches applied, his bowels freely purged with croton oil, mustard cataplasms applied to his feet, and in spite of the most active treatment, he was dead at two o'clock the following morning.

I was once requested to attend a coroner's inquest, held on the bodies of two children, under three years of age, who died suddenly. But it was rumoured they had been poisoned. It was proved in evidence that they had been seen in apparent health in the morning, though dead in the evening. The bodies were carefully examined, and the morbid appearances were a dark redness about the lower part of the pharynx, which extended into the windpipe about an inch in one and an inch and a half in the other. There was great cerebral congestion in both, and no vestige of eruption on the skin. On inquiring if there were other children in the family, and whether they were well, I was informed that there was one, and that it was ill. On examination it presented the usual symptoms of scarlatina. It was the youngest of the three. I cannot state whether it recovered or died, as I did not attend it. Observation has proved that young infants may labour under the simple or mild form of scarlatina, and older ones of the same family will be attacked with the anginal or malignant form of the disease. The jury found a verdict, that the children died a natural death.

Now these, and numerous other cases I might mention, confirm in my mind the opinions of Sydenham, Huxham, and others, as to the fatality of this disease.

Some of the German writers, among whom is Hahneman, extol belladonna, as a preventive of scarlatina. The medicine is employed as follows:

Rx. Extracti belladon. gr. ij;
Aquæ destillatæ, ʒ j.

Misce.

The dose is from one to five drops four times a day, to children under six years of age, and to those who are older, from six to ten drops.

I have not employed this remedy in a sufficient number of cases to justify me in offering an opinion of its value. Dr. Mac-michael has written in favour of it; but I am not aware that any other British physician has found it a prophylactic.

Rebiews.

On the Medical Properties of the Natural Order Ranunculaceæ: and more particularly on the uses of Sabadilla Seeds, Delphinium Staphisagria, and Aconitum Napellus, and their Alkaloids Veratria, Sabadilline, Delphinia and Aconitine. By A. Turnbull, M. D. London: Longman and Co. 1835.

THIS volume presents, in a connected form, the information contained in the several treatises already published by Dr. Turnbull, with some additional cases and illustrations. We are happy to find in the preface the following passage.

"The author would caution the profession against expecting too much from the employment of these remedies. In some cases they have given only a temporary relief, whilst in others they have had no effect: but generally speaking he has found them of much more advantage in the treatment of a very distressing class of affections, than any means hitherto discovered, and on this account he would recommend their use."

It is just possible that on former occasions our author may have been himself instrumental in awakening too sanguine expectations of success from the remedies in question.

Among the most striking examples of the efficacy of Dr. Turnbull's practice, is the following case of neuralgia, in which a cure seems to have been effected by the preparations of aconite, after all other remedies had failed. The case is that of Samuel Best, a journeyman printer, aged 32. The early history and treatment of the disease is recorded in a clinical lecture of Dr. Elliotson's, published in the *Lancet* of December 8th, 1832, to which we refer the reader.

"This patient came under treatment,"

says Dr. Turnbull, "about the end of October, 1834, and in detailing his subsequent progress, I shall confine myself to a weekly report, in order to avoid repetition. The history which he gave of his case, was substantially the same as that quoted above. He stated, that since December 1832, he had been suffering in an extreme degree, that he had been in the hospital about eighteen months subsequent to that date, and had been using every remedy that was likely to afford relief, but in vain. He stated, that the only ease he had, was from taking large doses of morphia, to the extent of from ten to twenty grains a-day; but that even these procured him only a few hours of broken rest.

"The pain was seated in the fingers and wrist of the left hand, but particularly in the middle finger, through which, and along the wrist, it darted like a stab with a knife. He could not bear the slightest degree of motion in any of the joints, either of the fingers or wrist, without bringing on a violent paroxysm of pain, and for the same reason he could not suffer the middle finger to be touched. His nails were long and curved. The ring and little fingers were benumbed and painful, and a similar feeling extended up the arm as far as the shoulder. He had had no pain in his face for three months, but he stated that the pain in the hand, at times, almost deprived him of his senses. His appearance was wretched, and indicated the sufferings he endured.

"*First Week.*—Under these circumstances, he was ordered to rub the saturated tincture of the root of the *Aconitum Napellus*, prepared as already directed, for twenty minutes, along the back of the hand and fingers. The friction at first gave him extreme pain, but towards the end of the time he could bear it better, and it gave rise to a sensation of heat in the affected finger, which was attended by a marked diminution of the pain. He was ordered to repeat the friction for ten minutes, twice a day, and to take six drops of tincture of Aconite, prepared for internal use, every four hours, in water. The immediate effect of this treatment was, to enable the patient to do without his daily dose of twelve grains of acetate of morphia, which he had been in the habit of taking for many months before.

"The friction excited sensations of heat and numbness in the hand, and could be borne with greater ease at each successive application, and he could sleep three or four hours at a time without interruption. The dose of the tincture was gradually augmented in the course of this week, to ten drops every four hours, and the friction was ordered to be used till heat and tingling were produced, whenever the pain came on.

"The pain was removed every time the

tincture was applied, and the quantity taken internally occasioned tingling and numbness in the extremities, and acted as a diuretic. The patient slept six or seven hours at a time: he had intervals of perfect freedom from pain, with distinct paroxysms, varying in intensity: and on the seventh day, from the commencement of the treatment, he was so far recovered, that he could bear to have his nails cut, which had not been the case for nine months previously.

"*Second Week.*—During the next seven days, the same treatment was continued. He took the tincture internally, in nearly the same dose, and rubbed it on the affected joints, whenever the pain came on. Under these means, the accessions of pain gradually diminished in intensity, and the intervals of complete relief became longer, so that at the end of this week, he had little pain except on motion.

"*Third Week.*—This week he was directed to continue the same treatment, to use the affected joints as much as he could: this, however, brought on attacks of pain, but these were at once removed by frictions, continued until tingling was produced.

"*Fourth Week.*—On the first day of this week, he was directed to substitute for the tincture, the following ointment.

Rx. Aconitinæ. gr. ii;

Adipis. 3 i. ut fiat unguent.

and to rub with it whenever he had pain.

"The tingling caused by this ointment was very considerable, and generally lasted three or four hours afterwards. He had occasion to use it three times a day, and one grain of Aconitine was added to the second prescription, as the first began to lose its effect. In a day or two he discontinued the tincture internally, and was directed to use the ointment of the ammoniated extract of Aconite, made according to the formula already given, in order to try the comparative effect of this application. In this case it was found to produce a more powerful sensation in the parts than the Aconitine itself, and to be very useful in removing attacks of pain when they came on. He used nothing except the remedies mentioned above, and at the end of four weeks and three days from the commencement of the treatment, he was totally free of pain, and has continued to be so ever since. He can use his hand with perfect freedom, but complains of its not being so strong as the other, probably on account of his having been obliged to keep it for four years almost in the same position.

"On the 6th of January last, he had an attack of pain in the right cheek, on account of his having been exposed to the effects of cold; this was, however, immediately removed by the Aconitine ointment; he has had no return of it, and is at present in excellent health."

We have no doubt that a fair trial will be

given by the profession to the medicines recommended by Dr. Turnbull; and should they be found to possess even half the efficacy supposed, they will be of more value than most other articles of the *materia medica*.

—o—

Foreign Medicine.

M. Rostan's Clinical Remarks on the Diseases of the Nervous Centres (continued from p. 562).

Sanguineous Congestion.—The *first* form alluded to, which is described by M. Andral, is only cerebral hyperemy. The *second* exhibits all the characters of congestion, of apoplexy. The *third* form is congestion with general or local paralysis, which M. Rostan does not think should be separated from the second, since he says, it is only one degree more of the same disease, and it is inconvenient to multiply distinctions when the morbid phenomena do not present well marked shades. In the *fourth* form, at the same time that there is loss of sensation, irregular convulsive movements supervene; this he considers to be connected with some process of phlegmasia and irritation, as well as compression; altogether it is a complex state. In the *fifth* form the intellectual faculties retain their integrity, but the phenomena of paralysis are exhibited from the very first; in this case M. R. thinks there is not simple congestion, but a slight hæmorrhage, with laceration of the encephalic substance; such a condition he found to obtain in the case of the celebrated Pinel. That professor had been seized, according to M. Rostan's personal knowledge, with eight attacks of paralysis, similar to those which M. Andral considers to be dependent on encephalic congestion. Eight times he saw the muscular contractility suspended, more or less completely, in one part of the body; and when he died, it was readily ascertained in the dissection, that there existed eight cysts that evidently corresponded with the anterior events. To this case many similar ones might be added, which shew that we should scruple to refer to simple cerebral congestion, the phenomena described in M. Andral's fifth form of that disease.

The *sixth* form is characterized by convulsive phenomena without antecedent loss of sense; to this the observations on the fourth form may apply.

In the *seventh* form there is furious delirium; this M. Rostan does not consider as referable to mere sanguineous overflow, but as the result of an inflammatory irritation. This applies still more strongly to the non-admission of the *eighth* form of congestion that has been advanced—a form that, even according to M. Andral, is accompanied with continued fever.

For a purely systematic purpose it has latterly been attempted to refer the phenomena of congestion to one sole physiological perversion, and to elucidate the proximate cause of the sanguineous fluxions that take place towards the head. In doing this, purely hypothetical considerations take the place of facts, on which account it is unnecessary to dwell on them.

Passing to the study of the causes of the disease in question, M. Rostan mentioned in succession—dilating on each etiological circumstance in a way we cannot follow in this sketch—the sanguineous constitution, youth, adult age, excessive eating, particularly when the exits are small, the use of some excitants, as spirits, coffee, &c., striking increase or decrease of temperature, watching, violent exercise, circular movements, immoderate venery, &c.

A peculiar nervous state simulates encephalic congestion; but a just appreciation of the circumstances in which it is developed facilitates the diagnosis. But there are other diseases accompanied with loss of sense and relaxation of the limbs—hæmorrhage, softening of the brain, meningitis, asphyxia, and syncope, induce similar phenomena; these should be carefully distinguished from true congestion. In apoplexy it often happens that the diagnosis is impossible, and the progress of the disease alone affords light to the practitioner.

Softening of the brain and meningitis are preceded by very peculiar phenomena, more or less strongly marked, and which will hereafter be mentioned. In asphyxia, the actual cause of the symptoms may almost always be easily recognized. In syncope, the paleness of the face and suspension of the circulation remove all doubt. If, in the enumeration of the morbid states that may be confounded with cerebral congestion, mention has not been made of narcotism and drunkenness, it is because these two conditions are evidently owing to an afflux of blood towards the brain, that is dependant on particular influences.

The serious nature of the affection we have described varies, according to its intensity, its duration, progress, the rare or frequent return of it, and a thousand other circumstances. In general it is of slight consequence, more especially if the disease has been well ascertained and combated from the commencement.

Dissection of an individual that has died by encephalic congestion discloses the following alterations:—The integuments of the face and cranium are considerably injected; the sinus of the dura mater distended with black blood, varying in quantity and viscosity, and sometimes coagulated. The pia mater is very much congested; the cortical substance of the brain has a brownish yellow tinge: incision of the medullary substance shews a punctuate condition of it, arising from the issue from the capillaries of

blood that distended them; the choroid plexuses are likewise considerably injected. A limpid, transparent, colourless or slightly roseate serosity is exhaled from the plates of the dura mater, on the surface of the convolutions, or even from the ventricular spaces which it distends.

In the face of such alterations as these, men that shew themselves averse to every scientific progression have asserted that anatomical examination will never give any account of the varied phenomena that are manifested during life. Strictly speaking, this objection may have some foundation, but is no argument against the endeavour to advance our knowledge of the diseases of the nervous centres. Are we any more advanced in the explanation of the varied phenomena that characterise affections of the thorax? and yet who will deny the importance of the modern investigations of them—who will deny the precision of the investigating means presented to us by Avenbrugger and Laennec?

Bloodlettings, proportioned to the strength of the subject and the intensity of the disease constitute the basis of the treatment of encephalic congestions; opening the jugular may be advantageously practised. Abstinence from food secures such means most felicitously; mild drinks are indicated. Above all, care must be had to maintain the patient in a posture that shall keep the head always higher than the rest of the body. If mischief happens, notwithstanding gentle derivatives, mild purgation of the intestinal canal may be advantageously given.

Meningitis.—This is a disease the existence of which is frequently obscure, which has no pathognomonic symptom that allows of its positive detection, and which nevertheless may bring on serious consequences if not properly diagnosticated in its commencement. This difficulty of diagnosis will not be wondered at if we consider the obscurity that still reigns over the functions of the meninges, and the varied and slightly characteristic disorders which alterations of them induce. In fact, it is only through the medium of the brain that the lesions of the meninges are made known to the observer, from which it may be *à priori* concluded that the diseases of the cerebral envelopes have a striking analogy with the affections of the brain itself.

But, before proceeding further in the subject, it is better to establish whether the pia mater and arachnoid are capable of being separately affected. Though formerly a matter of much controversy, it seems now to be settled in the affirmative. Pathological anatomy shews us the arachnoid sometimes covered with a plastic exudation, having all the characters of false membrane; it shews us also adhesions of varied extent and intimacy between the two folds of the enveloping serous membrane, without, however, any participation of the subjacent cel-

lular tissue in this pathological process. It must, however, be allowed that these facts, otherwise having all the appearance of truth, are not very numerous, and that it is impossible during life to pronounce with certainty on the existence of alterations thus separately attacking the arachnoid. On the other hand, it often is the case that the pia mater and the subserous cellular tissue participate in the inflammation of the enveloping membrane, which makes it necessary in a practical lecture to confound the diseases of both the organs in question.

Another question that presents itself is, whether the membranes can be inflamed independently of any suffering of the brain. Probably dissection can answer this in the affirmative. The practitioner, however, must answer in the negative, for his sole object is not to observe the lesions of the corpse, but those of the living body, and looking to the principal symptoms of meningitis, he cannot refuse to admit a state of direct or sympathetic suffering of the nervous substance.

M. Rostan first analyses the value of each particular symptom, subsequently grouping them so as to display the progress and collective phenomena of meningitis. Headache is a very frequent symptom, being present in two-thirds or three-fourths of the meningeal inflammations; it is not characteristic of this or that alteration in particular. It generally passes from one point to another, but always remains for some time in one: sometimes it is fixed and persists in one only; at other times it is only periodical. In some cases it corresponds to the affected point of the arachnoid; at others it is distant from it; its intensity is for the most part considerable, and often so acute is it that the patients cry out in agony. This last character is important, for very few diseases exhibit such intense headache. Sometimes the latter alone announces a phlegmasia of the meninges; at other times it is associated with other symptoms. It always shews the invasion of the disease: it sometimes disappears in the course of it, a sign that is not always favourable, being frequently dependent on a peculiar state of oppression of the sensorial functions, itself the expression of very serious organic modifications.

In meningitis, cutaneous sensibility is sometimes exalted, more frequently diminished, and sometimes even entirely annihilated, particularly when the disease has run its course, and threatens the speedy dissolution of the patient.

The sight may undergo similar modifications, but some important phenomena are attached to it. Thus we may observe indifferently fixation and immobility of the globe of the eye, in this or that position, or regular movements, something resembling the vibrations of a pendulum, or abrupt,

given by the profession to the medicines recommended by Dr. Turnbull; and should they be found to possess even half the efficacy supposed, they will be of more value than most other articles of the *materia medica*.

Foreign Medicine.

M. Rostan's Clinical Remarks on the Diseases of the Nervous Centres (continued from p. 562).

Sanguineous Congestion.—The *first* form alluded to, which is described by M. Andral, is only cerebral hyperemy. The *second* exhibits all the characters of congestion, of apoplexy. The *third* form is congestion with general or local paralysis, which M. Rostan does not think should be separated from the second, since he says, it is only one degree more of the same disease, and it is inconvenient to multiply distinctions when the morbid phenomena do not present well marked shades. In the *fourth* form, at the same time that there is loss of sensation, irregular convulsive movements supervene; this he considers to be connected with some process of phlegmasia and irritation, as well as compression; altogether it is a complex state. In the *fifth* form the intellectual faculties retain their integrity, but the phenomena of paralysis are exhibited from the very first; in this case M. R. thinks there is not simple congestion, but a slight hæmorrhage, with laceration of the encephalic substance; such a condition he found to obtain in the case of the celebrated Pinel. That professor had been seized, according to M. Rostan's personal knowledge, with eight attacks of paralysis, similar to those which M. Andral considers to be dependent on encephalic congestion. Eight times he saw the muscular contractility suspended, more or less completely, in one part of the body; and when he died, it was readily ascertained in the dissection, that there existed eight cysts that evidently corresponded with the anterior events. To this case many similar ones might be added, which shew that we should scruple to refer to simple cerebral congestion, the phenomena described in M. Andral's fifth form of that disease.

The *sixth* form is characterized by convulsive phenomena without antecedent loss of sense; to this the observations on the fourth form may apply.

In the *seventh* form there is furious delirium; this M. Rostan does not consider as referable to mere sanguineous overflow, but as the result of an inflammatory irritation. This applies still more strongly to the non-admission of the *eighth* form of congestion that has been advanced—a form that, even according to M. Andral, is accompanied with continued fever.

For a purely systematic purpose it has latterly been attempted to refer the phenomena of congestion to one sole physiological perversion, and to elucidate the proximate cause of the sanguineous fluxions that take place towards the head. In doing this, purely hypothetical considerations take the place of facts, on which account it is unnecessary to dwell on them.

Passing to the study of the causes of the disease in question, M. Rostan mentioned in succession—dilating on each etiological circumstance in a way we cannot follow in this sketch—the sanguineous constitution, youth, adult age, excessive eating, particularly when the exits are small, the use of some excitants, as spirits, coffee, &c., striking increase or decrease of temperature, watching, violent exercise, circular movements, immoderate venery, &c.

A peculiar nervous state simulates encephalic congestion; but a just appreciation of the circumstances in which it is developed facilitates the diagnosis. But there are other diseases accompanied with loss of sense and relaxation of the limbs—hæmorrhage, softening of the brain, meningitis, asphyxia, and syncope, induce similar phenomena; these should be carefully diagnosed from true congestion. In apoplexy it often happens that the diagnosis is impossible, and the progress of the disease alone affords light to the practitioner.

Softening of the brain and meningitis are preceded by very peculiar phenomena, more or less strongly marked, and which will hereafter be mentioned. In asphyxia, the actual cause of the symptoms may almost always be easily recognized. In syncope, the paleness of the face and suspension of the circulation remove all doubt. If, in the enumeration of the morbid states that may be confounded with cerebral congestion, mention has not been made of narcotism and drunkenness, it is because these two conditions are evidently owing to an afflux of blood towards the brain, that is dependant on particular influences.

The serious nature of the affection we have described varies, according to its intensity, its duration, progress, the rare or frequent return of it, and a thousand other circumstances. In general it is of slight consequence, more especially if the disease has been well ascertained and combated from the commencement.

Dissection of an individual that has died by encephalic congestion discloses the following alterations:—The integuments of the face and cranium are considerably injected; the sinus of the dura mater distended with black blood, varying in quantity and viscosity, and sometimes coagulated. The pia mater is very much congested; the cortical substance of the brain has a brownish yellow tinge; incision of the medullary substance shews a punctuate condition of it, arising from the issue from the capillaries of

blood that distended them; the choroid plexuses are likewise considerably injected. A limpid, transparent, colourless or slightly roseate serosity is exhaled from the plates of the dura mater, on the surface of the convolutions, or even from the ventricular spaces which it distends.

In the face of such alterations as these, men that shew themselves averse to every scientific progression have asserted that anatomical examination will never give any account of the varied phenomena that are manifested during life. Strictly speaking, this objection may have some foundation, but is no argument against the endeavour to advance our knowledge of the diseases of the nervous centres. Are we any more advanced in the explanation of the varied phenomena that characterise affections of the thorax? and yet who will deny the importance of the modern investigations of them—who will deny the precision of the investigating means presented to us by Avenbrugger and Laennec?

Bloodlettings, proportioned to the strength of the subject and the intensity of the disease constitute the basis of the treatment of encephalic congestions; opening the jugular may be advantageously practised. Abstinence from food secures such means most felicitously; mild drinks are indicated. Above all, care must be had to maintain the patient in a posture that shall keep the head always higher than the rest of the body. If mischief happens, notwithstanding gentle derivatives, mild purgation of the intestinal canal may be advantageously given.

Meningitis.—This is a disease the existence of which is frequently obscure, which has no pathognomonic symptom that allows of its positive detection, and which nevertheless may bring on serious consequences if not properly diagnosed in its commencement. This difficulty of diagnosis will not be wondered at if we consider the obscurity that still reigns over the functions of the meninges, and the varied and slightly characteristic disorders which alterations of them induce. In fact, it is only through the medium of the brain that the lesions of the meninges are made known to the observer, from which it may be *à priori* concluded that the diseases of the cerebral envelopes have a striking analogy with the affections of the brain itself.

But, before proceeding further in the subject, it is better to establish whether the pia mater and arachnoid are capable of being separately affected. Though formerly a matter of much controversy, it seems now to be settled in the affirmative. Pathological anatomy shews us the arachnoid sometimes covered with a plastic exudation, having all the characters of false membrane; it shews us also adhesions of varied extent and intimacy between the two folds of the enveloping serous membrane, without, however, any participation of the subjacent cel-

lular tissue in this pathological process. It must, however, be allowed that these facts, otherwise having all the appearance of truth, are not very numerous, and that it is impossible during life to pronounce with certainty on the existence of alterations thus separately attacking the arachnoid. On the other hand, it often is the case that the pia mater and the subserous cellular tissue participate in the inflammation of the enveloping membrane, which makes it necessary in a practical lecture to confound the diseases of both the organs in question.

Another question that presents itself is, whether the membranes can be inflamed independently of any suffering of the brain. Probably dissection can answer this in the affirmative. The practitioner, however, must answer in the negative, for his sole object is not to observe the lesions of the corpse, but those of the living body, and looking to the principal symptoms of meningitis, he cannot refuse to admit a state of direct or sympathetic suffering of the nervous substance.

M. Rostan first analyses the value of each particular symptom, subsequently grouping them so as to display the progress and collective phenomena of meningitis. Headache is a very frequent symptom, being present in two-thirds or three-fourths of the meningeal inflammations; it is not characteristic of this or that alteration in particular. It generally passes from one point to another, but always remains for some time in one: sometimes it is fixed and persists in one only; at other times it is only periodical. In some cases it corresponds to the affected point of the arachnoid; at others it is distant from it; its intensity is for the most part considerable, and often so acute is it that the patients cry out in agony. This last character is important, for very few diseases exhibit such intense headache. Sometimes the latter alone announces a phlegmasia of the meninges; at other times it is associated with other symptoms. It always shews the invasion of the disease: it sometimes disappears in the course of it, a sign that is not always favourable, being frequently dependent on a peculiar state of oppression of the sensorial functions, itself the expression of very serious organic modifications.

In meningitis, cutaneous sensibility is sometimes exalted, more frequently diminished, and sometimes even entirely annihilated, particularly when the disease has run its course, and threatens the speedy dissolution of the patient.

The sight may undergo similar modifications, but some important phenomena are attached to it. Thus we may observe indifferently fixation and immobility of the globe of the eye, in this or that position, or regular movements, something resembling the vibrations of a pendulum, or abrupt,

given by the profession to the medicines recommended by Dr. Turnbull; and should they be found to possess even half the efficacy supposed, they will be of more value than most other articles of the *materia medica*.

—o—

Foreign Medicine.

M. Rostan's Clinical Remarks on the Diseases of the Nervous Centres (continued from p. 562).

Sanguineous Congestion.—The *first* form alluded to, which is described by M. Andral, is only cerebral hyperemia. The *second* exhibits all the characters of congestion, of apoplexy. The *third* form is congestion with general or local paralysis, which M. Rostan does not think should be separated from the second, since he says, it is only one degree more of the same disease, and it is inconvenient to multiply distinctions when the morbid phenomena do not present well marked shades. In the *fourth* form, at the same time that there is loss of sensation, irregular convulsive movements supervene; this he considers to be connected with some process of phlegmasia and irritation, as well as compression; altogether it is a complex state. In the *fifth* form the intellectual faculties retain their integrity, but the phenomena of paralysis are exhibited from the very first; in this case M. R. thinks there is not simple congestion, but a slight hæmorrhage, with laceration of the encephalic substance; such a condition he found to obtain in the case of the celebrated Pinel. That professor had been seized, according to M. Rostan's personal knowledge, with eight attacks of paralysis, similar to those which M. Andral considers to be dependent on encephalic congestion. Eight times he saw the muscular contractility suspended, more or less completely, in one part of the body; and when he died, it was readily ascertained in the dissection, that there existed eight cysts that evidently corresponded with the anterior events. To this case many similar ones might be added, which shew that we should scruple to refer to simple cerebral congestion, the phenomena described in M. Andral's fifth form of that disease.

The *sixth* form is characterized by convulsive phenomena without antecedent loss of sense; to this the observations on the fourth form may apply.

In the *seventh* form there is furious delirium; this M. Rostan does not consider as referable to mere sanguineous overflow, but as the result of an inflammatory irritation. This applies still more strongly to the non-admission of the *eighth* form of congestion that has been advanced—a form that, even according to M. Andral, is accompanied with continued fever.

For a purely systematic purpose it has latterly been attempted to refer the phenomena of congestion to one sole physiological perversion, and to elucidate the proximate cause of the sanguineous fluxions that take place towards the head. In doing this, purely hypothetical considerations take the place of facts, on which account it is unnecessary to dwell on them.

Passing to the study of the causes of the disease in question, M. Rostan mentioned in succession—dilating on each etiological circumstance in a way we cannot follow in this sketch—the sanguineous constitution, youth, adult age, excessive eating, particularly when the exits are small, the use of some excitants, as spirits, coffee, &c., striking increase or decrease of temperature, watching, violent exercise, circular movements, immoderate venery, &c.

A peculiar nervous state simulates encephalic congestion; but a just appreciation of the circumstances in which it is developed facilitates the diagnosis. But there are other diseases accompanied with loss of sense and relaxation of the limbs—hæmorrhage, softening of the brain, meningitis, asphyxia, and syncope, induce similar phenomena; these should be carefully distinguished from true congestion. In apoplexy it often happens that the diagnosis is impossible, and the progress of the disease alone affords light to the practitioner.

Softening of the brain and meningitis are preceded by very peculiar phenomena, more or less strongly marked, and which will hereafter be mentioned. In asphyxia, the actual cause of the symptoms may almost always be easily recognized. In syncope, the paleness of the face and suspension of the circulation remove all doubt. If, in the enumeration of the morbid states that may be confounded with cerebral congestion, mention has not been made of narcotism and drunkenness, it is because these two conditions are evidently owing to an afflux of blood towards the brain, that is dependant on particular influences.

The serious nature of the affection we have described varies, according to its intensity, its duration, progress, the rare or frequent return of it, and a thousand other circumstances. In general it is of slight consequence, more especially if the disease has been well ascertained and combated from the commencement.

Dissection of an individual that has died by encephalic congestion discloses the following alterations:—The integuments of the face and cranium are considerably injected; the sinus of the dura mater distended with black blood, varying in quantity and viscosity, and sometimes coagulated. The pia mater is very much congested; the cortical substance of the brain has a brownish yellow color, and the medullary substance is in a more inctuate condition of it, and the capillaries of

blood that distended them; the choroid plexuses are likewise considerably injected. A limpid, transparent, colourless or slightly roseate serosity is exhaled from the plates of the dura mater, on the surface of the convolutions, or even from the ventricular spaces which it distends.

In the face of such alterations as these, men that shew themselves averse to every scientific progression have asserted that anatomical examination will never give any account of the varied phenomena that are manifested during life. Strictly speaking, this objection may have some foundation, but is no argument against the endeavour to advance our knowledge of the diseases of the nervous centres. Are we any more advanced in the explanation of the varied phenomena that characterise affections of the thorax? and yet who will deny the importance of the modern investigations of them—who will deny the precision of the investigating means presented to us by Avenbrugger and Laennec?

Bloodlettings, proportioned to the strength of the subject and the intensity of the disease constitute the basis of the treatment of encephalic congestions; opening the jugular may be advantageously practised. Abstinence from food seconds such means most felicitously; mild drinks are indicated. Above all, care must be had to maintain the patient in a posture that shall keep the head always higher than the rest of the body. If mischief happens, notwithstanding gentle derivatives, mild purgation of the intestinal canal may be advantageously given.

Meningitis.—This is a disease the existence of which is frequently obscure, which has no pathognomonic symptom that allows of its positive detection, and which nevertheless may bring on serious consequences if not properly diagnosticated in its commencement. This difficulty of diagnosis will not be wondered at if we consider the obscurity that still reigns over the functions of the meninges, and the varied and slightly characteristic disorders which alterations of them induce. In fact, it is only through the medium of the brain that the lesions of the meninges are made known to the observer, from which it may be *a priori* concluded that the diseases of the cerebral envelopes have a striking analogy with the affections of the brain itself.

But, before proceeding further in the subject, it is better to establish whether the pia mater and arachnoid are capable of being separately affected. Though formerly a matter of much controversy, it seems now to be settled in the affirmative. Pathological anatomy shews us the arachnoid sometimes covered with a plastic exudation, having all the characters of false membrane; it shews us also adhesions of varied extent and intimacy between the two folds of the enveloping serous membrane, without, however, any participation of the subjacent cel-

lular tissue in this pathological process. It must, however, be allowed that these facts, otherwise having all the appearance of truth, are not very numerous, and that it is impossible during life to pronounce with certainty on the existence of alterations thus separately attacking the arachnoid. On the other hand, it often is the case that the pia mater and the subserous cellular tissue participate in the inflammation of the enveloping membrane, which makes it necessary in a practical lecture to confound the diseases of both the organs in question.

Another question that presents itself is, whether the membranes can be inflamed independently of any suffering of the brain. Probably dissection can answer this in the affirmative. The practitioner, however, must answer in the negative, for his sole object is not to observe the lesions of the corpse, but those of the living body, and looking to the principal symptoms of meningitis, he cannot refuse to admit a state of direct or sympathetic suffering of the nervous substance.

M. Rostan first analyses the value of each particular symptom, subsequently grouping them so as to display the progress and collective phenomena of meningitis. Headache is a very frequent symptom, being present in two-thirds or three-fourths of the meningeal inflammations; it is not characteristic of this or that alteration in particular. It generally passes from one point to another, but always remains for some time in one: sometimes it is fixed and persists in one only; at other times it is only periodical. In some cases it corresponds to the affected point of the arachnoid; at others it is distant from it; its intensity is for the most part considerable, and often so acute is it that the patients cry out in agony. This last character is important, for very few diseases exhibit such intense headache. Sometimes the latter alone announces a phlegmasia of the meninges; at other times it is associated with other symptoms. It always shews the invasion of the disease: it sometimes disappears in the course of it, a sign that is not always favourable, being frequently dependent on a peculiar state of oppression of the sensorial functions, itself the expression of very serious organic modifications.

In meningitis, cutaneous sensibility is sometimes exalted, more frequently diminished, and sometimes even entirely annihilated, particularly when the disease has run its course, and threatens the speedy dissolution of the patient.

The sight may undergo similar modifications, but some important phenomena are attached to it. Thus we may observe indifferently fixation and immobility of the globe of the eye, in this or that position, or regular movements, something resembling the vibrations of a pendulum, or abrupt,

irregular, almost infinitely varying agitations of it. The pupil also undergoes modifications, being sometimes strongly contracted, and scarcely admitting the rays of light, at other times considerably dilated, and motionless, notwithstanding the transitions from darkness to light.

These physiological perversions may be confined to a single eye, or be present in both simultaneously. The exertion of the function of vision may be painful to the patient, in consequence of its exaltation: on the other hand, the function is sometimes diminished, perverted, abolished. The patients occasionally labour under the most extraordinary hallucinations, sometimes seeing only the half of objects, at others, beholding them double.

Similar perversions of hearing occur; but we pass to the perversion of motility. At the commencement of meningitis the patients are frequently seized with a general or partial agitation, which, as it continues some time severely, cannot fail to engage the attention; to this the name of jactation has been given by authors. The most varied acts arise from this necessity for movement that seizes on the patients. Sometimes the head only turns in a rotatory way; more rarely it is the trunk that is subjected to the changes of position, or the jaws are alternately separated and joined—an act known by the name of *machonnement*. Occasionally the tendons of the fore-arm are alternately rigid and relaxed, constituting twitchings: and sometimes the limbs are shaken by a peculiar tremor that causes every movement to be hesitating. Finally, partial or general contractions, such as are observed in tetanus, are manifested, and announce a lesion of the encephalic substance.

These disorders sometimes become suddenly driven to the highest pitch of intensity. The muscles of relation contract with extraordinary energy, then are utterly relaxed; contract again, and so on, without any fixed periods, forming convulsions. Though mostly present, it sometimes happens that the muscular motility is diminished in the course of meningitis, or even entirely abolished, betokening lesion of the cerebral substance, or, at least, compression of the brain.

(To be continued.)

Comparative frequency of Aneurism in different Arteries of the Body.

M. Lisfranc has endeavoured to ascertain the influence of sex and age in producing aneurism, and its comparative frequency in different arteries. The following are the results:—

Women are in general less liable to the disease than men, but the statements of authors require to be modified. According

to Mr. Wilson, Mr. John Hunter affirmed that he had never met with a woman affected with true or spontaneous aneurism. In Mr. Hodgson's sixty-three cases, in twenty-nine of which the disease was situated in the aorta, the proportion was, fifty-six men to seven women, or eight to one. M. Lisfranc's estimate differs widely from this. In one hundred and fifty-four cases collected by him, none of which could be the subject of a surgical operation, the proportion was one hundred and forty-one men to thirteen women, or nearly eleven to one.

Of the comparative frequency of the disease in different arteries, M. Lisfranc gives the following table:—

1. Popliteal aneurism,	.	.	59
2. Crural, do.	{ at the groin,	{ 26	
	{ other points,	{ 18	
3. Carotid,	.	.	17
4. Subclavian,	.	.	16
5. Axillary,	.	.	14
6. External iliac,	.	.	5
7. Brachio-cephalic,	.	.	4
8. Humeral,	.	.	3
9. Primitive iliac,	.	.	3
10. Anterior tibial,	.	.	3
11. Gluteal,	.	.	2
12. Internal iliac,	.	.	2
13. Temporal,	.	.	2
14. Internal carotid,	.	.	1
15. Cubital,	.	.	1
16. Peroneal,	.	.	1
17. Radial,	.	.	1
18. Palmar,	.	.	1

Hodgson's numbers are, femoral, fifteen; inguinal, twelve; subclavian and axillary, five; carotid, two.

The age at which aneurism most frequently appears has not been sufficiently investigated. M. Lisfranc has collected one hundred and twenty cases in which the ages of the patients were ascertained, and the following is the result:—

13	.	.	1
15 to 20	.	.	3
20 to 25	.	.	5
25 to 30	.	.	12
30 to 35	.	.	24
35 to 40	.	.	15
40 to 45	.	.	20
45 to 50	.	.	17
50 to 55	.	.	11
55 to 60	.	.	6
60 to 70	.	.	3
70 to 80	.	.	3

From this table it would appear that aneurism occurs most frequently between the age of thirty and fifty. In the ten years above and below that period, the diminution is very remarkable. Before twenty and after sixty, the disease is very rare. Aneurism by anastomosis is met with most frequently before the age of fifteen, very rarely among adults, and M. Lisfranc knows of no case occurring in old age.—From M.

Lisfranc's work "*Des diverses Methodes et des differens Procédés pour l'Obliteration des Arteres, &c.*"

Newly discovered arrangement of the Arteries in the Erectile Tissue of the Penis. By Professor J. Müller, of Berlin. (*Archiv für Anatomie und Physiologie*, No. II. for 1835.)

The second number of Müller's (late Meckel's) *Archiv* contains the account of an interesting discovery recently made by the editor, Professor J. Müller of Berlin, relating to the disposition of the small arteries of the penis, which tends to explain the structure of the erectile tissue of that organ—a subject which, notwithstanding the investigations of Cuvier, Tiedemann, Moreschi, and Panizza, was still involved in much obscurity. These observations point out a fact entirely new in the structure of the arteries of the erectile texture, and promise to throw some light on the nature of the erectile condition of the blood-vessels.

Most of those who have investigated the structure of the erectile textures of the penis by injections, have contented themselves with filling the veins of the organ, and thus, although the structure of the venous caverns of the *corpora cavernosa*, and the dilated veins of the *corpus spongiosum urethræ* was sufficiently well understood, yet very little was known respecting the mode of termination of the smaller arteries. It has been generally believed that the same small capillary arteries which nourish the penis carry the blood into capillary veins, that the blood passes from these into the dilated venous branches or sinuses, and that the state of erection depends on the retardation of the flow of blood in these venous spaces.

Professor Müller has, by a careful injection of the arteries of the penis, pointed out, besides the capillary branches which nourish the penis and transmit the blood into the capillary vessels and dilated veins, a number of very remarkable appendices connected with the smaller arteries, both in the *corpora cavernosa penis* and *corpus spongiosum urethræ*, which, from several circumstances, it is very probable are the vessels more immediately concerned in maintaining an increased quantity of blood in the penis during erection.

The easiest way of rendering these two sets of arterial branches apparent is to inject the principal artery of the penis, before its subdivision, with size and vermilion of moderate consistence, and then, making a longitudinal section of one of the *corpora cavernosa*, to wash away any part of the injected mass which may have passed into the venous spaces. The ramifications of the nutrient arteries will then be easily seen upon the inner sides of the venous spaces, the arteries becoming smaller and smaller, until at last

they pass into the minute capillary network, the branches of which cannot be seen with the naked eye. Besides these nutrient ramified arteries, there will also be seen, upon a careful examination, another set of arterial branches of a different size, form, and disposition, which are given off nearly at right angles from both the larger and smaller trunks of arteries. These arterial processes are about one-hundredth of an inch in diameter, and one-twelfth long, and are quite easily seen with the naked eye. They project into the cavities of the spongy substance, and terminate either bluntly or by dilated extremities, without undergoing any ramification. These short arterial processes are turned round at their extremities into a semicircle or more, and present a contorted appearance, which circumstance has suggested to Professor Müller the name of Helicine arteries, which he has applied to them.

The helicine arteries of the penis are more easily seen in man than in any other animal which Professor Müller has examined. He has found them in all the animals in which he has sought for them; they are to be seen at the posterior part only of the penis in the stallion, but in the dog they exist throughout the whole organ.

In man, the helicine twigs of the penal arteries sometimes come off singly, and at other times they form tufts or bunches, consisting of from three to ten branches, and having in general a very short common stem. The swelling at the extremity, when it occurs, is gradual, and is greatest a little way from the end. The helicine branches given off from large arteries are not of a greater size than those coming from smaller ones, and even the smallest capillary arteries of the *profunda penis*, which can be seen with the help of a glass only, give off helicine twigs of a much greater size than themselves.

Each helicine branch projecting into a venous cavern is covered by a thin membrane, which Professor Müller regards as the inner coat of the dilated vein, and when there is a tuft of helicine twigs, the whole tuft is covered with one envelope of a gauze-like membrane. This covering is considerably thicker on the helicine arteries in the posterior part of the *corpus spongiosum urethræ* than in the *corpus cavernosum*, but it seems probable that this is in some measure connected with the state of repletion of the arteries, for when the injection has run very well it becomes difficult to distinguish the external covering.

Professor Müller states, that he could not discover any apertures either in the sides or in the ends of the helicine arteries, but he seems to regard it as probable that minute apertures do exist, which may be of a nature to allow the passage of blood in some states and not in others.

The helicine arteries are not, as some

might be inclined to suppose, loops of vessels which have been incompletely filled, and which, after making a coil, pass into venous spaces, as E. H. Weber discovered to be the case with the arteries of the maternal portion of the placenta; they are merely projecting branches from the arterial trunks containing blood.

The helicine arteries are more numerous towards the root than near the point of the penis. They exist in the *corpus spongiosum urethræ*, especially towards its bulb, but they are not so easily seen there as in the *corpora cavernosa*. They have not yet been observed in the glans. Their structure is nearly the same in all the animals in which they have been observed: those of the ape bear the nearest resemblance to those of man, and in most animals they are less obvious than in the human subject. In the horse and dog they give off small nutrient twigs from their sides, which render them more difficult to be seen in these animals than in man.

Professor Müller conceives these helicine or tendril-like arteries to have an intimate connection with the process of erection, and there is every probability that this is the case; but experiments and observations are still wanting to show in what manner these arterial branches are affected in the erected and non-erected condition of the texture in which they exist.

We recommend to the attention of our readers this discovery of Professor Müller's, whose researches have already done a great deal for the advancement of physiological anatomy. The memoir is accompanied with a well executed engraving, containing numerous representations of the helicine arteries, which we regret that time has not enabled us to copy.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 728.)

Sympathetic Bubo.—This disease consists in inflammation of two or more of the inguinal glands. It is usually preceded by inflammation of the absorbents of the penis, which become enlarged, more especially near the pubes, and the diseased action extends to the inguinal region. The diagnosis between a sympathetic and syphilitic bubo is, that several glands are affected in the former, and one only in the latter; and that the former very seldom suppurates except in very irritable constitutions, or when mercury has been employed.

The *treatment* consists of purgation, leeching, and evaporating lotions, which generally effect a cure. In scrofulous subjects, the disease may assume a chronic form and prove extremely obstinate. The best plan of treatment is improving the general health, and employing the preparations of iodine.

Gleet.—The term gleet is applied to a thin transparent discharge, which continues after the acute symptoms of urethritis have disappeared. It sometimes becomes yellow or green, and may be tinged with blood, after venereal or other excesses. It proceeds from lacunæ of the urethra, which remain inflamed; it is not supplied by the vesiculæ seminales, the prostate, or Cowper's glands, as was once imagined. This discharge is often extremely obstinate, and may continue for several weeks, months, or even for a year or two. Sir A. Cooper relates cases, proving that this disease is contagious for some months after its appearance. He maintains that so long as it continues it is contagious. He relates a case of a gentleman who laboured under gonorrhœa fourteen months prior to his marriage, and had a variety of advice, but a yellow discharge always continued. He was repeatedly told that this was not contagious, but he communicated the disease to his wife. Several instances of the same kind have been related by other authors. I need scarcely observe that a gleet discharge in cases of stricture is not communicable. The same observations as to the contagiousness of gleet in the male applies to the disease in the female. It is on this account that women in apparent health communicate blenorhagia or urethritis.

Treatment.—The best plan of treatment of gleet, consists in the exhibition of those substances that have a specific influence on the urethra, such as copaiba, cubebæ, Chio turpentine, lytta, with bougies, and injections. While we administer the internal remedies, we employ bougies every other day, or as frequently as the irritability of the constitution will permit; and at the same time an injection of oxymuriate of mercury, in the proportion of half a grain to an ounce of water, or of sulphates of lime, copper, or alum.

This plan generally succeeds, but it may fail; and in such cases a blister applied along the urethra very frequently succeeds.

Some surgeons praise pills composed of Chio turpentine and lytta, with cold bathing or cold affusion on the genital organs*. There are two other diseases very frequently produced by urethritis; and these are gonorrhœal ophthalmia, and rheumatism.

It sometimes happens that acute conjunctivitis generally of one, but sometimes of both eyes, suddenly occurs during the acute stages of urethritis. The inflammation at first is slight, but it soon becomes exceed-

* We have found the following remedies generally successful:—

R. Pulv. secalis cornuti, 3 ss;
 ——— piperis cubebæ, 3 j;
 ——— cinnam. comp.
 ——— sacchari purif., aa 3 j.

In chartulas viij divide, ex his suma ur
 ——— ter in die.

ingly violent and rapidly destructive to the organ affected. According to Mr. Cline, Sir. A. Cooper, Dr. Veitch, M. Delpech, and others, it may arise from metastasis of urethritis, as well as from the conveyance of the urethral discharge through the medium of the fingers to the eye. According to Scarpa and Beer, the application of gonorrhœal matter to the conjunctiva sometimes produces but a slight degree of inflammation, and Mr. Pearson denies that there is any connection between the one and the other, as he had seen many thousand cases of gonorrhœa, but not one instance of ophthalmia. Mr. Guthrie, Mr. Lawrence, and many others, are however of opinion that the disease is very often communicated by inoculation.

Dr. Veitch, on the other side, has proved by numerous experiments, that the gonorrhœal discharge applied to the eye of the affected person does not cause gonorrhœal ophthalmia. He applied the matter of purulent ophthalmia to the urethra of the affected individual without exciting urethritis. But when he applied the same matter to the urethra of a different person, it produced virulent gonorrhœa. He further states that an hospital assistant, named Smith, applied gonorrhœal matter to his own eyes, with impunity. Mr. Wardrop, M. Delpech, and Mr. Bacot, have subsequently recorded cases of gonorrhœal ophthalmia, excited by the accidental application of towels and sponges which were used by persons affected with contagious urethritis. It therefore appears that there is the greatest diversity of opinion on the pathology of this disease. Leaving this to be settled by others, I shall proceed to consider the effects of this disease and the best mode of treatment.

The immediate effects of gonorrhœal ophthalmia are sloughing, suppuration, and ulceration of the cornea, with interstitial deposition; and these are followed by escape of the humours of the eye, collapse of the globe, obliteration of the anterior chamber, flattening of the front of the eye, prolapsus of the iris, obliteration of the pupil, anterior adhesion of the iris, and opacity of the cornea.

The indications of *treatment* are the general and local abstraction of blood, purgation, counter-irritation, both generally and locally applied. Mr. Lawrence, in his work on the Venereal Diseases of the Eye, most strenuously recommends large and repeated bleeding, so long as blood can be got from a vein, and he relates six cases, five of which terminated successfully by this method. His advice to take blood from a vein while it can be obtained, has been most severely censured by the reviewers, and other surgeons, which has led him to omit it in his *Treatise on Diseases of the Eye*, lately published. He, however, advises active depletion, even after partial sloughing of the cornea has com-

menced, and states that this treatment was completely successful in preserving the sight. Sir A. Cooper has found moderate depletion, with the ordinary treatment, generally successful. (Lectures). Mr. Guthrie very strongly recommends an ointment of nitrate of silver, which he denominates the black ointment, on the principle of exciting an action greater and of a different nature to that already existing in the part. The formula for his ointment is the following:—

Rx. Argenti nitrat., gr. ij—x;
Liq. plumbi subacet., m xv;
Unguenti cetacei, ʒj.

A portion, from the size of a pin's head to that of a garden pea is introduced between the eyelids, and these being closed, are to be rubbed gently with the finger, so as to diffuse the ointment over the whole conjunctiva. A part of it usually escapes externally, by the motion of the lids, and should be wiped off. The pain caused by it may continue for a few minutes or for several hours, or sometimes for a day, and is best relieved by anodyne fomentations. The ointment may be re-applied after the lapse of three days, and it is seldom necessary to reiterate it oftener. Three or four times it has been successfully tried in common chronic, purulent, and strumous ophthalmia, with thickening of the conjunctiva, opacity, vascularity, and ulceration of the cornea. Mr. Guthrie seems to prefer the ten grain nitrate of silver ointment (*London Medical and Surgical Journal*, 1832, vol. i, p. 265). Many practitioners are of opinion that this ointment is much too violent and too indiscriminately employed at the Westminster Ophthalmic Hospital. Patients treated with it for months, have applied at other institutions with total loss of vision from nebula, which was removed by milder measures. The strictures of the *Lancet* bear out this assertion.

Gonorrhœal Rheumatism.—It has been long remarked that gonorrhœa may excite a rheumatic or painful affection of the joints. In such cases the urethral discharge is sometimes diminished, or entirely suppressed. According to many writers there is a metastasis to the articulations; but be this as it may, the usual remedies for gonorrhœa must be employed, viz. copaiba, cubebs, &c., with the preparations of colchicum, more especially the liquor colchice, which will be used with most advantage.

Gonorrhœa in Women.—Gonorrhœa in women is generally less violent than in males. The inflammation is seated in Cowper's glands on each side of the urethra, and extends to the orifice of the meatus urinarius, and thence to the bladder. The disease extends the orifice of the vagina, and affects the external genitals, the nymphæ, clitoris, the whole vagina, and lining membrane of the womb.

The disease is much less painful in women than in the other sex, on account of the

shortness of the urethra and the more rapid evacuation of the urine over the short urethral surface. The discharge, when profuse, flows over the perinæum, in some cases comes in contact with the mucous lining of the anus, and inflames it. In such cases, there will be inflammation of the lining membrane of the rectum, accompanied by copious discharge when the bowels are evacuated.

With respect to the *treatment*, it consists in the exhibition of those remedies which have a specific effect upon the mucous membrane of the urethra, together with a free use of diluents, and the local application of the liquor plumbi subacetatis dilutus. This may be used as a vaginal injection. The carbonate of soda and liquor potassæ are the best remedies to relieve the ardor urinæ or scalding, on evacuating the bladder. It is generally supposed that there is no medicine which possesses a specific effect over the gonorrhœal discharges in women; but I have been assured of cases in which cubebs and copaiba had as speedy effects as in the male. It is scarcely necessary to observe, that gleet in females continues as long contagious as in males. Mr. Hunter has proved that it will produce gonorrhœa in a healthy male, a long time after gonorrhœal symptoms have ceased, but the same discharge will not affect a person who has frequently laboured under contagious urethritis.

Genital Discharges in Children.—It was long since recorded by obstetric writers, that male and female infants may labour under a purulent discharge from the generative organs, and that this may appear at any period from birth to puberty. It is most common, however, from the second to the twelfth year, especially in delicate scrofulous female children. It may attack one or many children in the same family, at the same time; and is generally supposed by parents, and often by medical practitioners, to be caused by contagion communicated from girls or young women, or to arise from attempts at female violation. These suppositions are generally erroneous, for the disease usually arises from irritation in the digestive system, and is aggravated by inattention to cleanliness. That these causes are sufficient to produce it, must appear obvious on referring to the preceding remarks on urethritis. When mothers discover the body linen stained by a genital discharge, they become alarmed, and question the little patient very minutely, whether any one had tampered with her. The child is terrified by repeated threats, and generally states that some male person has taken improper liberties with her. The mother applies to a medical practitioner, who may be ignorant of the nature of this disease, and who unhesitatingly pronounces it to be contagious urethritis. The mother now applies to a magistrate against the sus-

pected person, the child prevaricates, the surgeon swears that the disease is gonorrhœa, and must have been communicated. There is now strong presumptive evidence against the accused, and he is forthwith committed to prison, on a charge of felony.

Examples of this kind are of very frequent occurrence, and some have very recently happened in which the medical evidence went to prove that a man had communicated gonorrhœa, who was found on inspection to be free from genital disease of any kind, immediately after the occurrence of the alleged offence. The delicate and strumous appearance of the child, and the liability of such to irritation and excoriation of the genital organs, with the inattention to cleanliness among the lower classes, afford strong presumptive evidence in favour of the spontaneous origin of the disease. Moreover, an attempt at sexual intercourse by boys at the age of puberty, or adults, and female children, would be followed by laceration, contusion, or inflammation of the female genitals, and these could scarcely be succeeded by purulent discharge within twenty-four hours. The necessary result of external violence in such cases, would be the formation of an abscess, and healthy pus, and not a muco-purulent discharge.

In all charges of violation of female children, the age of the accused should be considered, the injuries which should follow, when there is great disproportion of the sexual organs of the parties, and lastly, whether he labours under any venereal disease. We should also inquire whether the child, or any of the children in the family laboured under a discharge of a similar description at any former period. It often happens that two or more children are affected at the same time; and this fact would go to disprove the contagious origin of the discharge, or that external violence produced it. Infants from one year old to puberty are liable to it, and we observe cases almost daily in dispensary and private practice. I have known many cases in the children of the most respectable families as well as the poor; and I am convinced the disease is not contagious. It is true it may occur in two female children in the same family at the same time; but in general it attacks but one, and no other, however numerous the family. It is generally cured in a few days, by regulating the bowels, improving the general health, and by making proper local applications.

The discharge generally proceeds from the preputium clitoridis and nymphæ, and is soon suppressed by the black lotion composed of liq. calcis and calomel, with attention to cleanliness, frequent ablution, and moderate purgation. The general health should be restored by the hyd. c. creta, rhubarb, and tonics. When these remedies are employed for a week or two, they generally effect a cure.

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from page 726.)

Organs of Respiration and Circulation.—Before describing the changes induced in the lungs by putrefaction, we will state in a few words what is found worthy of observation in them twenty-four or thirty-six hours after death. If the mortal agony has not been protracted, the portion of the lungs that was most dependent when the body grew cold will be engorged; if, as generally happens, the individual has died in the supine position, and the position of the body has not been changed, the congestion will be found in the dorsal portion of the lungs; if in a prone position, in the anterior portion; and if in a vertical position, as in death from hanging, in the inferior portion. In all these cases the engorgement may be so great as to diminish the cohesion of the parenchyma, and entirely to expel the air from the most depending parts. It is unnecessary to add that the bronchial tubes are also reddened in the parts where the blood is accumulated. *If the agony of death has been long, or the patient has died of a thoracic affection, with considerable embarrassment of the respiration, the sanguineous congestion will occupy that portion of the lungs which was most dependent at the moment of death.* If, under such circumstances, the body of a patient who has died on his back be immediately turned on the belly, the engorgement will notwithstanding be found in the dorsal portion of the lungs, while the part most dependent when the body grew cold will present scarcely any traces of congestion. It follows, from the foregoing considerations, that the position of the individual at the moment of death, or at the time when the body grew cold, cannot be determined merely from the lividity of this or that portion of the lungs, because the duration of the mortal agony is also to be taken into account.

The congestions of which we have been speaking sometimes communicate to the lungs, especially at their posterior part, a black colour, which might be regarded, by an attentive observer, as the result of gangrene or sphacelus.

Let us now examine the different conditions of the lungs at a longer or shorter period after inhumation. They preserve their natural appearance for a considerable time, although they soon become emphysematous; they remain gorged with blood at their back part only for a short time after death: at the end of some months their structure may still be recognised, and the presence of morbid lesions detected. At a later period they are more or less collapsed,

and no longer fill the cavities of the pleuræ; their colour changes to a bottle-green, more or less intense, and inclining to slate colour or blue; on cutting into them their natural texture can now rarely be recognised; they are soft, easily torn, and contain a bistre-coloured fluid. Still later, they present the appearance of two small flattened membranes, close to the lateral parts of the spine; sometimes they are covered with a white mould, and their aspect is so changed that they are recognised only by their situation. At last they gradually lose their moisture, flatten more and more, and form a thin mass composed of several dry and black laminæ, applied to the posterior part of the thoracic cavity, and near the vertebral column: they soon altogether disappear.

The mucous membrane of the trachea and larynx at first becomes of a light olive or blackish green colour; sometimes, however, especially at its upper part, it is gray, slightly tinged with violet, variegated here and there with blackish spots. Afterwards, instead of the green tint, it presents a reddish or wine-lee colour, particularly at the parts corresponding to the cartilaginous rings; lastly, its hue changes to dark brown or black. In some instances the epithelium of this membrane is detached in small layers of various colours. Gray fatty granulations are also sometimes observed of the size of two pin's heads, and of an irregular shape, apparently formed by other granulations much smaller; these corpuscles, as well as the detached shreds of the epithelium, might at first sight be mistaken for foreign bodies introduced into the windpipe. Besides these changes, the larynx and trachea become softer and softer, the cartilaginous rings lose their elasticity, and, after some time, we find only the thyroid and cricoid cartilages separated from each other, spongy, as if worm-eaten, semi-transparent and yellowish, and some rings of the trachea, flexible, and of a yellowish brown colour. At a more advanced period no vestige of these organs remains.

Diaphragm.—This muscle preserves its natural appearance for a considerable time: six or seven months after inhumation we have been able to distinguish its aponeurotic centre and muscular fibres; at a more advanced period it becomes thin, dry, and of an olive or brown colour; it is sometimes perforated with holes, and is finally reduced to a brown and very attenuated membrane, which no longer preserves the form or texture of the muscle. In some instances hard white granulations, composed of phosphate of lime, are found on both its surfaces.

Heart and Blood-vessels.—Before describing the changes undergone by these organs after inhumation, let us consider the state in which they are found twenty-four or thirty-six hours after death. The heart

often appears in its natural state; sometimes it is pale; in other cases it presents a vivid red tinge, or is streaked with red, either in its muscular substance or on its internal surface; lastly, its consistence may be diminished. In like manner, the arteries and veins may be uniformly of a red colour, or streaked with red in their interior; they are usually, however, in their natural state. This red tinge is found indifferently after death from all kinds of diseases, and is to be regarded as a cadaveric phenomenon, evidently resulting from the transudation of blood after death. This is easily proved by direct experiment: thus, if a certain quantity of fluid blood be introduced into an ureter whose colour is perfectly white, and the two extremities tied, the tissue of the canal speedily acquires a red colour. Again, M. Chaussier has demonstrated, that if water coloured with ink be injected into the mesenteric vein, that portion of the stomach which is covered by the liver will, in the course of a few hours, be tinged with black; and the liquid transuding through the coats of the stomach will form spots of larger or smaller size on the epiploon and colon.

If the heart be examined some time after inhumation, it is observed to be sensibly softened and flabby; of a violet colour, more or less intense, or, more rarely, green; it is empty, or contains blood partly fluid and partly coagulated; its colour grows deeper and deeper, especially in the interior, where it finally becomes black; occasionally brown spots are seen on the valves, which are the effect of imbibition, and white, hard sandy granulations are sometimes observed on the internal surface of the auricles, or on the exterior of the heart. At a later period the heart becomes flattened, and reduced to the shape of a tongue, which is of a blackish-brown colour, supple, attenuated, and torn at some points, bearing some resemblance to a double pouch of India-rubber; the parietes may still be separated, so as to exhibit the two ventricles, but the natural texture of the organ is lost; some blackish bands, however, may still be seen, which appear to be the remains of the *columnæ carniæ*. Finally, this, like all the other organs, disappears, and leaves in its place a black, bituminous-looking layer, which is easily removed by washing. The sooner the soft parts of the thoracic parietes are destroyed, the earlier the heart also disappears.

Pericardium.—The pericardium first assumes a reddish, then a deep red, and lastly a blackish-brown colour; it becomes more and more softened, and finally vanishes. We have often found it to contain a larger or smaller quantity of bloody serum.

Blood-vessels.—Two or three months after inhumation, a certain quantity of black blood, fluid or coagulated, is generally found both in the veins and arteries. In some instances, however, we have found

none at the end of a month, and in others we have seen, instead of blood, a sanguinolent fluid of a rose colour, as late as eight or nine months after death. The coats of the blood-vessels first become rose coloured, then red, then deep violet, and at last brown. These tints are strongest in the internal membrane, which sometimes also assumes a bottle-green colour; the coloration is sometimes uniform, and at others confined to patches or striae. For several months the tunics of the vessels are easily separable from each other. In one of our dissections we found the aorta still entire, and perfectly to be recognised at the end of fourteen months after inhumation.

Digestive Organs—Alimentary Canal.—The changes which take place in the alimentary canal after inhumation can only be ascertained by a comparative examination of the state of the parts a short time after death, and several weeks, and even months, after interment. How can alterations of colour, consistence, &c., be recognised, unless we are familiar with the ordinary colour and consistence of the tissues a few hours after death? With a view to such comparison, we shall briefly describe the more frequent appearances in the alimentary canal of those who have not died of inflammation in these parts; and as our observations have been made chiefly on the bodies of aged persons, it is to such that the following remarks are more especially applicable.

Whatever disease an old person may have died of (as cerebral hæmorrhage, ramollissement of the brain, pneumonia, pleurisy, diseases of the heart, &c.), it rarely happens that the mucous membrane of the digestive tube is in a state of perfect integrity; it is seldom that we do not find, in the stomach and intestines, various deviations from the natural state, which, however, can only be considered as morbid in a very small number of cases: nay, more, these alterations are often much more strongly marked than those which result from acute diseases of the intestines sufficient in themselves to occasion the death of a patient. Of all the affections foreign to the alimentary tube, those which occasion the most remarkable changes in its lining membrane, are diseases of the heart and great vessels; and as few septuagenarians die without some morbid alteration of the latter organs, there are also few in whom some changes in the gastro-enteric membrane are not observable. A derangement which is at first only mechanical, as mere injection of the part with blood, may arrive at a point at which it becomes morbid; thus the blood accumulated in these permeable tissues, and acting as a foreign body, often induces a sort of inflammation: the redness is then cherry, or inclining to violet or the colour of wine-lees, and induces deeply the mucous membrane of the stomach, or is chiefly

remarkable at particular points. In other cases, the accumulated blood escapes into the intestinal canal, and gives rise to consecutive hæmorrhages. But previously to reaching that state which may be considered morbid, the gastro-enteric mucous membrane passes through several conditions, which interfere very little, if at all, with the functions of the intestines, and may therefore be regarded as scarcely deviating from those of health.

The œsophagus is usually more injected than natural, and violet-coloured patches or spots of larger or smaller size, exactly resembling ecchymoses, are seen scattered here and there, especially in the inferior third, and towards the cardia; these spots are under an epithelium thicker and denser than that which covers the mucous membrane of the stomach—if, indeed, this texture exist at all in the latter situation. The œsophagus is sometimes contracted in certain parts, at which also its walls are thickened, and the lining membrane thrown into longitudinal folds: no other traces of inflammatory action are observable.

The stomach presents infinite varieties of colour, consistence, volume, diameter, &c. Its mucous membrane is soft and spongy, receiving a vast number of capillary vessels, easily permeable to a greater or less quantity of blood, when the circulation is in any way impeded; it is, indeed, extremely rare to find this membrane throughout of the white colour slightly tinged with rose, which indicates its perfectly healthy condition. But, in the examination of this membrane, it must not be forgotten that it is penetrated with the greatest facility by colouring matters contained within the cavity of the stomach; nor will the most careful and repeated ablutions remove entirely the colour acquired by such imbibition; thus, wine and decoction of bark produce a red colour in this membrane, which inattentive or inexperienced observers might attribute to sanguineous congestion. Other medicinal or alimentary substances may produce the same effect. The presence of a red colouring liquid ought to make us suspicious as to the nature of the coloration of the mucous membrane of the stomach. It may be observed that the colour derived from imbibition is uniform, and does not present those arborizations which characterize the sanguineous injection of the capillary vessels; moreover, washing and maceration remove in part, if not entirely, this adventitious colouring. The mechanical and chemical causes of coloration having been thus considered, we have to examine the effects of stagnation of blood in the vessels.

The colour of the mucous membrane varies, according to the degree of injection, from a light rose colour to a deep black, and this without any material derangement of the digestive functions. The great curvature of the stomach, the great *cul de sac*,

and especially the pyloric extremity, are the seats of this sanguineous congestion, whether from the greater development of the capillary system, or because fluids remaining there favour the injection of the vessels. The colour is seldom or never uniform, but patches occur of greater or smaller extent, and of a rose, bright red, wine-lee, brown, blueish, slate, or black colour; these patches are about the size of the palm of the hand, some larger and some smaller. It is not uncommon to meet with the greater part of the above-named colours in the same stomach, and the lines which divide them are often distinctly defined, so that a brown or red patch is seen immediately contiguous to one of a rose colour. The mucous membrane is often marked with spots which have a scorbutic appearance. The surface of this membrane may be smooth, polished, rugous, dotted, mamillated, and sometimes studded with very small fungosities; large blue veins are also often seen creeping under the lining membrane of the stomach and small intestine, which is of a white or slightly ash-colour. In all these cases, the individual when living was not troubled with any complaint in these viscera.

The consistence of the mucous membrane is far from being the same throughout its extent; in some parts it adheres so slightly that it is raised by rubbing it with the back of the scalpel, and is confounded with the mucus, from which it is scarcely distinguishable; in other parts it is with difficulty detached, even with the edge of the knife. The coats of the stomach are sometimes translucent, and vessels of considerable calibre are seen meandering in their substance; in this case the stomach is of great size—it may be double its natural dimensions. In some instances the viscus is condensed and contracted; its coats are thicker and stronger than natural, and its lining membrane wrinkled, and arranged in numerous folds, which are generally longitudinal. Partial dilatations and contractions are also observed, and the mucous membrane is thrown into folds at the contracted point. We occasionally find the greater part of the mucous membrane elevated from its attachments towards the large end of the stomach, without any disease having existed, but in such cases the circulating system is too highly developed.

Such are the most frequent changes remarked in the stomachs of old persons who have died of diseased heart. These changes, up to a certain point, need not be considered as deviations from health, since they admit of the free exercise of the functions of the stomach. It may be objected to this view of the subject, that the disease of the stomach may have been latent in these instances; to which we reply, that such cases being exceedingly numerous, and explicable on physiological principles, we would rather

regard them as modifications of the healthy state, than as exceptions from pathological rules. The intestines present alterations analogous to those of the stomach. The duodenum is often red, injected, brown, &c., but usually much less so than the stomach. The bile which it contains communicate to it a shade of greenish yellow, which distinguishes it from the stomach, except when bile has ascended into the latter cavity by the pylorus. The portion of the intestines most exempt from alteration is the jejunum; though coloured yellow or green by the bile contained in its numerous villousities, it is rarely the seat of any considerable congestion, of hypertrophy, or atrophy, of dilatation or contraction; such phenomena, however, do sometimes occur.

The ilium, quite as frequently as the stomach, exhibits the violet, brown, black, or blue injections already described; these appear to be owing to the dependent position of the intestine when the body is lying on its back, and are probably produced a few hours before or after death. The mucous membrane of this intestine is very often of a deep red or wine-lee colour, which pervades its whole surface, but is more intense at certain points. The cavity of the intestine is often contracted, and its walls are thickened; more rarely the cavity is dilated, and its walls thinner than natural; this extenuation is sometimes so great that the intestine is transparent and pellucid, and appears as if reduced solely to its serous membrane. Alternate contractions and dilatations are occasionally found.

The rectum, and the ascending, transverse, and descending colon are far from being exempt from the changes under consideration; they present them, however, less frequently, and in a less marked degree. Thickening, contraction, and dilatation, are much more frequent in these parts than vascular congestion; the colour of the large intestine seldom varies from the white, slightly tinged with rose, which is natural to it except where there has been actual disease: to exhibit its natural colour, however, it must be carefully cleansed from the fecal matter which may have tinged it.

On comparing the digestive canal of old persons who have died labouring under disease of the heart, with the same canal in other persons not so affected, it was found that in a man of seventy-five, who died from a burn after eight days' illness, the gastric mucous membrane was grayish, and that of the intestines ash-coloured; that in a woman of eighty, who died of old age, the lining membrane of the stomach was also of an ash-colour, that of the duodenum white, with a slight tinge of yellow, that of the jejunum, ilium, colon, and rectum, whitish, and that of the cæcum grayish. M. Billard, from whom we have taken these two facts, places among the colorations to be considered as cadaveric, where the gastro-enteric

mucous membrane is healthy, yellow patches of greater or less extent, or simple bands of the same colour on the mucous surface of the duodenum and jejunum.

(To be continued).

PROGRESS OF DIFFERENT CLASSES IN
THE PROFESSION.

Ἰκανὸς οὖν ἔχομεν τοῦτο, ὅτι πάντα οὕτω
γίγνεται ἐξ ἐναντίων τὰ ἰκαντὰ πράγματα.

PLATO.

SOCRATES, or rather Plato speaking in his name, tells us that everything springs from its opposite: that everything good is an amelioration of something bad, and everything bad a deterioration of something good. This is rather a large position; the principle, however, holds true with reference to many things, and among others to the state of the medical profession in our own country. It is sufficiently obvious, at the present moment, that the *heraldry* of the profession is at direct variance with the real state of things, and also with the opinion of the better informed portion of society. Thus the physician ranks higher than the apothecary, but the latter is generally the superior man; the fellows of the College rank higher than the licentiates, but are, in reality, miserably inferior to them; yet the English physicians were at one time deservedly held in the highest estimation, and among these the fellows of the College had an unquestioned ascendancy; while the apothecaries were originally nothing more than a set of quacking druggists, who exercised illegally an art of which they were ignorant. Now it is profitable to inquire into the causes which have led to so singular an inversion. The altered relation of the physician and apothecary has, we conceive, arisen from the former having been fettered by an absurd

prejudice which has not had equal influence on the latter. Several centuries ago the distinction between physic and surgery was of little moment, because surgery was then merely a rude and mechanical art; but as the art gradually improved into a science, and became intimately allied to physic by a community of principles and a reciprocity of illustration, the evils resulting from their arbitrary disjunction began to be very perceptible, and these evils have weighed much more heavily on the physician than the apothecary: the former, restrained by scholastic rules, has studied and practised one half of his art violently severed from the other, and thus removed from the common physiological basis on which both ought to stand; the latter, at once deprived of the advantages, and free from the trammels, of academic education, has acquired knowledge how he could, and thus, approximating more to the position of an original observer of nature, has learned to despise a distinction equally false in reasoning, and injurious in practice; and has gradually improved into the British general practitioner of the present day, who only requires to be emancipated from the *trade*, to become the most respectable medical character in Europe. We have said nothing about pure surgeons, because we consider them as mere artizans having no connexion with the profession of medicine—we do not deny, however, that several most distinguished men have the misfortune to be numbered among this class of mechanics.

But, setting aside general practitioners, we have asserted, and without much fear of contradiction from unprejudiced persons, that the fellows of the College who arrogate to themselves, and are supposed by some weak people to possess, a superiority over other physicians, are in effect very much inferior to the greater number of the same class in this country. Whence then is this

inferiority? There is no question that the fellows of the London College of Physicians were formerly not only the first physicians, but among the first *men* of their age. Linacre, the founder of the College, might have confided his immortality to letters, even though he had been unknown in medicine. In later days, Mead and Friend were among the most distinguished cultivators and patrons of literature. Now it is to this very superiority of learning in the fellows of the olden time, that those of the present day owe their degradation. Learning is a thing not easily estimated, because the multitude are unlearned; medical knowledge is not easily appreciated, because the multitude know nothing of medicine; hence the existing generation of fellows, resting their reputation for learning *on the erudition of their predecessors*, and their character for medical skill *on the ignorance of the public*, are contented to enjoy, in dignified indolence, the prescriptive privileges of their order, and to labour under a real inferiority to the great mass of European physicians.

We may perhaps be accused of unfairness to the fellows of the College, in thus denying the superior learning which they so pompously assert, and others too credulously admit. Our answer is “by their fruits shall ye know them.” What have they produced? The few learned works connected with medicine achieved in the present day belong not to them. Will any of their body show us a classical work equal to Milligan’s *Celsus*? Dr. Milligan was of Edinburgh. Will they show us a work comparable in general research to Copland’s *Dictionary*? Dr. Copland is not a fellow. Will they shew us a work as rich in medical antiquity as Adam’s translation of Paulus *Ægineta*? Mr. Adams is a surgeon, residing in some place so obscure that its locality is unknown to us.

What are the practical precepts to b

derived from all the foregoing considerations? What but the necessity of preventing any body of men from mystifying society with a *name*, by the appointment of a competent and equitable board of examination, which shall determine the qualifications of *individuals*, without reference to the privileges of orders, or the fame of predecessors; the necessity of emancipating the general practitioner from those restraints in despite of which he has become the best informed and most useful member of the profession; and the necessity of placing all members of the profession on a high level of honourable equality, where merit will create for itself, and the respect of society will create for it, distinctions of a nobler kind than those conferred by the present *natural history* system of medical politics, wherein doctors are arranged in classes and orders, like plants or minerals, according to their external characters!

—o—

A QUARTERLY contemporary of ours has, we are told, said something contumacious of us; we do not know exactly what it is, for we have not read his journal. We have always felt amicably inclined towards the journal in question, from the respect we bear to its editor, and we shall therefore say nothing disagreeable on the present occasion; but we particularly request our contemporary to let us alone in future, or we shall be under the unpleasant necessity of alluding to his glass tenement.

Hospital Reports.

WESTMINSTER HOSPITAL.

Calculus in the Bladder.—Lithotripsy. Nine ounces extracted.

(Case of Mary Kean, continued from p. 158).

Our readers will recollect that in this case lithotripsy had been performed by Mr. Guthrie, in February last, and that a large quantity of fragments of a calculus, amounting

in weight to between seven and eight ounces was brought away.

At the period of our last report, dated February 23rd, the patient was going on well, her general health had decidedly improved, and it appeared probable that she would soon be well enough to leave the hospital. She had, however, lost all power of retaining the urinary secretion, from the injury which the urethra had necessarily sustained during the operation. Dr. Henry Davies, who saw her at the request of Mr. Guthrie, we understand, expressed his opinion that it would be some months before she recovered the power of retention.

For several weeks after this operation, she appeared to be gradually regaining her strength, and to be doing as well as could be wished, particularly as she did not complain of any local symptoms. But towards the latter end of April, or early in May, she did not make so much progress towards amendment, but had deranged digestion. It was thought that change of air might be of use to her, and she accordingly was allowed to go into the country for a few weeks.

June 6th. She has now returned, and appears rather worse than when she left. She complains of severe pain in the region of the bladder, passes bloody urine frequently, and the other day she passed a fragment of calculus. It has since been ascertained by Mr. Soden, the house-surgeon, that a considerable piece of calculus remains in the bladder, which will probably require breaking up, before it can be removed. The fragment of calculus passed weighs about thirty grains, and evidently consists of a nucleus of the original calculus of lithic acid.

15th. Has less pain than at last report; continues to pass at intervals very small calculous fragments. Mr. Guthrie, who saw and examined her yesterday, says that he is unable to decide whether a new calculus has formed, or whether it is a portion of the old one which remained after the operation.

23rd. She appears better than when she returned from the country; has passed very little bloody urine lately. This improvement has taken place under a course of *pareira brava*, and *morphia*. She has used the sponge tent, to dilate the urethra, once, with the view of having the calculus removed.

25th. The sponge tent was introduced into the urethra this morning.

Mr. Guthrie, with the assistance of Mr. White, in the afternoon, proceeded to remove the calculus, which was readily enough accomplished. It did not require to be broken up, and was extracted with a small forceps, without occasioning much pain to the patient. It was a large oblong piece of calculus, and weighed about an ounce and a half, thus making the total weight of the calculus about nine ounces.

27th. Looks much better since the calculus was extracted. Her appetite improves,

and the local pain and inconvenience are quite relieved. Of course the incontinence of urine remains.

29th. Very small fragments of calculous matter, of the size of pins' heads, have come away since the operation; but it has been ascertained, by a careful examination, that all the calculus has now been removed. She continues to improve in her general health.

Hysteria—Constant Abduction of the Little Finger—Aphonia, &c.

Mary Vaughan, aged 16, was admitted into Percy ward, April 22nd, under the care of Mr. White.

It appears that a day or two previous, she had fallen down stairs, and received an injury to the little finger of the left hand. A difference of opinion exists as to the nature of the accident; some of the gentlemen who saw her when she first came to the hospital, state that an actual dislocation of the finger outwards had taken place, and that the head of its first phalanx rested between the distal heads of the two inner metacarpal bones; which luxation they believe to have been reduced by the house surgeon, Mr. Soden. Others deny any such dislocation having occurred, and consider the accident to have consisted merely in a severe sprain, affecting the ligaments, with perhaps a rupture of one or more of the tendinous sheaths, and a consequent displacement of the tendons; and this certainly would appear the more probable of the two. However this may be, the finger remains in a state of constant abduction, notwithstanding that its head is now in the right place. A roller has been applied, and in this way the finger kept in its proper situation, but although this has been persisted in during several days, immediately upon its removal, the finger regains its abnormal situation.

In addition to this, she has had, during the last two months, a great degree of aphonia, and at the present time never speaks louder than a whisper. She says she has not been well for three months, lost her appetite, and had a furred tongue, for which she had been under medical treatment. The catamenia have never been completely established; the first time she menstruated was six months ago, and she has had three scanty "shows" since, the last a fortnight ago. Although these anomalous symptoms may legitimately enough perhaps be considered as manifestations of hysteria, yet there do not appear to be any of the symptoms usually regarded as pathognomic of this affection. There have been no convulsive attacks, nor does she complain of the "globus hystericus." Mr. White has ordered her to take assafœtida, and the following has been prescribed.

Rx. Tinct. assafœtidæ, 3 iij;
Aq. menthæ pip. 3 viij;

Misce.

Capt. Cochl. ij. ter quotidie.

May 9th. She complains of pain in the arm, especially upon pressure. The finger remains as before.

13th. During the last two or three days has had great pain in the larger joints, attended with thirst, loss of appetite, furred tongue, flushed countenance, and other symptoms of acute rheumatism. She has been ordered to omit the assafœtida mixture, and to take the "mistura diaphoretic" of the hospital. The aphonia continues unmitigated.

16th. The rheumatic attack has been nearly subdued, but the abduction of the little finger returns as soon as ever the bandage is removed; the aphonia is as at last report.

June 6th. Much the same. Complains of stiffness and tenderness of the arm, extending upwards from the hand. She is directed to take exercise in the open air daily.

15th. Much the same, both as respects the finger and the voice; she is taking effervescing saline draughts daily.

29th. Little or no improvement either in the finger or voice; there is great tenderness of the left arm and mammæ, the latter of which has during some time been somewhat swollen. The amenorrhœa continues. The tongue is flabby, covered with a white fur, dotted with red papillæ, and surrounded with a red border and median furrow.

Rx. Mist. ferri. comp. 3 j ter die.

July 3rd.—The same as at last report. She is to become an out-patient, the case being one of that description in which but little benefit can be obtained by medical treatment.

Errata in last report.

No. 179, p. 733, for diastysis read diastasis.

—o—

NORTH LONDON HOSPITAL.

Secondary Syphilis, successfully treated by Hydriodate of Potash.

ELIZABETH FITZGERALD, aged 19, was admitted May 26th, under the care of Dr. A. T. Thomson. She has frequently been affected with gonorrhœa; and about two years since contracted syphilis, for which she was treated, for four months, in one of the London Hospitals, and left it apparently cured. Two months ago a syphilitic eruption appeared on the face, and spread quickly to the eyes, causing an inflammation and swelling of the eyelids, and impairment of vision. The eruption extended subsequently over the head and the whole body. There is no swelling or ulceration of the genitals—no soreness in the groin, and no discharge.

Previous to her admission she had taken a purgative, which acted powerfully. She was ordered—Potassæ hydriodat. gr. v. ter in die. The head to be shaved.

29th. Somewhat better, but still pain and swelling in the lids of the left eye.

June 1st. Increased the dose of the hyd. of pot. to $7\frac{1}{2}$ grains; milk diet.

3rd. Eruption disappearing from the head.

12th. Still improving; but she complains of a pain over the sacrum, and some leucorrhœal discharge; to be cupped to 3 viij .

17th. Eruption nearly gone. The roots of the alæ nasi are very sore. She was ordered to inject a weak solution of the oxy-muriate of mercury.

23rd. Has continued to improve since last report; the nose much better.

30th. The eruption quite gone.

Erysipelas Phlegmonodes.

Thomas Simmonds, aged 35, of most intemperate habits, was admitted, June 11th, under the care of Dr. Elliotson. In consequence of catching a severe cold, he had inflammatory sore throat, implicating the velum pendulum palati, and the tonsils, especially the left. Twelve leeches and a cold lotion were applied, and a purgative given, which in some measure relieved the throat.

June 12th. The absorbent ganglions on the left side of the throat were considerably enlarged, and a small abscess had formed, burst, and discharged a considerable quantity of offensive matter.

15th. Much better; but complains of severe rheumatic pain in the right elbow; twelve leeches to be applied to it.

17th. The glands are still swollen; he states to day, for the first time, that they are always enlarged; he was a little delirious towards the evening; pulse 70, strong; bowels open. The head to be shaved, and a blister to be applied to the occiput and back of the neck.

18th. Has passed a restless night; is feverish, but does not complain of any pain in the head. As the delirium was supposed to arise merely from irritability, two grains of opium were administered, which completely tranquilized him, and he passed a good night. On the 18th, the abscess was opened, and a quantity of good pus evacuated. The pupils seemed contracted, and the eyes very prominent. Sulp. quin. ter die.

19th. Attacked to-day with erysipelatous inflammation in both arms and legs, which are much swollen; there is considerable fever; bowels are open. Cold solution to be applied, and the opium repeated.

20th. Has passed a restless night; the fever undiminished; complains of tenderness at the epigastrium. A line was drawn across the arms with nitrate of silver, with the intention of stopping the progress of the disease. Dr. E. remarked that he should have also applied it to the diseased parts themselves, had they not have been so painful.

22nd. Seems better, but still very restless; the nitrate of silver has stopped the extension of the inflammation; he is not delirious; but there is a degree of wildness about his eyes. His bowels have been freely opened, and the fever has considerably abated. Ordered to have beef tea and porter; and as the inflamed surface is abraded in several places, zinc ointment to be applied to it.

25th. He seemed to be gradually improving, the inflammation being rather less; his pulse, however, was weak, and he had an attack of diarrhœa, which was relieved by a mixture of chalk and kino.

26th. Erysipelas not increased in the arms; they are soft and swollen, but no fluctuation can be felt: pulse 120, but exceedingly weak: talks incoherently every now and then: the erysipelas has quite disappeared in the legs: he was ordered half a pint of white wine. The abscess has continued to discharge ever since it was opened. About four o'clock this afternoon he was suddenly seized with a severe spasmodic pain in the chest, with dyspnœa: he rapidly got worse, and died at 9 P. M.

Sectio Cadaveris forty-two hours after Death.—On cutting into the affected parts, the cellular tissue was found broken down, and a considerable quantity of thick pus escaped, mixed with a sanious fluid. This pus had become infiltrated between the muscles, destroying the intermediate septa, and in some places the muscular fibre seemed broken down. These appearances were particularly observed in the left arm; the other extremities were also affected in a similar manner, but in a less degree. There was nothing particular in the head, except that the scalp was rather œdematous. The lungs were healthy—there was a small quantity of bloody serum in the pericardium—the heart was healthy, but the left ventricle was slightly thickened. The abdomen healthy. The abscess in the neck was found quite gangrenous.

Dr. Elliotson remarked, that he believed the plan of treatment he had adopted, was, under all the circumstances, the most proper for the case. He believed that if blood had been taken, the man would not have recovered—he was of most dissolute, intemperate habits—he had been some time in the treadmill, which indeed he had just left. This no doubt had added considerably to the debility engendered by a dissipated life, and antiphlogistic treatment would have destroyed him. It is most likely that had he succeeded in curing the arms, legs, and throat, erysipelatous inflammations would have come on in some other part of the system, and carried him off.

LUNATIC ASYLUMS.—TREATMENT OF THE INSANE.

To the Editor of the London Medical and Surgical Journal.

SIR—You are fully aware that mental aberration is often the disease of genius, sensibility, and virtue—a consideration which ought to animate all to aid in the removal of this affliction, not only on such grounds, but on the general principle of humanity. With these sentiments, it is gratifying to find that this subject, as well as that of mad-houses, has engaged your attention; because you possess the capacity and the means of being useful to a class of men heretofore doomed to encounter the greatest difficulties and privations. I concur with you in thinking that physicians should not allow themselves to become the proprietors of mad-houses, because in so doing, they become tainted with a trading spirit, and thereby sink the dignity of their profession, and thus probably lose that sensibility and high sense of honour so essential in this department of the medical profession, towards securing a successful exercise of their talents. The physician should be at once the medical attendant, the guardian, and the advocate of the deranged, obligations altogether inconsistent with the character of the proprietor of a madhouse, as the faithful performance of these elevated duties assumes a very questionable shape, when the physician himself is found the proprietor of such an establishment, because his interests are opposed to his professional fame, particularly when the patient happens to be wealthy. The learning, the humanity, the liberality, and dignity of sentiments become tarnished by being placed under such suspicious circumstances; however, I see no reason why medical men should be absolutely interdicted from so employing their time and their talents. The great object is to render those who become proprietors of such institutions faithful in the performance of their duties; and this can alone be accomplished by the appointment of inspectors of lunatic establishments, whose sole office shall consist in visiting one or other of the madhouses under their control once in twenty-four hours, and at any hour, night or day, that may be deemed necessary, as it is during night that the most disgusting scenes present themselves, and consequently requiring correction at some of these establishments. In short, let efficient inspectors be nominated, because as these appointments are at present arranged, they are worse than useless. Would the commissioners of poor laws be of any use, were they allowed to take fees or solicit patronage from the establishments they inspected? The inspectors of lunatic institutions, besides ascertaining that the proprietors did their duty, should also see that the friends of the deranged fol-

lowed a becoming course. Many of the lamentable scenes of these institutions spring from the neglect or avarice of the friends of the lunatic, and not from the system itself. I have remarked with pain, that the recovery of the deranged patient, when under treatment, was quite a secondary consideration, when compared with the expense of its probable attainment, which expense alone occupied the minds of those who were his heirs, and who consequently ought to have been the anxious promoters of his restoration to mental health; but let me also, for the credit of human nature, state that numerous instances of sympathy, of generosity and affection, have come under my observation, and it is to control the former and animate the latter, that arrangements should be made. Those maniacs who possess the means, and while good bodily health exists, should not be abandoned as incurable; medical aid should be persisted in, whatever the duration of the disease may be, as such perseverance will tend to diminish the number of the insane. Such a system of inspection would ensure attention to the patient from his physician and his friends, as it would enforce the necessary application of the maniac's wealth towards this paramount object; and when the restoration of his mental faculties should appear unattainable, it would procure for him kindness and humanity under this dispensation, so signal and afflicting. It is probably unnecessary to observe that the physician appointed to the office of inspector should have been a careful observer of the diseases of the mind, and should not be allowed to practise at any madhouse. The present system of tolerating those who inspect and control madhouses to be employed by their proprietors, is objectionable in the highest degree, and to my mind has been lamentably injurious to the interest and recovery of the insane.

Here, evils appear not only to have originated, but to have increased to an extent calculated to shake the public confidence as to the present system. No individual ought to be committed to a madhouse on the certificate of two medical men, as such a measure, involving more than life, should be preceded by an inquest consisting of five, two of whom should be non-professional men. The maladies of the mind have increased, are increasing, and will shortly arrive at a frightful state, should some steps not be taken with the view of opposing the progress of this hydra, more terrible than the visitations of Egypt, when under the Divine displeasure. The late Mr. Rose was the author of the Savings Banks, and he also took great pains in this department of human misfortune, which efforts claims for his memory, national gratitude; but what would be his mortification, were he to return to life and find that legislation has not as yet been instrumental in stopping this horrible on-

slaught and degradation of the human mind, and that nothing had resulted from his exertions but a sordid system of profligate jobbing and patronage? Hanwell appears to have originated in this spirit, and the genius of corruption and jobbing seems to have governed every step of the erection of that asylum.

That edifice, built at so much expense, ought to have been rendered instrumental in opposing the progress of insanity; but instead of which, it has been converted into a workshop for making straw hats, and allowed to be occupied by incurables—an arrangement exhibiting a gross and culpable indifference to the interests of science and humanity.

I have the honour to be
Your most obedient humble servant,
PHILO DEMOCRITUS.

The animadversion of our valued correspondent is perfectly just, as nothing can be more reprehensible than the system pursued in this country for the medical treatment of the insane. The medical commissioners have as yet proposed no suggestions or rules for the treatment of the unfortunate inmates of lunatic asylums, and so far as we know, do little more than pocket their salaries. But this might be expected from individuals selected by private interest, who had neither experience nor observation as to the nature or treatment of the disorder of the unhappy persons committed to their superintendence. The appointments of these commissioners was a government job, and those in power preferred their friends, without once inquiring into their competency.—ED.

M. VIREY ON THE GENERATION OF ANIMALS AND PLANTS.

(Continued from page 608.)

THE boundaries of the universe would become too confined, if we supposed this reproductive power active in all its sources, without anything to arrest it; because nature is impetuous in reproduction, on account of the inconceivable attraction of pleasure, so that the equilibrium of the universe could not subsist without the power of destruction, which re-establishes the level or medium of all beings.

But happily the power of reproduction is more limited in the human species, though sexual union is more frequent than between other animals; and we see in this that which is in favour of nature.

Each of the two ovaries of the human female contains from fifteen to twenty ova or eggs; and very few women have had this number of infants. I have never heard or read of a woman who reared more than twenty-one children, but I have known one who had twenty-seven, and another thirty-two, including abortions and premature births.

This last was a woman who was under my care at St. John's Hospital. She was of a sanguineous temperament with auburn hair. She had twins twice, triplets once, miscarried twice of twins, had a child eight months after marriage, twins in seven months afterwards, twins dead at the full time, twins again, one dead the other alive, and now aged 23 years. One of her sisters had only one child, and the other no offspring. Her husband, his brother, and near relations, have had large families, from twelve to eighteen children.

An interesting fact presents itself to the mind, in this stage of our inquiries—Were all the ova of the human race contained in the ovaries of [the first of our species? This question is involved in impenetrable obscurity, and will perhaps for ever remain so. Admitting for a moment, that there were originally a vast number of the human species, which is contrary to divine revelation, what an incalculable number of transmigrations of ovaries and ova there would have been in the successive reproduction of our species since the creation! What differences of constitution! what innumerable imperfections and hereditary diseases! A more correct idea of these will be formed after we describe the influence of temperament, health, disease, climate, season, food, habits and civilization, over fecundity.

It may, however, be remarked, that fecundity is greater with man than with woman. Pregnancy, the puerperal or child-bed state, and lactation, are opposed to reproduction, but a husband might, if the laws of morals, religion, and society, permitted, engender with numerous healthful women during these states. It is also to be borne in mind that the male is more robust and free from diseases than the female, and that he enjoys the generative faculty much longer. Women seldom have offspring in temperate climates, after the age of 45 or 50, when the menstrual function ceases; while men continue to propagate until the age of 65 or 80, and even later, of which there are numerous and daily examples. A very remarkable instance was lately recorded in the public press, (1832 or 33), of a Scottish gentleman, who had 57 illegitimate children by different women; he died intestate, and possessed of a large property, none of which came to his numerous offspring. The generative faculty continues longer with men. Thus, Thomas Parr married at 120, and performed his conjugal duties so well at 140, as to make him forget his old age. He died full of vigour at 152, not of disease but plethora.

M. Virey gives the following account of fecundation and fecundity, in the *Dict. des Sciences Medicales*, which I abridge:

Epochs of Life when Fecundity commences and ceases.—It is generally observed, that women begin to lose their fecundity from the age of 42 to 49. This faculty diminishes in men, from the age of 50 to 60 years, but it

may exist for some years later. These periods are not rigorously exact, though generally so; but climates, passions, and modes of life, cause many modifications. The eastern people, for example, arrive at puberty from the ninth to the twelfth year, and the faculty of procreation ceases at the age of 25 or 30, when they require most powerful excitants to render them capable of performing their conjugal duties; whilst the women cease to be fecund at this period. The northern people become puberous much later, and preserve the faculty of engendering for a longer time. It is not rare to meet with women in cold climates, who engender at the age of 50, and men from 65 to 80 years of age.

Is there a genital season for man? It has been generally supposed that man is not subject to the influence of the seasons in the exercise of his genital functions; in fact, he enjoys this faculty in all seasons, latitudes, and temperatures. Nevertheless, certain physical influences of the air, aliments, mode of life, render certain seasons of the year more prolific than others.

Conditions necessary for Fecundation.—It is the general opinion of physiologists, that in order to give the act of fecundation all the perfection possible, it is necessary, independently of a good constitution and perfect health, and the integrity of the genital organs, that the mind of both man and woman should be completely absorbed during the act of sexual union, for otherwise the offspring will be feeble and delicate, as we observe in the children of those who are altogether enfeebled by excessive labour. The sons of illustrious men are in general unworthy their parents, while we observe on the contrary, that men who have become celebrated by character for genius, valour, &c. have been the fruits of a pure or ardent love, were adulterous or illegitimate, and have had parents whose physical power predominated. The whole soul is directed to one function during the act of generation, and every organ in the body is excited. Every one knows the power exercised by the imagination on sexual congress; a look, a word, a sigh, a whisper, a touch, will exalt or diminish amorous impulse. A vast deal has been written on procreation, but the secret of generation has never been discovered, and the only satisfactory conclusion arrived at is, that there must be a union of the sexes. All physiologists agree, that both sexes contribute to the formation of the new being.

In those countries where the people live without wars, emigration, or laborious employments, but enjoy naval and other commerce, which so remarkably benefit man, there is a superabundance of males among the monogamous, more especially in cold climates, where it is infinitely augmented. There results a less proportion of women to men, polyandri is established, and the male sex predominates. This predominance is observed in all northern nations,

and wherever Europeans pass into other countries.

Causes which favour Fecundation.—The causes which favour the increase of population are the quality, quantity, and species of aliments, the climates, modes of life, occupations, habits, temperaments, &c.

An abundance of nourishment augments the number of men and animals. The years of prosperity are remarkable for the increase of births, the years of scarcity or famine for the diminution. Fecundity is greater in cold than in warm climates. The Icelanders have from fifteen to twenty children, the English and Germans six or eight, the French four or five, and the Spaniards and Italians only two or three. There are, however, individual exceptions, some as regards climate. Thus, for example, the African negresses are remarkably fruitful; and in Egypt women have often two or three infants at one birth.—*Encycloped. Methodique.* It was remarked by Baron Larrey in his *Chir. Militaire*, that several women who followed the French army to the east, and who had no infants in Europe, became pregnant after the use of the baths in Egypt. Other historians and travellers have attributed to the waters of the Nile the great fecundity of the Egyptians. This faculty of procreation extends to animals, and depends more upon the perfect uniformity of the temperature, than to any virtue in the water of the Nile.

The contrary opinion is believed by the credulous Mussulman, and even in the southern provinces of France. M. Renoult informed M. Virey, that on the return of Captain Roustau, in 1801, who sailed several times to the Levant and Egypt, the women of Toulon applied to him and purchased some of the waters of the Nile, on account of their reputed fecundating powers.—*Lett. Des Sciences Medicales, Art. Fecondation.*

It is generally either immediately before or immediately after menstruation, that women are most likely to become pregnant. In either condition there is a determination of blood to the uterus. This is necessary for the periodical secretion, and after this is completed the organ is more sensible and vascular than at other times.

It is held that fecundation is effected with more facility when both individuals are intent upon this object; but it often happens that procreation is accomplished when the parties had their minds occupied in other matters, or when neither desired it. Every obstetrician has been consulted by women who were unconscious of the date of conception; and hence the frequent mistakes made in "reckoning;" women often exceed the time at which they expected delivery, sometimes two, three, four, or six weeks, and even longer. According to writers on medical jurisprudence and obstetrics, there are no moral or physical sensations which enable a woman to know the moment when she became pregnant.

It has been long remarked that fine women are not so fecund as others; but there are some exceptions.

A difference of temperaments between the sexes, a defect of love, antipathies, disgusts, infirmities, a state of delicacy, or whatever opposes cohabitation, excessive corpulency, or thinness, excessive exercise of the mind or body, vivid passions, intemperance, the abuse of venereal pleasure, render both less fitted for the function of generation. The multiplication of the species is prevented by an excess of amorous pleasure.

It has been long observed that the multiplication of the species is diminished where enjoyment is easy and repeated.

Clothing, occupations, different kinds of exercise, have a certain influence upon this faculty. Atrophy or wasting of the testicles may result from tight clothing, and these organs, when compressed by much horse exercise, become completely wasted, or reduced to a state of nullity. The Scythians were impotent from this cause, as attested by Hippocrates: who said, "*Cur multi Scytharum eunuchi, ac ad coitum impotentes.*"—*De aere, locis et aquis.* The Tartars and Arabians are often sterile from too much horse exercise.

COURT OF COMMON PLEAS, DUBLIN.

Monday, June 15th, 1835.

HUGHES v. MARSH.

Extraordinary Medical Charges.

THIS was an action, brought for the sum of 4,737*l.* 15*s.* 3*d.* by an apothecary, for medicines and attendance, according to his counsel's opening speech, from 1832 to 1835. The plaintiff's brother, however, proved that the attendance and supply of medicines commenced in 1828. It also appeared that the defendant was regularly attended by Mr. Wilmot, one of the professors of surgery in Dublin. The defendant's counsel then read a part of the plaintiff's bill of particulars. "It appeared that the charges in the bill for one year amounted to 3,597*l.* 15*s.* 3*d.*, and for a month, to 485*l.* 19*s.* 5*d.* Eight enemas were charged for in one day, at 10*s.* each; 3*l.* 10*s.* for one day's attendance; and three guineas for a night. There were 1703 attendances charged for, and for administering enemas, 1,119*l.* 15*s.*

Mr. Wm. Halliday, a late director of Apothecaries' Hall, considered the bill moderate, while Mr. Halahan and Mr. Leech considered the bill high and exorbitant.

Verdict, for plaintiff, 800*l.*

In the whole course of our experience, we have never heard of so exorbitant a bill as the above. Nearly 5,000*l.* for three years' attendance, and medicines furnished by an apothecary! In one year the charge is 4,000*l.* less by five shillings and ninepence! And only think of all this medicine, with 3*l.* 10*s.*

for a day's attendance, and three guineas for a night's. And lastly, 1,119*l.* 5*s.* for administering enemata!!! Certainly if Mr. Hughes has many such patients, he must make a rapid fortune, unless a few juries should estimate his charges more moderately.

—o—

REFORM IN THE COLLEGE OF PHYSICIANS.

The fellowship is now thrown open to all licentiates of four years' standing, and these are to be elected by a Council, which are appointed by the President and Fellows. Candidatureships are abolished, and every one who applies for examination, must have studied five years, and have three years' hospital attendance.

These rules are of little value, and cannot render the College popular, or increase its friends.

OUR PLATES.

We this week commence our plates of Medical Botany, in alphabetical order, and shall insert letter-press when the subject deserves it. There can be nothing said on the *acacia vera*, which may not be found in any work on *materia medica*.

BOOKS.

Supplement to Obstetric Tables; comprising graphic illustrations, with descriptions and practical remarks, exhibiting, on dissected plates, many important subjects in midwifery, by G. Spratt, Surgeon Accoucheur; Part II. Plates. London. 1835. Churchill.

This is a very instructive work to every student and obstetrician. The part before us contains eight tables, exhibiting thirty-five obstetric views, and principally of practical subjects. Two of the tables very clearly illustrated ovology and embryology, others shew the genital organs, and the size of the uterus and mammae, at the different periods of uterogestation, more placental presentations, the operation of version or turning, and lastly craniotomy. The other subjects have been delineated in the first part of the work. The author is entitled to great praise for the manner in which he has executed these plates, and they are the work of his own hands. To those who are commencing the study of obstetrics, and to those who have been self-instructed, Mr. Spratt's work will prove extremely instructive and valuable.

Lectures on the Diseases of the Lungs and Heart, by Thomas Davies, M.D., &c. &c. 8vo. pp. 512. Longman and Co.

This work contains all that is known on diseases of the lungs and heart, and will be one of reference and authority.

An Essay on the Nature of Diseases. By A. Green, L.L.B., 12mo. pp. 52. Simpkin, Marshall, & Co.

LECTURES
ON THE
INSTITUTIONS OF MEDICINE,

DELIVERED BY JOHN FLETCHER, M.D., F.R.C.S.E., AT THE ARGYLE SQUARE SCHOOL OF
MEDICINE, EDINBURGH; SESSION 1834-35.

LECTURE XXV.

*Various Doctrines of Sympathy considered—Evidences of the Passage of Sympathies by the
Respiratory System of Nerves (continued).*

III.—THAT the influence of the respiratory system of nerves would not be interrupted by sleep or coma might almost have been anticipated from a knowledge of the origin of the respiratory tract in the tuber annulare; and hence the persistence of respiration and the other sympathetic actions, properly so called, not only in natural sleep, but even in apoplexy, till the disease has reached this justly reputed citadel of life, when the extension of the primary irritation of the lungs along the pneumogastric nerves to the common centre of the respiratory system, and thence to the nerves distributed on the respiratory muscles, being thus intercepted at the summit of this common centre, the fundamental vital action is stopped, and death is the result. Upon the same principles, of the comparative independence of the respiratory system of nerves upon the brain, is to be explained the occasional respiration, for some time after birth, of acephalous infants, provided the origin of the pneumogastric nerve is entire, but not otherwise (a); and even the continuance, as lately observed, of some other sympathetic actions after the artificial removal of the greater part of the brain. It is hardly necessary to observe that, although sympathy, properly so called, is thus independent of the brain, passion or instinct, originating as it does in a primary irritation of that organ, cannot be so—the respiratory nerves are ready to convey this irritation, but they cannot convey what is not imparted to them.

IV.—With respect to the correspondence, in all classes of animals, of the development of the respiratory system of nerves, and the manifestation of the stimulus of sympathy, and passion or instinct, this argument in favour of the theory under consideration seems to be in general well founded. It has been already remarked, that in some of the invertebrate tribes rudiments of a distinct respiratory tract have been lately detected (b), giving rise to nerves coming off by single roots, between the double roots of the regular nerves, precisely in the same manner as in the human body, and that these nerves seem to be distributed principally upon the respiratory apparatus, so that in them, as well as in the higher tribes of animals, respiration appears to be effected by sympathy. So obscure are these nerves that it is impossible to say to what particular respiratory nerves of the vertebrate animals they correspond; it is probable, however, that they answer only or chiefly to the pneumogastric, and that it is by the association of the different portions of this nerve, at its common origin, that the sympathy between the organ corresponding to lungs and the active instruments of respiration is maintained. Such appears to be the stimulus to the action of the muscular cloak-bags of the fresh-water mussel (c) (*Mya*, 7), and cuttle-fish (d) (*Sepia*, 10), and the muscles moving the shell of the bivalve mollusca in general; as well as to that of the muscles which move the plates of horn which surround the gills of the cray-fish (e) (*Cancer*, 16), and the elytra or abdominal wings, under which lie the principal stig-

(a) Brâchet (Sur les Fonctions de Syst. Nerv. Gangl. 1823).

(b) Newport, (Phil. Trans. 1833-34).

VOL. VII.

(c) Carus, pl. ii, fig. 11.

(d) Carus, pl. iii, fig. 2.

(e) Carus, pl. vi, fig. 4.

mata of some insects, as some kinds of beetle (*Scarabæus*, 24), and grass-hopper, (a) (*Gryllus*, 25), and perhaps also the stigmata themselves of some others, as the silk-worm (b) (*Phalæna*, 20). In as far then as the respiratory process of the invertebrate tribes of animals is active—for this is by no means always the case—it seems to be effected on the same principles as in the vertebrated, and the development in them of the respiratory system of nerves appears, in a great manner, to correspond to this their chief manifestation of proper sympathetic action. The display of passion and instinct, indeed, by some invertebrate tribes, in the acceleration of the action of their heart or corresponding organ, the increase or vitiation of their secretions, and the perturbations of their movements in general from violent emotion, as well as in the ordinary actions of taking aliment, of discharging excrement, and of copulating, and the more extraordinary ones of selecting each its proper kind of food, of hoarding up grain, of depositing its eggs only in certain places, of choosing the proper element for its locomotion, of migrating, and of constructing the curious fabrics elsewhere alluded to, is much more remarkable than that of sympathy, properly so called; but not more so than the presumed general distribution of the pneumogastric nerve—supposing their respiratory system to be confined to this—seems to be quite competent to account for. We must remember, moreover, that the instinctive actions of the invertebrate animals seem to be numerous and striking, only because their rational actions are few and ambiguous—they are relatively, not absolutely remarkable, and not at all disproportioned, perhaps to the development in them, obscure as it is, of the respiratory system of nerves. But it is in the vertebrated tribes principally that this correspondence between the development of the system of nerves in question, and the manifestation of sympathy and passion or instinct is observable. The first respiratory nerve, as we ascend in the scale of animals, capable of being recognised as decidedly corresponding to any one found in man is the pneumogastric, which is met with in fishes, and which, as standing in them, in the place of almost all the rest, is of very great size. It is by this nerve principally that, not only their gills, but the muscles of their jaws, fauces and thoracic ribs, which it was necessary should sympathize with the gills, in the process of respiration, as well as those of the gill-flaps, which are in like manner, instrumental to expiration, are supplied; and a further reason for the great size of this nerve in fishes is perhaps to be found in the very laborious nature of their respiratory and other sympathetic and instinctive actions, as effected in so dense a medium as water. Fishes evince few other striking examples of proper sympathetic action, with the exception of that of the heart and stomach—both which receive their nerves likewise from the pneumogastric—with every organ of the body; but their motions under the stimulus of passion or instinct are numerous and remarkable. Of this we have examples in the change of colour—analogue perhaps to blushing—which many fishes, as the perch, (*Perca*, 28), and stickleback, (*Gasterosteus*, 28), undergo from emotion; as well as in the increase and vitiation of their several secretions, by means of which it is probable that the diodons and tetrodons inflate themselves when irritated, so as to render all their spines erect, and in the violent instinctive movements by which many species of fishes, of the genera *Scarpa*, *Perca*, *Trachinus*, *Trigla*, *Raia*, &c. inflict sometimes severe wounds on their aggressors—to say nothing of the more ordinary instinctive actions which they perform in common with animals in general, or of those more extraordinary, by which their migrations and other habitual processes are effected. To all these the very extensive distribution of the pneumogastric nerve, as well on the external, as on the internal organs of fishes seems quite adequate; and it is strongly in favour of the presumption that it is by means of this nerve that the stimulus of passion or instinct in general is in them conveyed, that the electrical apparatus of such fishes as possess one, like the electrical eel, (*Gymnotus*, 26), the electrical silure, (*Silurus*, 29), and the torpedo, (*Raia*, 31), which is well known to be so much under the influence of this stimulus, is supplied principally by an immense branch of the nerve in question. The only other proper respiratory nerve possessed by fishes is the pathetic, which seems, in all, to be subservient to effecting the sympathetic motions of the iris, as well as in those fishes in which the eye-ball is moveable, to regulating the motions of this organ under excitement. It is not till we come to reptiles that we meet with, in addition to a pneumogastric and pathetic nerve, a facial and a glossopharyngeal; which are, to them, in place of that portion of the pneumogastric nerve of fishes which supplies the muscles of the jaws and fauces, by which organs exclusively the Batrachian and Chelonean reptiles, and, in a great measure, the Ophidian also inspire, the Saurian reptiles alone using their intercostal muscles to any great extent in this operation. The last of course possess further intercostal nerves, as nerves of inspiration, and all are furnished with lumbar nerves, as nerves of expiration, the place of both of which is, in fishes, supplied by those portions of the pneumogastric nerve which go to the muscles respectively of the thoracic ribs and of the gill-flaps. Now, if the last mentioned nerve be, in fishes, a vehicle of sympathy and passion or instinct, it seems fair to conclude that all those which are successively substituted for it—in these in-

(a) Carus, pl. vii, fig. 21.

(b) Malpighi.

stances the facial, the intercostal, and the lumbar—have a common origin, and are so likewise; and that such nerves become more numerous only in proportion as the actions resulting from these stimuli are to become more remarkable. The other proper sympathetic actions of reptiles are not very striking, but some of those resulting from passion are exceedingly so. Of this nature is the change of colour which the chameleon (*Lacerta*, 35) is so well known to undergo from emotion, as well as perhaps the increased brilliancy in the eye of the rattle-snake (*Crotalus*, 34)—in which appears to consist its reputed fascinating power—from desire (a); and it is perhaps to the same head that we must refer the copious flow of tears, which, as said to be shed by the crocodile (*Crocodylus*, 35), on some occasions, has been so long regarded as emblematical of hypocrisy, the increase and vitiation of the cutaneous exhalation of the alliaceous and mephitic toad (*Rana*, 32), when the animal is irritated, and the bath of sweat which, under similar circumstances, is said to envelope the salamander (*Salamandra*, 32), and which seems to have given rise to the notion that the animal can inhabit fire. The pouching of the neck also by some species of serpents, as the cobra-da-capello (*Coluber*, 34), from emotion, is an instance of the influence of passion, in reptiles, on the action of muscles generally voluntary. The proper instinctive actions of reptiles, ordinary and extraordinary, are not, generally speaking, very remarkable; and, upon the whole, the manifestation by this tribe of animals of sympathy and passion or instinct seems to be in no degree disproportionate to the development in them of the system of nerves in question. With respect to birds, they have only the same respiratory nerves as the higher tribes of reptiles, but their distribution is somewhat different—that of the facial nerve in particular, which being now no longer wanted as a nerve of inspiration—a process which is effected, in birds, exclusively by the intercostal muscles—and not yet required to effect a change in the general expression of the countenance from emotion—their horny bill being of course unsusceptible of any such change—is turned backwards over their neck and shoulders, where it is productive of the most striking changes from this cause, as in the bristling of the feathers of the neck on preparing for the fight: it is accordingly very large in the game cock (*Phasianus*, 41), but very small in the duck (*Anas*, 36), which has very little power of displaying emotion in this way. Besides the process of respiration, birds, like reptiles, manifest but few instances of proper sympathetic action; but of those, so much more numerous, which are excited by passion, we may take as examples the blushing of the wattles of the turkey cock (*Meleagris*, 41), the vomiting of the vulture (*Vultur*, 40), the erection of the neck feathers by the game-cock—analogue perhaps to the pouching of the neck by the cobra-da-capello—and many others displayed by birds under strong emotions of various kinds. Their proper instinctive actions also are often very remarkable, and some of these, as their selecting of proper places for depositing their eggs, the running by the aquatic tribes into the water the first time they see it, the construction of their nests and their migrations, have been already alluded to—they appear to be all, however, as well as the actions before spoken of, easily explicable upon the presumption that it is by the respiratory system of nerves that the stimulus, on which they severally depend, is conveyed. Finally, in mammals the complement of this system of nerves is at length filled up by the addition of the accessory, the phrenic, and the external respiratory. The two latter become necessary from the addition, in mammals, of those proper inspiratory muscles, to the motions of which these nerves are subservient; and it is in mammals accordingly that we meet with for the first time, not only a perfect inspiratory process, but that extensive train of sympathies in which the diaphragm is implicated, such as yawning, hiccoughing, and so forth (b). The accessory nerve is, in mammals in general, in place of the facial nerve of some reptiles and birds—an excellent presumptive proof of a common origin—serving, in quadrupeds, to raise the mane, as well as to inflate the neck and arch the shoulders, when they are irritated; while their facial nerve, distributed, as it is, as well on the skin of the cheeks and tunicæ conjunctivæ, as on the muscles of the cheeks, nostrils, eye-lids, and eye-brows, not only involving most of these parts, as other respiratory nerves do other organs, in one common sympathetic action during any impediment to respiration, but gives an intensity and variety to the countenance from emotion, of which no other tribe of animals offers any example. This nerve is relatively small in the sheep (*Ovis*, 45), but becomes progressively larger in the deer (*Cervus*, 45), the ox (*Bos*, 45), the ass and horse (*Equus*, 46), the camel (*Camelus*, 46), the

(a) The reputation of the rattle-snake in this way with respect to small birds, squirrels, &c., seems to have suggested to Milton the idea of endowing the serpent in the flower garden with a similar power.

“—its gentle, dumb expression turned at length the eye of Eve.”

Some quadrupeds also, as the wolf and

hyæna, appear to possess a similar power.

(b) Physiologists have continually echoed one another in ascribing sneezing to a convulsion or spasm of the diaphragm. Such an affection may produce a sigh, a whoop, a yawn, a hiccough, a stitch, a paroxysm of angina pectoris, &c., according to its extent, degree, or duration; but by no possibility can it produce a sneeze.

dog (*Canis*, 59), the lion (*Felis*, 50), and the monkey (*Simia*, 51), corresponding almost precisely with the degree of expression evinced by each; but in no one does it make any approach to its relative size in man, who so infinitely surpasses all animals in this respect. In the greater number of the actions indeed which mammals in general display, from either sympathy or passion, they seem to differ from man only in degree. In the remarkable sympathy between the female genital organs and mammæ, which is peculiar of course to mammals, some quadrupeds are hardly inferior to the human species (*a*); and if man appears to stand almost alone, in his susceptibility of a flow of tears from affliction, and of laughter from mirth, it is perhaps not because there is no tendency, in other mammals, to the same actions from the same primary stimuli, but because they are in general incapable of the peculiar emotions in which these primary stimuli consist (*b*). The proper instinctive actions also of other mammals, are equally similar in general to those of man—an analogy very well corresponding with the general similarity in their respiratory system of nerves—and, upon the whole, it can hardly be denied that there is, in all tribes of animals, a more or less intimate relation between the development of this system of nerves and the manifestation of sympathy and passion or instinct, and that consequently this argument in favour of regarding the former as the vehicles of the latter, regarded as stimuli to irritability, is admissible. It may be repeated, also, that the frequently vicarious nature of the several respiratory nerves, which this summary review discloses, in the various tribes of animals—the pneumogastric nerve of fishes, for example, standing in place of the facial nerve of most reptiles, the facial nerve of most reptiles in place of the intercostal nerves of birds, and that of birds in place of the accessory nerve of mammals, while the intercostal nerves of birds do, not only their own duty, but that of the phrenic and external respiratory nerves of mammals, is strongly corroborative of the opinion that they constitute one collective system; and when we know that at least some of these nerves convey sympathy, while others equally certainly convey passion or instinct, we can hardly refuse to allow to them all a general unity, not only of origin, but of office, or to admit that this office is the one above ascribed to them.

V.—When on the subject of the similarity in structure of the ganglionic and sensiferous systems of nerves, as a presumptive argument in favour of the analogy of their office, it was incidentally remarked that the nerves of the respiratory system and the proper motiferous nerves have a structure equally similar; and if the former fact furnished a fair presumption that, as the sensiferous system was known to be the seat of one kind of susceptibility, the ganglionic was that of another, it is equally fair to presume from the latter that, as the motiferous system is known to convey one kind of stimulus—that of volition—the respiratory system conveys another—that of sympathy and passion or instinct. As the nerves of the two former systems are pexiform and soft, with ganglions also of a very similar structure, so those of the two latter are fibrous and hard, and without perhaps any ganglions at all. It is true the pneumogastric nerve, and perhaps some others of this system, frequently present ganglions in their course; but it is probable that such ganglions belong rather to some of the numerous nerves with which they are in their course associated, than to the nerves in question considered as exclusively respiratory (*c*)—but to this source of ambiguity further allusion will be made in future. In the mean time the general similarity in the structure of the respiratory and motiferous nerves will be very obvious if we compare the facial, the pneumogastric, or the phrenic nerve with the motor oculi, the abductor, or the hypoglossal; and the general dissimilarity in that of the respiratory and sensiferous nerves, if we contrast the facial and trigeminus nerves, as distributed upon

(*a*) We learn from Herodotus that the ancient Scythians were accustomed to increase the flow of milk from their mares by irritating the vagina.

(*b*) The only brutes said on good authority to weep from sorrow, are some species of monkey, the seal, and the camel, the first by Humboldt, the second by Steller, and the last by Pallas: the dog, however, should certainly be added to the list. The alleged "big, round tears," which "course one another down the innocent nose" of the deer, the hare, and other animals, when hotly pursued, are in fact only sebaceous matter, which under these circumstances flows in profusion from a collection of follicles in the hollow of the cheek; and the far-famed "crocodiles' tears," although *bond*

fide tears, do not flow from affliction. But if crying is not confined to man, he is perhaps exclusively "a laughing animal," as he has been sometimes defined, no brute apparently being capable of that sense of the ridiculous, arising from incongruous associations, in which this action originates. The reputed laughing of the hyæna and some other animals, it need hardly be observed, furnishes no exception to this remark.

(*c*) "C'est a tort," says Adelon, speaking of the pneumogastric nerve, "que Reil le disait formé d'une serie lineaire de ganglions: il a evidemment la même structure, les mêmes propriétés, que les autres nerfs spinaux et encephaliques. — (Physiol. de l'Homme, 1824, t. iv, p. 218.)

the face. In as far then as similarity in structure implies analogy of office, this argument in favour of the theory in question appears to be tenable.

VI.—The fact that, while the ganglionic and sensiferous nerves are alike almost inadequate to transmit the galvanic aura, the respiratory and motiferous nerves alike transmit it with facility, has been already more than once alluded to; and as, in this one respect at least, the similarity in structure is attended with an identity of office, we have an additional reason for believing, that the natural function of both, which we know is not identical, is at least analogous.

VII.—But a still more direct argument in favour of the doctrine that it is by means of the respiratory system of nerves that the stimulus of sympathy and passion or instinct is conveyed, is derived from the fact that a direct mechanical stimulus applied to the trunks of the nerves of this system occasions in general a display of irritation, not only in the parts to which these nerves immediately proceed, but also in such others as are known to be sympathetically connected with them (*a*). Thus, any such stimulus applied respectively to the trunks of the glosso-pharyngeal, the pneumogastric and the spinal accessory nerves, as well as to some others of this system, has been found, after a longer or shorter period, to accelerate respiration—a circumstance which can be attributed only to the association, at their origins, of these nerves with the intercostal and phrenic nerves—and as, in these instances, the nerves in question were obviously vehicles of sympathy, of which passion or instinct is merely a modification, it seems fair to infer that such is the office of all the nerves of this system, which are so frequently vicarious of each other, in all cases of the operation of these agents as stimuli to irritability.

VIII. It has hitherto been presumed that the respiratory system of nerves is the vehicle of sympathy and passion or instinct, principally from the facts that all the organs liable to be acted on by these stimuli, as well as those which are the seat of the primary irritation, may be presumed to be furnished with these nerves; that the conveyance of these stimuli is certainly independent of both the sensiferous and motiferous departments of the nervous system; that the more striking are the evidences, in all tribes of animals, of the action of these stimuli, the more is the respiratory system of nerves developed; that the nerves of this system are in structure similar to the motiferous nerves, which are known naturally to convey a stimulus analogous to these; that the two systems may be made to convey certain stimuli in common; and that certain other stimuli applied to the trunks of the several respiratory nerves frequently excite sympathetic actions; but the most conclusive evidence in favour of this theory is the circumstance that the conveyance of sympathy and passion or instinct is at once intercepted by the obstruction of the nerves in question. It has been proved that after the division of the pathetic nerve, by cutting across the tendon of the superior oblique muscle (*b*), the eye-ball is no longer turned downwards and outwards, either in any impediment to respiration, or in rage and other exciting passions, but, on the contrary, remains permanently twisted upwards and inwards; the action of the superior oblique muscle now not only not overcoming, but no longer counteracting that of the inferior oblique—which is moved by the motor oculi—as is naturally the case in dismay and other depressing emotions, when the eye-ball is always turned in this latter direction. It is obvious, therefore, that these movements of the eye-ball, from sympathy or emotions, exciting or depressing, depend on the pathetic nerve, which naturally communicates in the former kinds of emotion more, and in the latter less, than its usual stimulus (*c*); since there still remained, after the experiment above alluded to, other muscles by which the outward and downward motion of the eye-ball might have been effected, had the nerves with which these muscles are supplied been competent to convey the stimuli in question. The section of the nerve in this place was not of course calculated to impede either the contractions of the iris from sympathy, or the flow of tears from either sympathy or passion. But still more remarkable effects follow the division of the facial nerve (*d*). There is now no longer on the side affected any participation by the muscles of the eye-lids or eye-brow, nostrils or face, in the general perturbation arising from impeded respiration (*e*), no tingling of the gums from irritations of the internal ear, nor any

(*a*) This has been sufficiently established by the recent experiments of Mr. Broughton, the general result of which was read to the British Scientific Association assembled at Edinburgh in 1834.

(*b*) This experiment was performed by Sir Charles Bell on a monkey.

(*c*) This influence, at one time active, and at another passive, of the pathetic nerve, renders it easy to understand how the supply of a respiratory nerve to one only of the two oblique muscles of the eye should

be quite compatible with the doctrine which ascribes to the oblique muscles in general all the involuntary motions of the eye-ball.

(*d*) Nature has not unfrequently performed this experiment in the course of suppurations before the ear; and it has been often artificially performed on the ass, the deer, the monkey, and many other animals.

(*e*) It is a common notion that the nostrils are expanded in difficult respiration in order to admit more air to the lungs—an end which would be so much more effectually

other indications of what has been called passive sympathy, or of a primary irritation, having extended from a distant organ to the parts furnished by this nerve; nor, on the other hand, is there any acceleration of respiration from sprinkling cold water on the face, any flow of tears from onions, or sneezing from snuff, or other acrid substances applied to the nostril (a), any coughing from irritating the external auditory canal, or any other indications of active sympathy, or of a primary irritation of the parts furnished by this nerve, having been transmitted to distant organs. Further, the colour of the cheek and the refulgence of the eye remain now quite unchanged under those emotions which usually excite blushing and increased brilliancy of the eyes (b); there is no longer any winking from apprehension of danger—the orbicularis palpebrarum being now unable to overcome the resistance of the levator palpebræ superioris, which is moved by the motor oculi, nor any frowning from anger. The nostril remains pinched, however exciting may be the emotion—the elasticity of its cartilages being now, as is naturally the case under depressing passions at all times, no longer antagonised, and more than antagonised by the requisite muscles—and the general expression of the features from sorrow, mirth, or any other mental perturbation, continue unaltered (c). In birds again, after the division of the facial nerve, the power of expressing emotion by the movements of the neck and shoulders is entirely lost. It may be said indeed, that the facial nerve being not only a respiratory nerve, but the only motiferous nerve of the parts on which it is supplied—as will be explained in future—these facts prove nothing in favour of the presumption that it is by the respiratory system that the stimuli of sympathy and passion or instinct are conveyed: but as the simply motiferous nerves certainly never do convey these stimuli, while the simply respiratory as certainly do so, it must be perceived that it is in the latter capacity that it operates in this way. The effects of a division of the glosso-pharyngeal nerve have not been very well ascertained; but those of an injury or division of the pneumogastric nerve are sufficiently well known. If both are divided, among many minor consequences, such as that of intercepting, in quality perhaps of chief nerve of the whole respiratory system, all sympathy between the nostrils and fauces respectively and the muscles of the abdomen, so that neither sneezing nor vomiting is excited by the two former (d),

attained by opening the mouth. They are distended, under these circumstances, for the same reason as under exciting passions, as when a person flatters himself he has accidentally said a good thing, &c.

(a) "When carbonate of ammonia," says Sir Charles Bell, "was put to the nostrils of an ass, the facial nerve of which had been cut, the side of the nose and face on which the nerve was entire, was curled up with the peculiar expression of sneezing; but on the other side, where the nerve was divided, the face remained quite relaxed; and the same effect has resulted in dogs and other animals, on which the experiment has been repeated." (*Exposition of the Natural System of the Nerves*, &c. 1824). It has been elsewhere remarked that the division of the olfactory or trigeminus nerve has no such effect.

(b) In the case of a terrier, in which the nerve had been divided on one side, Sir Charles Bell expressly remarks, "There is a brilliancy in the eye of the sound side, while that of the injured side is perfectly inanimate"—a fact which has been frequently noticed since; (*Appendix to Exposition*, &c. 1827); and which is of particular value as demonstrating the influence of this nerve, and therefore probably of all the other nerves of this system, on the capillary vessels, the seat of all the molecular actions of the body.

(c) A monkey, on which this operation had been performed by Sir Charles Bell, no longer displayed, on the injured side, the characteristic motions of the eye-lids and

eye-brows from fear or anger; and, when enraged, could grin only on the opposite side, like a paralytic drunkard: and a terrier, which had been subjected to it, lost all power of expression on the affected side; and, when he wished to shew his teeth, the face, which had been balanced before, became twisted to the healthy side, and the eye-lids of the two sides being, in this state of excitement, very differently affected, presented a sinister and ludicrous expression. Mr. Shaw, speaking of a little girl, the right facial nerve of whom was diseased, remarks, "When she laughs heartily, the right cheek and the same side of the mouth are unmoved, while the muscles of the left side are convulsed with laughter; and Sir Charles Bell, in relating a similar case which fell under the notice of Dr. Gregory, observes that all power of expressing emotion with the eye-brow and corner of the mouth of the affected side was entirely lost—the nostril also was permanently collapsed, and the cheek, during emotion, "flapped like a blind before an open window." Such cases have so often attracted attention since the publication of Bell's remarks upon the subject, that these facts are now unquestionable.

(d) Brâchet (*Sur les Fonctions du Syst. Nerv. Gangl.* 1823). From the circumstance that no respiratory efforts are made on any impediment to respiration, and no food taken, however empty may be the stomach, after a section of this nerve, it has been presumed by Brâchet, as before observed, that the pneumogastric nerve is the vehicle of the irritations on which the sensation producing

the natural respiratory process, the regular action of the heart, and the healthy function of the stomach are all simultaneously impeded, and death is sooner or later the result (a). Now all these effects appear to result from the obstruction of sympathy and passion or instinct; the former of which at least, if not the latter also, is certainly necessary to call the respiratory muscles into action, nor is it less essential perhaps to that of the heart and stomach, no two organs having so intimate a sympathy with every other as these, and such a stimulus as this extensive sympathy affords being, in all probability, quite necessary to

a desire to breathe under any impediment to respiration, and that of hunger respectively depend; in other words, that it is not a respiratory, but a sensiferous nerve. These effects, however, may certainly with an equal show of reason be referred to a defective conveyance of the natural stimulus whence all instinctive actions arise, as to a want of certain sensations, which however necessary they may be as precursory to passion or instinct, certainly constitute no part of the chain by which it is conveyed as a stimulus to irritability.

(a) Dividing the pneumogastric nerves has been a favourite experiment of physiologists ever since the time of Galen, and its fatal effects have been ascribed to the impediment, at one time, as by Cruickshank, Bichat, Le Gallois, Magendie, Broughton, Holland, Dupuy, Mayer, and Brachet, of the function of the lungs; at another, as by Willis, of that of the heart; and at a third, as by Valsalva, Haller, Blainville, and Haighton, of that of the stomach. That the first opinion is the true one there can be no reasonable doubt; but, presuming that such is the case, the fatal effect may be brought about, it is said, in any one of six different ways.—1st. By obstructing the conveyance of the natural stimulus of sympathy from the lungs to the respiratory muscles, as has been above presumed. 2ndly. By occasioning a deposition of mucilage in the bronchi, as supposed by Brachet. 3rdly. By occasioning such a collection of air in the air-cells as to produce vesicular, or, by a rupture of some of these cells, interlobular emphysema, as supposed by Mayer sometimes to occur. 4thly. By causing the congestion of the blood in the pulmonary vessels, which, according to Mayer, is the most common result. 5thly. By paralyzing the muscles which keep open the rima glottidis—the circo-arytenoid—so that it becomes permanently closed, as supposed by Holland and Dupuy. And, lastly, by paralyzing, on the contrary, the muscles which close the rima glottidis—the proper arytenoid—so that it remains permanently open, and matters thus pass, as the cardia is likewise palsied, from the alimentary into the respiratory passages, which is another occasional occurrence, according to Mayer. It may be observed, however, that the second, third, and fourth of these modes of operating all resolve themselves into the first, since they are the natural results of the obstruction of respiration; and, accordingly, every attack of asthma is commonly terminated by a deposition of mucilage, and, in the chronic disease, there is usually a greater or

less collection of air—so that, mistaking effects for causes, Bree has traced asthma to bronchitis, and Watson, Baillie, and Laennec, to emphysema—while the total want of the accustomed molecular changes of the blood, resulting from a total cessation of the respiration, might have been expected to occasion its congelation, upon principles already stated. And with respect to the fifth and sixth modes of operating, it appears that palsy of the crico-arytenoid muscles takes place only when the recurrent nerves, *per se*, are divided, and that of the proper arytenoid, with the upper laryngeal nerves *per se*; while the division of the trunks of the pneumogastric nerves, by paralyzing both, keeps the rima glottidis midway between extreme constriction and extreme dilatation, but of course totally immovable—when, however, death results from the entrance of alimentary matters into the air-passages, it must be regarded as entirely accidental. The alleged possibility of obviating all difficulty of breathing, after this operation, by inserting a tube into an aperture made in the trachea, as done by Holland and Dupuy, occurs only, for an obvious reason, after the division of the recurrent nerves; if the pneumogastric nerves are divided near their origin, as done recently by Brachet, the insertion of a tube in the way proposed, has been found to be quite inadequate to prevent asphyxia. The *modus operandi* of the division of the pneumogastric nerves with respect to the heart has been less investigated than with respect to the stomach. It has been abundantly established by Wilson Philip, Clarke, Abel, Hartings, Vavasour, Milne Edwards, Breschet, and others, that, if these nerves be divided in animals which have recently taken food, digestion is materially impeded, and that it is restored by passing the galvanic aura along the eut nerves—and hence has been derived one of the principal arguments in favour of the untenable and almost unintelligible hypothesis that galvanism and the nervous energy are identical—but it is still questioned in what manner the division of the pneumogastric nerve operates in this instance. It has been above assumed that it is by obstructing the conveyance of the natural stimuli of sympathy and passion from other organs to the stomach—the main centre, as it were, of the sympathetic influence of every organ of the body. It cannot be by imparting to the stomach its irritability that these nerves are essential to digestion, since we must, consistently with what has been already at so great length insisted on, conceive that this is derived from the ganglionic system; nor by

maintain their healthy functions. There is indeed good reason to believe that asthma, habitual syncope, and dyspepsia, when merely functional, are all analogous diseases, and all dependent on an inadequate conveyance, by the pneumogastric nerve, of the stimuli of sympathy and passion or instinct respectively to the respiratory muscles, the heart, and the stomach; and it is a strong corroboration of this opinion that the substitution of the strong stimulus to galvanism is equally beneficial in them all—but into a full consideration of this subject it would be improper to enter at present.

furnishing it with its ordinary stimulus, since this is provided by its contents; further, the stomach is not endued with sensibility, and is exempt from the control of the will. What then can the pneumogastric nerves communicate to it but the additional stimuli in question, which may be regarded as hardly less essential to its healthy secretions and motions than that of sympathy to the action of the respiratory muscles, particularly when it is remembered that both are equally disturbed by a section of these nerves and equally restored by galvanism. Maguire believes that the division of these nerves affects digestion only in as far as it affects respiration; but this seems as improbable as that it affects respiration only in as far as it affects digestion. It most probably affects both directly and *per se*; although its fatal effects seem to be owing to its influence chiefly on respiration, as the function most immediately essential to life. According to Holland and Dupuy, who follow the same idea, it ceases to impede digestion as well as respiration, if a tube be afterwards inserted into an aperture of the trachea: but this remark has been replied to already. Lastly, it is the opinion of Leuret and Lassaigne (*Rech. Physiol. et Chim. sur la Di-*

gestion, 1825) that the only effect of cutting the pneumogastric nerves, as far as regards digestion, is that of paralyzing the cardia, so that, by the contractions of the cardiac end of the stomach, the portion of chyme which is first formed is propelled backwards into the gullet, instead of forwards into the pyloric cavity; and, during the subsequent relaxation of this cardiac end, returns into the left cul-de-sac, so that no new portion of the alimentary mass ever becomes exposed to the action of the gastric fluid; but this opinion is a very improbable one: the palsy of the cardia may be a collateral effect of the division of these nerves—like many of those which take place in the lungs from the same cause, but it appears to be—like most of those—resolvable into the generally impeded function of the organ in question. It should not be forgotten, that a very common effect, with respect to the stomach, of dividing the pneumogastric nerves, according to Brodie (*Phil. Trans.* 1814), is inflammation: a fact which further illustrates the strict analogy in the office of these nerves here and in the lungs, the bronchitis, to which the fatal effects have been in the latter case attributed, being an equally common occurrence from the same cause.

LECTURES

ON THE

PHYSICAL EDUCATION AND DISEASES OF INFANTS, FROM BIRTH TO PUBERTY.

By DR. RYAN,

*Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;
Session 1834-35.*

LECTURE XLIII.

Diseases of the Digestive Organs—Vices of Conformation, and Diseases of the Œsophagus and Stomach.

GENTLEMEN—Having described the diseases of the fauces or throat as a portion of the digestive tube in infants, I shall now direct your attention to vices of conformation of the Œsophagus, stomach, intestinal tube, and of the abdominal and pelvic viscera.

Vices of Conformation of the Œsophagus.—

The commonest vices of conformation of the Œsophagus, are partial or total absence of this part of the digestive tube; obliteration of this canal, as described by Meckel, Lallemand*, and Blundell†; termination of

the tube in a cul-de-sac, or a division at some part forming two canals, placed side by side, as noticed by Blaes, who is cited by Meckel. Sonderland, a physician at Barmen, gives a case of absence of the Œsophagus.

When the Œsophagus is impervious, the breast milk or any other aliment is vomited, the infant emaciates, and generally dies in a few hours, for example sixteen or twenty-four after birth. In such cases it has been tried to support life by nutritious clysters, but these were found insufficient.

Alterations of Tissue developed during intra-uterine life.—M. Billard informs us that in two hundred infantine bodies which he examined in 1826, at the Foundling Hospital in Paris, he found the Œsophagus more or less affected in one hundred and ninety. The surface was red or violaceous (of a violet colour), but he and M. Baron consider that this redness is not pathologic, and is the result of the incomplete development of respiration and circulation. The former has, however, narrated cases in which the redness was morbid.

Œsophagitis.—Inflammation of the Œsophagus is rare in adults, and is generally caused by the swallowing of poisons, as calomel and certain other acids. It is however common to new born infants, as the

* Journ. Complem. du Dict. des Sciences Medicales, t. viii.

† Blundell's Lectures on Midwifery, in the Lancet.

œsophagus is generally the seat of more or less congestion, and this is increased by the use of irritating or improper food, which is almost universally administered.

In some cases the inner surface of the œsophagus is covered with a secretion (muguet), is ulcerated or gangrenous. M. Billard has described gangrene of the tube so early as the sixth month.

The causes of œsophagitis are primitive vascularity of the affected part, increased by improper food, as farinaceous aliments, ardent spirits, or exposure to vicissitudes of the weather.

The inflammation may be simple, erythematous, with secretion (muguet), or gangrenous.

The symptoms are vomiting immediately after taking the breast milk or other food; there is pain on deglutition, evinced by cries, the infant rapidly emaciates, and death closes the scene in a few hours. All these symptoms may however be occasionally produced by spasm of the œsophagus, but in such cases the vomiting will be occasional and unaccompanied by pain.

In all cases of new born infants, it is a bad and dangerous practice to give them very hot fluids, on account of the congested state of the œsophagus, which predisposes it to inflammation. All food or drink should not be warmer than breast milk, that is as near the temperature of the body as possible—98 deg. It is this state that causes the frequent vomiting of new born infants.

Treatment.—When the vomiting occurs as soon as the infant sucks or drinks, and is accompanied by pain indicated by distressing cries; cold fluids, milk and water, barley water, or spring water, should be exhibited, leeches and fomentations applied, and these followed by counter-irritation, while the bowels should be regulated by clysters. The strength may be supported by clysters of beef tea, milk, or arrow-root, frequently repeated.

œsophagitis is of much more common occurrence in inflammatory diseases of the throat than is generally supposed, and dissection proves this fact. It is, I repeat, a common cause of vomiting in very young infants, and is excited by the high temperature of the artificial food exhibited by mothers and nurses.

Vices of Conformation, and Diseases of the Stomach.—The stomach has occasionally presented vices of conformation. It has presented three divisions like those of some of the inferior animals, and in other instances did not open into the duodenum. The cardiac orifice has been very much contracted, and the valve of the pylorus absent (Fleischmann,* quoted by Meckel). Even the complete absence of the stomach has been observed in infants deprived of other organs.

The displacements of the stomach are frequent, as attested by M. Baron at the

Foundling Hospital in Paris, and this organ may also form hernia.

The congenital diseases of the stomach and intestines demand great attention, and the practitioner should be able to distinguish between the sound and morbid state of the organ, when called on in medico-legal inquiries, more particularly in supposed infanticide.

M. Billard has given a graphic description of the normal and abnormal states of the digestive tube, which I shall quote freely.

Diseases of the Stomach during intra-uterine life.—It appears, according to the repeated observations of M. Billard, and I can attest the same fact, that the internal surface of the stomach of the foetus in utero, and of the new born infant, is of a white rose colour in a healthy state, that its villosities are more prominent than in the adult, and that about the fourth or fifth month, the internal membrane is easily separated from the muscular and subjacent cellular tissue.

The stomach at birth contains mucosities with small masses of concremented mucous, somewhat similar to the white of egg, and occasionally of a yellow colour. On removing this coat with the nail, or back of a scalpel, the mucous or internal coat of the stomach is sound.

M. Capuron and others consider this mucosity as saburrous. The fluid may be tinged brown or red, according to the pathological state of the stomach.

Congestions.—Congestions of the stomach are very common to new born infants; they vary from the capilliform injection to the general violaceous tint of the parietes of the organ. They are sometimes partial or in spots, which may be of a pale, deep, or dark red colour. They are observed on any part of the interior of the stomach, may be highly inflamed, or succeeded by ulceration. It is always important to consider the cause of the death of the infant. As it usually dies of asphyxia, we commonly find a sanguineous congestion of the stomach, which corresponds with that of the abdominal viscera, in which dark fluid blood is generally discovered. There is also effusion of blood on the inner surface of the stomach of infants who die during, or very soon after birth. We are therefore not to attribute these congenital congestions to inflammation, but to the mechanical cause which produces them. It is however true that gastric inflammation may exist during intra-uterine life. MM. Billard and Denis have frequently observed follicular ulcerations in such cases, and what was remarkable, that the bodies were not emaciated, a fact that shows the disease had only commenced in the last days of pregnancy. When an infant vomits a brownish fluid, there is reason to suspect follicular ulceration or congestion.

Diseases of the Stomach developed after Birth.—The derangements of the stomach

may be divided into, 1. Disorders of function without any appreciable lesion of the parietes; 2. Organic lesions of the stomach with or without derangement of function. I shall describe them according to the morbid appearances, and not as is generally done according to names or terms, which are often erroneous.

Vomitus—Vomitio—Vomiting—Stomachal Indigestion.—Vomiting, which is only a symptom of some disease of the stomach, bowels, gums, brain, chest, or other parts of the body, is ranked as an idiopathic complaint by most of the standard writers on diseases of children. It is produced by a thousand, indeed by innumerable causes in young infants as well as in adults, more especially in the former by repletion, or taking too much breast-milk, improper articles of artificial food, as gruel, pap, panada, rusks, &c. &c., pastries, fruits both fresh and dry, fatty substances, poisonous herbs, sedative medicines, the verdigris of badly tinned copper vessels, the irritation of dentition or teething, the repercussion or sudden disappearance of cutaneous diseases termed exanthemata, as small pox, measles, scarlatina &c., the impression of cold and humidity or moisture, sudden fear, anger, the presence of worms in the bowels—in fact by many other causes. It is therefore evident, that vomiting is a symptom, and not an idiopathic or primary disease. But as preceding professors and writers* have described it as a primary complaint, and as mothers and nurses look upon it in this view, I am induced to comment upon it as a disease. Sometimes the infant vomits the milk unchanged, and at other times it is coagulated or curdled. In some cases there is a simple regurgitation, excited by cough, hiccup, forced laughter, or a great quantity of milk taken at a time. The milk is sometimes coagulated in large masses, and this is said to be effected by acid in the stomach. M. Billard found the stomach filled with coagulated milk in fifteen cases in which death took place from other diseases; in three there was slight injection of the stomach, and in the other twelve the parietes were white and perfectly sound. Is this coagulation, inquires M. Billard, the result of the richness of the milk in cheese, or of acids in the stomach, which coagulate this liquid? Do these acids exist in the stomach previously to the ingestion of the milk? Are they the result of the coagulation of the milk? Does this indigestion depend on the vital and nervous action employed during digestion? These are questions which cannot be answered. M. J. L. Petit supposed that the changes through which the milk passed were effected to render it more easy of digestion.

The milk or other food given to an infant will be vomited unchanged when there is

inflammation of any portion of the digestive canal, as œsophagitis, gastritis, enteritis, or any obstruction of the intestinal tube.

Again, the derangements of the cerebro-spinal and circulatory systems, as irritation in the head or chest, may disorder infantine digestion, and excite vomiting.

It is also reasonable to suppose that gastralgia and entralgia may produce excessive irritability of the stomach and bowels, and give rise to spasmodic vomiting.

Poisoning is another cause of disordered digestion in infants. This is produced by preparing their artificial food in copper vessels. Mothers and nurses should be cautioned against using such vessels, and of the necessity of cleaning them three or four times a day, or before putting them in use. This is always done by a good nurse or an experienced mother, but it is very much neglected by ignorant and inexperienced individuals.

I have stated on a former occasion, that nature has made every infant a voracious glutton. She has acted wisely; there is an imperious necessity for an incessant supply of nourishment to add to the blood, for the development of the body. Infants suck, and take every other food too rapidly. They in general take too much, unless restrained by the reason and common sense of those who have the management of them. If an infant or an adult overload the stomach, uneasiness, irritation and vomiting will be the consequence. Here again conservative nature interposes and maintains her laws, and she will not allow them to be violated with impunity. Repletion; gluttony, or over feeding impedes digestion, and if carried to great excess, excites over distention of the stomach, so as to cause uneasiness; and nature has endowed the stomach as well as all other organs in the animal body, with a privilege to expel or get rid of all sources of annoyance.

When an infant vomits to reject a superfluity of nourishment, it acts in obedience to nature's dictates, and effects its duty with little pain or trouble. It discharges its stomach in an instant, without any pain or inconvenience; and the moment the excess of food or the offending cause of its annoyance is removed, it becomes cheerful and happy, resumes its delightful playfulness and enjoys its wonted healthfulness. Were we to prescribe for this species of vomiting, we should interfere most unnecessarily. We have only to advise the affectionate—indeed in this case, the over affectionate mother, or the too anxious nurse—to give the breast less frequently, and to caution her against dandling the child after it has sucked or taken other food.

When the infant is voracious and sucks too much, it should be restrained, and when its stomach is over-loaded Rosen advises to tickle the throat with a feather dipped in olive oil. If the milk is too rich or too caseous, a substitute ought to be provided, such as that of another woman or of a healthy young

* Boerhaave, Van Swieten, Rosen, Underwood, Capuron, Gardien, &c.

cow. Five parts of milk with one of tepid water and some loaf sugar, is an excellent food for young infants. We should also advise animal and vegetable jellies, calves' foot jelly, good beef or chicken jelly, arrow root, sago, semolina, &c., mixed with milk and sweetened. If we suspect gastritis, we should be cautious in using stimulants, such as fennel water, infusion of rhubarb, weak wine, or diluted ardent spirit. Some practitioners are too apt to order these medicines, without considering whether there is congestion or inflammation of the stomach in existence. These remedies may however be employed under certain conditions.

When the infant vomits the breast milk in a curdled state, there is acid in the stomach, and this should be neutralised with magnesia, lime water, soda water, prepared chalk, &c. A teaspoonful of lime water, or half a wine glassful of soda water, either alone or mixed with milk, and sweetened, may be administered to an infant under a year old. M. Billard prefers sugar and water (*eau sucrée*). In this case the bowels may be too confined or too loose, and will require appropriate remedies.

When the stomach secretes an acid gastric juice, the alkaline remedies already recommended are required to neutralize it; and afterwards mild tonics, as iron, syrup of quinine, &c. &c. are necessary.

We should carefully examine the regimen of the nurse as well as that of the infant, and regulate both. A longer interval should elapse between the repasts of the infant.

When vomiting is symptomatic of other diseases, it is accompanied by illness, fever, restlessness, want of sleep, and the rejected matters are glary, yellowish, green, acrid, acid, rancid, and sometimes fœtid. If vomiting is caused by poisonous substances, the proper antidotes should be administered. Copper and mercury are the poisons most commonly employed, and are neutralized by white of egg, or other albuminous fluids. When occasioned by the sudden disappearance of certain diseases of the skin, the warm bath, fomentation, sedatives, with diaphoretics are necessary. Anodyne frictions over the pit of the stomach often afford relief. Soap or camphorated liniment, with a fourth part of laudanum, is often used with advantage. It is also advisable to dilute the acid or other irritating matters in the stomach, by exhibiting a solution of gum arabic in water, barley water, linseed tea, or decoction of quince seeds.

The following mixture is very efficacious in the vomiting of young infants, provided there are no symptoms of congestion or inflammation:—

Rx. Aquæ anethi, ʒj;
Sacchari purif., ʒij;
Magnesiæ cal., ʒj—ʒij;
Olei anisi, miv—vj;
Syrupi papaveris, ʒj.

Dosis cochleare parvum ter quaterve in die.

The cretaceous mixture with laudanum, or the sedative solution of opium, is frequently beneficial, more especially if there is purging as well as vomiting.

Rx. Misturæ cretæ, ʒiss;
Liquoris opii, miv—vj;
Olei anisi, miv—vj;
Syrupi simplicis, ʒiv.

Dosis ʒj, sæpe in die.

If there be violent and incessant vomiting, the rejected matter brown or tinged with blood, and if there be fever, with symptoms of plethora, we have reason to suspect the existence of congestion or inflammation of the mucous or inner coat of the organ, which would require depletion, warm bath, counter irritation, cold drinks, and the treatment which will be mentioned when treating of these diseases.

Singultus—Hiccough—Hiccup of Infants.—Hiccup is a symptom of gastric disorder, though ranked as an infantile disease by parents and writers. It consists in a sudden contraction of the diaphragm, which expels the air inspired by the lungs, and the force with which it escapes through the narrow glottis is effected with more rapidity than on its entrance. Hence the noise that accompanies the motion of expiration.

Hiccup is common to young infants, and particularly to those whose sensitive stomach is irritated by repletion or too much food, or by improper aliment, as gruel, pap, &c. This affection does not merit the name of a disease, as it usually disappears of itself without any remedy. It is often removed by diverting the infant's attention by speaking loudly to it, or tapping it on the back. Hiccup is often removed in children of a certain age, or in adults, by exciting sudden surprise, and also by the use of lemon juice, vinegar, sherry wine, or brisk table beer. These remedies are, in my opinion, improper for infants at the breast, who generally suffer from acidity in the stomach, and flatulence, which are best relieved by magnesia, cretaceous mixture with oil of anniseed and laudanum, in the proportions as described in the first mixture for vomiting.

Mothers and nurses are unnecessarily alarmed at hiccup, which goes off of itself by lessening the quantity or quality of food.

Lesions of the Stomach, with or without disturbance of function.—The diseases of the stomach at birth may be divided into passive congestions and inflammations, similar to those of the mouth, throat, and intestines, all being parts of the digestive apparatus. Thus we may observe congestions in every part from the mouth to the anus, and the different kinds of inflammation mentioned when describing stomatitis, as the erythematous inflammation, with alteration of secretion (muguet), follicular, and with disorganization of tissue. M. Billard has given the histories of all these cases, which are highly instructive; and his views are in strict accordance with modern pathology. He has done

much more for infantile pathology than any other writer, and I have therefore quoted him freely. He has laid the foundation of scientific infantile pathology, but his therapeutics are very far inferior to those of British practitioners. He has described diseases according to the anatomical lesions, and established a complete system of infantile pathology. This I shall lay under a free contribution.

Congestions of the Stomach.—We often observe the stomachs of infants at birth almost always congested, with more or less derangement of the general and pulmonary circulation, and the abdominal viscera are gorged with black fluid blood. We find on opening the bodies of new born infants, the internal surface of the mucous membrane congested. There is a ramiform or capilliform injection, or patches of various sizes, of a dark red or blueish colour; the coloration being more intense in the most dependent parts of the organ, absence of tumefaction, with friability of the mucous tissue, and most particularly, general congestion of the great venous trunks of the abdomen, of the liver, spleen, venæ cavæ, of the heart and lungs. The blood which stagnates in the vessels of the stomach, is imbibed by the parietes or walls of the organ, penetrates mechanically to the submucous cellular tissue, is infiltrated in the mucous membrane, and freely exudes on the surface of this membrane, so as to colour, with more or less intensity, the mucosities which cover it, and sometimes form a true passive hæmorrhage. We see a great number of cases of this kind in infants at the breast, and some of them resemble purpura hæmorrhagica. The following one is an excellent example, which possesses all the anatomical characters. It is given by M. Billard, from whose account of it I condense the particulars.

A male infant aged eight days, refused to suck, and was deprived of sleep. Its face was swollen, its extremities œdematous and violaceous, its respiration difficult, its cry altered, its pulse scarcely perceptible, the beatings of its heart were small and irregular, and about fifty in a minute, and it vomited a sanguinolent matter. It was enveloped in flannel, its extremities rubbed; and it was ordered the acidulated quinine lotion. It died the day after admission into the hospital.

The cadaveric autopsy presented tumefaction with violaceous redness of the upper lip, the buccal mucous membrane of a violaceous red, the tongue tumefied and ecchymosed at the base, the œsophagus highly injected, the stomach violaceously red in its whole extent; its parietes, which were soft and easily separated from the inner membrane, were infiltrated with black blood. The stomach contained a great quantity of a brownish sanguinolent matter, of a mucous consistence. The liver was intensely red, and gorged with blood; there was fluid blood effused in the cavity of the abdomen. The

left lung was crepitous, the right engorged with blood, and the pleura at this side contained a sanguineous effusion. The heart and large vessels were very much engorged, the parietes of the heart were as if imbibed (imbibeas) with blood, and there was a small quantity of blood effused into the pericardium.

The vessels of the meninges and surface of the brain were highly injected, and so were the choroid plexus and substance of the brain. We see in this case that not only the stomach but all the organs of the body were affected with sanguineous congestion, the venous blood engorged all parts of the circulatory tree. Thus then the coloration of the stomach, the effusion of blood in this organ, and the sanguinolent vomiting observed during life, were in this infant the result of a true passive hæmorrhage, which is very frequently met with at this period of life.

It is however true that congestion of the stomach is often only a simple injection, and not always accompanied by such a remarkable state of plethora as in the preceding case, yet congestion of the digestive passages is a very common disease in the first days of life, as well as at later periods.

There are scarcely any symptoms of stomachal congestion, when the disease is slight, but when violent there is indigestion with sanguinolent vomiting. Other symptoms are more characteristic of the disease; these are plethora of the infant, the circulation and respiration performed with difficulty, which are soon followed by pulmonary congestion with sanguinolent vomiting, which lead us to suspect passive congestion of the stomach, as experience has proved that this disease, both in infants and adults, is caused by disturbance of the circulation.

The indications of *treatment* are to cause the blood to flow in its ordinary course, to free the tissue of organs from a superabundance of this fluid, and above all, to remedy the congestion of the heart and lungs.

The means to accomplish these objects are sanguineous depletions, which will accelerate the subcutaneous capillary circulation, as well as that of the extremities. The treatment will be fully described when the diseases of the circulatory apparatus come under consideration. I may briefly state at present, that all means calculated to equalize the circulation ought to be actively employed.

—o—

MANUAL OF OPERATIVE MEDICINE, BY M. MALGAIGNE.

Freely Translated and Condensed

By GREVILLE JONES, Esq.

Lecturer on Anatomy and Physiology.

SECTION I.—ELEMENTARY OPERATIONS.

WE comprehend under this title the general methods to which recourse is had for the purpose of dividing, removing, or destroy-

ing the living structures, whether by the knife, burning, or ligature; the means of arresting hæmorrhage, and the modes of promoting re-union.

CHAPTER I.—OF INCISIONS, DISSECTIONS, AND PUNCTURES.

SECT. I.—INCISIONS constitute at least half of operative medicine. The opening of abscesses, the removal of tumours, the tying of arteries, amputations, the operations for hernia, lithotomy, &c., are all incisions variously modified. Hence there is no necessity to inculcate the importance of studying them.

Of Instruments.—Some incisions require instruments specially adapted for them, as the cataract-knife, amputating knives, &c., but the knife and scissors are those in ordinary and frequent use.

Of the Bistoury and its various positions.—

The ordinary bistoury has a straight or convex edge*. It is requisite, however, that what is called the straight bistoury should have a slight curve at the commencement of the blade, and, if they shut in handles, these instruments should be made in such a way that they can be fixed when open. The different methods of holding the bistoury are reducible to the five following positions: 1st position, as a pen, with the edge downwards; the thumb on one side of the blade, the first and second fingers on the other; the ring and little fingers serve to take a *point d'appui*. 2. As a pen, with the edge upwards. 3. As a knife in carving, the edge downwards; the thumb and middle finger placed on the point where the handle and the blade join; the index on the back of the blade; the ring and little fingers fixing the handle in the hollow of the palm. This position is varied a little, the fingers being in some cases advanced farther forwards on the blade, while when much force is required the index is turned round with the other fingers on the handle. 4. As a knife; the cutting edge upwards. This is the same as the former, except that the index is placed rather to the outer side of the blade, and the edge is turned in the opposite direction. 5. As the bow of a violin; the thumb and middle finger on the joint of the bistoury; the index on the flat side of the blade; the ring-finger on the outside of the handle; the little finger raised; the edge downwards. If much force is required, the little finger is applied to the handle, and keeps it pressed against the cubital border of the hand.

Of the Scissors (these are held of course in the usual way).—It was formerly supposed that the bistoury acted by sawing, the scissors by pressing. It is now under-

stood that they both partake, in different degrees, of each sort of action. The contusion which has been attributed to the use of scissors is a chimera, and the superior cleanliness of an incision made by them may be seen by cutting a compress, a leaf of paper, or even a hare-lip. When, however, we cut very hard or thick parts, it is well to draw them back a little while in the act of cutting.

Incisions are made either from without inwards, or from within outwards, and their direction may be *from* the operator, *to* the operator from left to right, from right to left, or from above downwards: the two last are easiest for the operator.

Incisions from without inwards.—The following rules are to be observed:—1. *Usually* to direct the incision either along the axis of the limb, or parallel to that axis, or in the direction of the vessels and nerves, of muscular or tendinous fibres, or of the natural folds of the skin; or, in the case of a tumour, along its greatest diameter. 2. *Usually* to incise at once the whole length and breadth of skin we intend to divide, in order to shorten the time and diminish the pain of the operation. 3. *Always* to stretch the skin before commencing the incision. 4. *Always* to retain such command of his hand and bistoury that the operator should not cut deeper or farther than necessary, nor make any *slips* by which himself, his assistant, or the patient may be wounded.

The skin may be put on the stretch, 1, with the hand laid flat, the thumb and index finger separated; 2, with the ulnar border of the left hand resting behind, the little finger on one side, and the thumb on the other; 3, the thumb on one side, the index on the other; 4, with the extremities of the four fingers placed in a line, having the same direction as that we propose to traverse with the bistoury; 5, by drawing the skin on one side, while an assistant draws it on the other; 6, by leaving the assistants to stretch the skin altogether, in order to keep both hands free.

The skin being rendered tense in one of these ways, the surgeon takes a straight bistoury in the third position, plunges it perpendicularly as deep as he wishes, lowers it until the edge forms with the skin an angle of 45°, cuts by sawing and pressing at the same time, and in terminating the incision, raises the instrument perpendicularly, to avoid making those grazing or partial sections of the skin which are called *tails*.

But it is often necessary to perform incisions with the knife at an angle of 20° to 45°, without making a puncture at first, nor raising the handle at last. In this case the knife passes several times along the skin, dividing layer after layer—these tails are inevitable—a slight inconvenience compared with the advantages this mode of operating occasionally offers.

There is a third mode of proceeding. A

* In the original there is a long description of these knives, but I have thought their forms too obvious to render its insertion requisite.—T.

fold of integument is raised, one side of which is given to an assistant to hold, the other side is held between the left thumb and fore-finger of the operator. He then passes the bistoury across the fold, so as to cut down to its base.

Compound incisions, though various, may be reduced to five principal forms, in the shape of a V, of a T, of a cross, of an ellipse, of a crescent.

When two incisions touch at a common point, the second ought to *terminate* upon the first, otherwise there would be some difficulty in stretching the skin, and where one incision is placed above another, it is proper to begin with the lowest, that the flow of blood may not obscure the parts. In making a crucial incision, it is usual to make three strokes of the knife, one transverse, as long as requisite; a second from below upwards, forming the inferior branch of the perpendicular incision; and a third from below downwards, which terminates where the others join: but when the skin is engorged, indurated, and does not roll under the knife, this kind of incision may be effected by two strokes.

Incisions from within outwards.—Independently of those made with the scissors, incisions of this kind are performed with a bistoury, either with or without a director.

Without a Director.—1st method. The straight bistoury, held in the 2nd position, is passed either through an existing opening, or is plunged perpendicularly into a collection of fluid; then, after being lowered until the back of the instrument forms an angle of 45° with the skin, it is carried onwards, stretching and dividing the skin by means of its edge, and is finally raised to the perpendicular to finish the incision. The skin is to be stretched by the ulnar edge of the left hand placed behind the right. 2nd method. A fold of skin being held up, the knife held in the fourth position, is plunged into its base as far as the shaft. The instrument drawn backwards cuts its way out. 3rd method. When we wish to enlarge a former incision, or to join another to it, the bistoury, held flat in the fourth position, should be pushed under the skin as far as may be considered necessary, then by lowering the handle the cutting edge is raised; the point is to be passed through the skin, and the instrument retracted, so as to cut from its point to its shaft the skin which it stretches and supports. 4th method. The incision for a flap. It is scarcely ever used except in amputation. The part which is to be cut into the form of a flap is lifted up with the fingers of the left hand; its base is traversed from side to side by the bistoury held flat in the third position, and by drawing this back, or by sawing it backwards and forwards if necessary, a semicircular flap is cut as long and as thick as directed.

With a Director.—1st method. A grooved director having been introduced under the

skin as far as it is proposed to carry the incision, the point of a bistoury, held in the second position, and inclined to an angle of 45°, is to be placed in the groove. It is carried onwards, cutting in its path, until it is stopped by the termination of the groove; it is then to be raised perpendicularly, and both instruments withdrawn. 2nd method. The director being introduced as usual, the bistoury, held flat in the third position, is glided onwards to the end of the groove; then the edge and point are raised, the latter penetrates the integuments, and the former cuts them throughout.

SECT. II.—DISSECTIONS are, properly speaking, merely incisions of the cellular tissue; but the bistoury or scissors are not always employed—the fingers, the handle of a knife, or the end of a director, are often used to tear or remove the cellular tissue, either for the sake of expedition, or because we fear to injure important organs.

Generally, in dissecting up a flap of skin, we raise its border with the finger and thumb, and holding the bistoury in the first position, pass it freely backwards and forwards from one side of the flap to the other—but where an important organ may be injured, as, e. g. in the operation for hernia, it is requisite to make the dissection *en dedolant**, that is, the incision of the skin being finished, the thin layers of the subjacent tissues are to be raised with a good pair of dissecting forceps, which, with a straight or convex bistoury, held in the fifth position, each of these layers is to be cut horizontally close below the points of the forceps.

SECT. III. PUNCTURES.—Independently of the operations of bleeding, vaccination, &c. the only object of a puncture is to explore a tumour or afford exit to gaseous or fluid collections. We shall only mention here punctures with the bistoury, lancet, and trocar.

The bistoury, held in the 1st, 2nd, or 5th position, if little effort is required, or in the 3rd or 4th, if there is a great thickness to traverse, is plunged briskly in a perpendicular direction to the requisite depth, which is ordinarily marked by the position of the index finger on the blade. It is withdrawn in the same direction. When we do not wish the opening of the skin and of the tumour to correspond, the bistoury is inserted obliquely.

The lancet is held as in bleeding, the three last fingers serving as a *point d'appui*.

The Trocar.—Its handle is fixed in the palm by the three last fingers, the thumb is placed on the junction of the canula with the handle, and the index finger at such a

* This rather untranslateable word means a sort of motion backwards and forwards with the wrist—it is derived from the Latin *dedolo*, to hew or fashion, and answers somewhat, though not exactly, to our vulgar term, niggling.

distance from the point as we wish the instrument to penetrate. It is then driven in and immediately retracted, the canula being left in to withdraw the fluid: to extract the canula, a gentle rotatory motion should be made.

CHAPTER II.—OF CATTERIZATIONS.

By this term we understand the application of heat or caustic substances to any part, the organization or vitality of which we wish to destroy.

SECT. I. OF THE APPLICATION OF CAUSTICS.—They are applied in fluid, soft, solid, or pulverized forms, in the application of all which we should observe the following general rules:—1. To cleanse with care the suppurating surface, and remove all moisture. 2. To preserve the neighbouring parts, particularly such as are lower than the sore, by covering them with plaster or charpie. 3. To sponge away carefully the blood or serum which may flow during the application of the caustic. 4. After the cauterization, to remove carefully, either by dossils of charpie or by repeated ablutions, any portion of caustic that may remain.

1. Of Fluid Caustics.—These are the hydrochloric, sulphuric, and nitric acids; concentrated solutions of potash, soda, nitrate of silver, liquid ammonia, the acid nitrate of mercury, the liquid deuto-chloruret of antimony; the collyrium of Lanfranc, the basis of which is formed by the yellow sulphuret of arsenic, and the green oxyd of copper; the phagedenic water, &c.

They are all applied in the same way. The part being well cleansed, a dossil of charpie or fine linen, fixed on a stick of appropriate length, or held by a pair of forceps, is to be plunged into the liquid and then applied to the depressions and elevations of all the surface to be cauterized. Afterwards the superfluous portion of the liquid is to be removed by dry charpie, or when the caustic has been applied to the bottom of a cavity, we may dissolve and remove it by abundant injections.

As to our estimate of the value of the different fluid caustics—the collyrium of Lanfranc*, the phagedenic water, the solution of nitrate of silver—are feeble escharotics, which are only employed in superficial ulcerations of the gums, mouth, or organs of generation. The concentrated acids act instantaneously, so that their action ceases at a trifling depth, and is easily graduated. The eschar which they produce is dry, yellowish with nitric acid, black with sulphuric acid. The solutions of soda and potash act some time after their application; it is necessary, therefore, to remove with much care any superfluous portion of them; but we cannot regulate with exactness their degree of action. The liquid deuto-chloruret of antimony forms rapidly a dry eschar, the extent

of which we can more easily limit. It is employed frequently and with success in poisoned wounds, and for warts, which have been excised as far as their bases. But for tumours of a suspicious nature, the acid nitrate of mercury is preferable to all. It gives rise to a dry and solid eschar, white at first, afterwards yellow; we can regulate this caustic pretty well, and it extends as deeply as may be necessary; but above all it disposes the subjacent parts to prompt cicatrization.

All the energetic caustics produce sharp pains; and their employment, especially with nervous subjects, over broad surfaces is to be avoided. The nitrate of mercury has been known to bring on violent colicky pains, diarrhoea, and even bloody stools (Dupuytren).

2. Of Soft Caustics.—None scarcely are used, except the ammoniacal pomatum and arsenical paste. The ammoniacal pomatum is formed of equal parts of ammonia and lard. A layer, variable in thickness and extent, according to the effect we are desirous of producing, is spread upon linen. This plaster is applied to the skin in the usual manner. After some minutes this becomes red; then phlyctenæ appear, and in 10 or 15 minutes afterwards, an eschar is formed.

The Arsenical Paste.—We dissolve, either with saliva or water, Rousselot's powder, so as to obtain a soft paste, more tenacious, and easily spread*. The diseased surface is to be cleansed or even pared with a bistoury, and covered with a layer of this paste about a line in thickness, and extending a very little beyond the border of the ulceration; cobweb or charpie, finely scraped, are to be spread over the caustic; compresses and an appropriate bandage finish the dressing.

The eschar is formed in a few days; is detached from the 10th to the 20th, sometimes later, with the paste adhering to it; leaving exposed a red, solid, granular surface, ready for cicatrization. Sometimes, especially when applied to the nose, the eschar and the paste in drying form a scab which does not fall until between the 25th and 40th day, and under which the ulcer is perfectly cured. Often one application suffices; but if after it the tissues present a bad appearance, a second application should be proceeded with immediately.

The cicatrix obtained by this method is thick, white, solid, and presents less deformity than that which succeeds the employment of the bistoury.

This caustic causes generally sharp and

* See for these formulæ Dr. Ryan's Translation of Edwards and Vavasseur.

* The powder of Rousselot contains dragon's blood, 0,22; red sulphurated oxyd of mercury, 0,70; white oxyd of arsenic, 0,08. This preparation is the invention of Cyndrett, is very useful as a rapid blister, especially when the endermic method is about to be tried, and except when too long applied, leaves no scar. T.

burning pains; employed over extensive surfaces it has given rise to the accident of poisoning.

3. *Solid Caustics*.—Those most employed are concrete potash, nitrate of silver, and lozenges.

Application of Potash.—A piece of diachylon plaster perforated with a hole of the form that we wish the eschar to have, *but only of half the size*, is to be placed on the skin. In the centre of this opening, one or more pieces of potash are to be placed, which should be covered by a diachylon plaster larger than the first, and afterwards with a compress and bandage. After six or seven hours the action of the caustic is exhausted. The apparatus is raised, and an eschar twice as large as the opening in the plaster and of a brownish yellow is discovered. It may be picked off with the bistoury, or its separation awaited according to circumstances.

In order to carry the potash to great depths, M. Dupuytren employed troches of pure potash, which he fixed in a port crayon. Much care is necessary to protect the surrounding and especially the inferior parts.

Potash applied to voluminous tumours has the advantage of reducing the tissues it touches into a kind of putrid mass, somewhat similar to hospital gangrene; and this black, soft, humid scab, which is nothing else than a true animal soap, is easily separated by being wiped with a sponge, charpie, or linen. Its application may be repeated daily, inasmuch as this caustic does not exasperate irritation nor provoke degeneration (Mayer).

Application of Nitrate of Silver.—The little cylinders in which this substance is cast, fixed in a port crayon, are very easily applied. If applied to a raw surface this should be previously cleansed; if to the skin, the caustic should be moistened. The eschar is dry, superficial, white and silvery at first, afterwards black, and falls off in a few days. The caustic should be wiped before it is returned into its case.

Of Caustic Lozenges.—By this term are designated some pastes composed generally of the oxydes of lead, mercury, arsenic, &c. of which cones and cylinders are formed that are afterwards dried. These are buried in different points of a tumour, which they cauterize deeply. Perhaps this method is too much despised at present.

Caustic Powders.—Under this form there was formerly in use the alkaline ashes of certain vegetables—the powder of iris, of savine, red oxyde of mercury, and calcined alum. The last may still be found a useful application to large wounds with luxuriant granulations. Experience shews that it represses them better than the nitrate of silver. The wound being cleansed, a layer of a line or more in thickness should be extended over it; two days after the caustic forms a sort of a scab under which the wound is

found to be of a lively red, and the granulations repressed. The application may be repeated as often as necessary; no inconvenience is to be feared.

SECT. II.—ON THE APPLICATION OF FIRE, OR SURGICAL PYROTECHNICS.—There are two methods of applying heat; by metallic cauteries, called also actual cauteries; by other substances, as boiling water, or oil, moxa, gunpowder, ignited phosphorus. We shall only treat of the former in this place; the latter belong to petty surgery.

Cauteries are formed of a wooden or ivory handle separable from the rest of the instrument, of a shaft or of a knob or cauterizing extremity. Both the last are of steel, the shaft, which is about from 7 to 9 inches in length, is sometimes entirely straight, sometimes is bent at a short distance from the knob. A cautery takes its name from the form of its knob. There are many of them, but they may be very well reduced to three. The olive-shaped cautery, the lance shaped, and the nummular, which is a dish, twelve lines in diameter and four in thickness, or instead of that the octagonal, merely a square plate with the edges flattened.

In operating, the knob of the cautery should be heated by an assistant in a portable furnace, with a fierce charcoal fire. It should be raised to a white heat, for the hotter the metal becomes, the better it destroys the parts and the less irritation it produces.

When the instrument is sufficiently heated, the shaft is to be laid hold of by a pair of pincers and fixed in the handle. The instrument is to be used in one of the three following modes, and when done with is to be quenched in cold water.

Objective Cauterization.—The nummular cautery of a white heat, is at first held about six inches from the part we propose to stimulate: afterwards nearer in proportion as it cools. One application is usually sufficient. This cauterization causes the tissues to swell and become red, develops very lively pain, in a word brings on an artificial inflammation, useful in atonic ulcers and some scrofulous tumours.

Transcurrent Cauterization.—It consists in traversing the skin lightly and rapidly with the lance-shaped cautery heated to whiteness, so as to form rays various in their extent and number, but which must never pass beyond the dermis. Some trace the lines first with ink, and occasionally the rays require to have the caustic passed along them twice or more. The eschar of these rays is of a golden colour, and seems at first a very light trace, but it enlarges by degrees and involves the dermis deeply. After the eschar falls off, cicatrization is prompt, and the skin of the part becomes remarkably contracted. The burn is dressed during the early days with dry flannels, rags warmed or steeped in wine to keep up stimulation.

When the inflammatory action is manifest, antiphlogistics must be had recourse to.

Inherent Cauterization.—This consists in applying the cautery heated to whiteness, sometimes to open vessels, oftener to degenerated tissues, or to wounds of a bad character. The form of the cautery and the means of protecting the neighbouring parts must vary according to the case and the region. With respect to the degree of severity that may be employed, the surgeon should remember that the effects of a cautery always extend beyond the point to which it is applied, so that if he make a mark three lines in size, the eschar will be two lines larger.

To protect the neighbouring parts, it has been proposed to cover them with wet linen; but these cool the cautery. Plaster, or a card pierced with an opening in the centre are better. If the parts affected are deeply seated, the wound which leads to them should be enlarged, and when the hæmorrhage has ceased the cautery may be applied through a canulæ of wood or iron. In all contrivances, the important object should be to cauterize with rapidity, that the action of the fire may not have time to spread.

The pain occasioned by cauterization is not so great as is supposed, especially if the cautery be made very hot; and is severe only in the skin. Hence it is advised to incise and dissect up the skin, when that is possible, before applying the fire. The adipose, glandular, and muscular structures are much less sensible, and anomatous, polypous, and sarcomatous tumours still less so (Percy); while the bones scarcely feel at all; indeed their cauterization has been known to produce an agreeable itching. Old men bear cauterization better than young people and children—even very young ones, better than others.

Reviews.

Traité complet de l'Art des Accouchemens ou Tocologie Theorique et Pratique avec un abrégé des Maladies qui compliquent la Grossesse, le Travail et les Couches, et de Celles qui affectent les Enfans nouveau-nés avec Atlas. Par. Alf. Velpeau, Professeur de Clinique Chirurgicale, &c. *A complete Treatise on the Art of Midwifery, or Theoretical and Practical Tocology, with a compendium of those Diseases which complicate Pregnancy, Labour, and the Puerperal condition; and of those which affect new born Infants; with an Atlas.* By Alfred Velpeau, Professor of Clinical Surgery to the Faculty of Medicine at Paris, &c. Third Edition, revised and enlarged. Brussels and London. 1835. Royal 8vo. pp. 547. Sixteen Plates.

We now resume our review of this valuable treatise, and commence with the section on gynecophysiology. The celebrated author

gives a full account of all that has been written on the function of menstruation, and concludes that the menstrual discharge is a secretion from the uterus, exhaling or perspiring from the organ; but that it is not known whether it transudes rather from the venous than the arterial capillaries. This, we may observe, is the conclusion long received in this country, and is opposed to that of those, who term the evacuation sanguineous. M. Velpeau opposes another popular and often professional error maintained since the publication of the works of the father of physic, that if menstruation does not occur at puberty, means ought to be employed to excite the uterus to supply it. Scientific obstetricians are, however, of opinion, that unless the health suffers, and unless the female is properly developed, such medicines are improper, and highly injurious. Our author knew a lady aged twenty-five, who had not menstruated from her eighteenth year, and who still enjoyed good health. Another aged thirty-two, had had not had her periodical health from the age of twenty, and she was in good health.

It is generally supposed that all complaints of young girls are induced by the absence of the menses; and mothers are daily applying for medicines for the purpose of inducing the evacuation. They say, "Oh, sir, she is not as she should be!" It is always to be recollected, that unless the signs of womanhood are evident, the uterine system is in the infantine state, and cannot perform its function until it is properly developed. In chlorotic girls, whose general want of development is apparent, it is absurd and dangerous practice to administer emennagogues, as it is attempting to force the uterus of a child to perform the function of that of a woman. We have seen enteritis caused by drastic medicines, administered in such cases; and on pointing to the undeveloped state of the uterus, which was no larger than that of a girl nine or ten years of age, we inquired of the practitioner how he expected it could perform menstruation? Yet it is a common practice to administer emennagogues under such circumstances. We fully agree with M. Velpeau, with Dr. Dewees, and most scientific gynecologists, that this practice is unjustifiable and dangerous.

It is also necessary to remind the young practitioner, that in cases of suppressed menstruation for two or three months, the general health being good, and all the symptoms of pregnancy absent, there is no real necessity of resorting to the use of emennagogues. Let him be cautious in such cases, and ascertain whether pregnancy be not the cause of the obstruction, which is very often the case. He should also bear in mind that menstruation is generally suppressed during pregnancy and lactation; a fact that some practitioners occasionally forget.

Our author next alludes to the cessation of the menses, and to the opinion, that most women become diseased at this period. He properly denies the predisposition to diseases at the critical period of life, and refers to the conclusions of statistical writers—MM. Chateauneuf, Lachaise, and others—who have proved that as many men as women die between the fortieth and fiftieth year. When proper attention is paid to the regularity of the bowels at the "critical" or "climacteric" age, we observe that women enjoy as good health as at any former period of life.

The next subject is re-production, which is properly introduced after the physiology of menstruation, and is treated with his usual ability by our author. He cites the opinions of all the eminent medical authors, from Hippocrates downwards, and condenses them into a very small space. He refers to his work on ovology, for a more minute description of the ovule after impregnation, though that before us is sufficiently satisfactory. He thinks that new researches are necessary on the *corpus luteum*, but he does not notice the admirable essay of Dr. Montgomery on the signs of pregnancy and delivery, published in the *Cyclopædia of Practical Medicine*. In this paper Dr. M. concludes, that conception never happens without the production of a *corpus luteum*; that this is never found in virgin animals, but is the effect of impregnation; and that every yellow substance in the ovary, is not a *corpus luteum*. The decision on this point is most important in medico-legal inquiries. Thus, in the case of Captain Angus, tried at Liverpool, in 1808, for the supposed murder of Miss Burns, great doubt arose that the condition of the uterus and its appendages

was such as exists after a recent pregnancy. It was not, however, until after the trial that the ovaria were examined, when they were divided in the presence of a number of physicians and surgeons, and a *corpus luteum* distinctly seen in one of them. Mr. Hay took the uterus and its appendages to London, submitted them for inspection to Drs. Denman and Haighton, to Messrs. H. Cline, Astley Cooper, Abernethy, and C. M. Clarke, all of whom certified that there was a *corpus luteum*, and such appearances that could *alone* be explained on the idea of an advanced state of pregnancy, and that it was universally allowed that the discovery of the *corpus luteum* proved the fact beyond a doubt. Angus had been previously acquitted; but had the medical witnesses been well versed in medical jurisprudence, his fate would probably have been very different.

The chapter on true or real pregnancy is comprehensive and instructive. The author considers that any one of the signs of pregnancy is equivocal, and entertains the opinions of Smellie and Gooch, that the changes of the cervix uteri are not so marked, as he once supposed, and as is generally imagined. He thinks that the dilatation of the uterus is a peculiar function, and not effected by the growth of the fœtus. He says that the uterine parietes retain nearly the same thickness during the whole course of utero-gestation, as in the unimpregnated state. Repeated observation enables us to state the contrary; the parietes of the uterus, however they may vary in size in different parts, are much thicker than in the unimpregnated condition. The degree of thickness varies considerably at the ninth month of pregnancy, and is often no thicker than in the virgin, though the substance is sometimes reduced to three lines, and is sometimes so thin as to be almost transparent. Mr. Griffith has informed us that he has a uterus in his possession in the last condition. In speaking of the substance of the uterus, we refer to it during pregnancy, and before labour, for after delivery, it may, from contraction, be double its usual thickness.

Adverting to the signs of pregnancy, our author advises examination by the rectum as well as the vagina. He next recommends *ballotement*, and finally, auscultation. He has not, however, found the last so certain

a mode as some German and British obstetricians have stated. In some cases he discovered the placental souffle very distinctly, in others he failed to detect it. We have, however, found it a most conclusive diagnostic. In a case to which Mr. Hughes, of Holborn, lately called us, we heard it distinctly, and pronounced the young lady pregnant before we felt the infant's head per vaginam. She stoutly denied her condition, but in a few days admitted it. In another recent case which we saw with Mr. Churchill, of Straton Ground, Westminster, we declared the lady pregnant; she also denied it, was afterwards examined by Professor Davis, of the London University, who confirmed our opinion, and at length our patient admitted its correctness. Both patients acted with consummate duplicity, and it would have been almost impossible to detect the latter, had it not been for the aid of auscultation. This diagnostic enabled us to detect another case, for which we refused to prescribe; the lady applied to another practitioner, who was deceived at first, and finally prescribed abortives, for which he was severely censured in one of the superior courts of justice. The *bruit de cœur* is conclusive evidence. When we hear the fetal pulse, and reckon it at 120 or 140, while the maternal is not more than half the number, there can be no doubt of the existence of a foetus.

Our author next introduces the subject of extra-uterine foetation; but as cases of this kind are extremely rare, we shall not notice them further.

False or apparent pregnancy is described with great correctness, and deserves great attention. The blunders made respecting the diagnosis of these cases are frequent, and always reflect discredit on those who make them. Who has not heard of pregnancy mistaken for dropsy and treated as such, or mistaken for abdominal inflammation, and leeches, bleeding, &c. employed? when a chopping boy made his appearance, to the no small discomfiture of the *Æsculapian*. Women had been declared pregnant who laboured under dropsy, and others who were pregnant, were ordered to be tapped at the very hour at which parturition took place. We have been called to attend women supposed to be in labour, who were not preg-

nant, and to perform the Cæsarian section on others, though there was one thing necessary, that was—the women should be pregnant first. We have known medical men attend for three and four days and nights on women who laboured under hydatids in the uterus, and polypous tumours. We were once called into an adjoining county at one o'clock of a Sunday morning in winter, after the severe fatigue of the preceding week, to perform the Cæsarean section; we informed the messenger, who was a medical assistant, that the lady was not pregnant, and our opinion proved to be correct. Though the foregoing cases show the difficulty of diagnosis, yet we have not met but one case out of several, and in this the greatest duplicity was used, in which we were not correct in our opinion. On one occasion a lady swore that she never knew man; yet we assured her that she was pregnant; our opinion was correct, as will appear by the history of the case in our *Manual of Obstetrics*. We may mention here, that she was impregnated in a state of inebriation, to which she was reduced by a cold-hearted seducer. Many practitioners of note assured her that she was not pregnant: but the development of the uterus advanced, and we assisted her at the birth of a son. What puzzles practitioners who are not duly informed, is the apparent pregnancy, the history given by the patient, and in some cases the regular and severe labour pains which simulate those attendant on real parturition. In the supposed case for which we were summoned to perform the Cæsarian operation, the pains returned every five minutes with great violence, but on examination, the cervix uteri was as in the unimpregnated state; the lady was hysterical, well formed, and in the prime of life, and had never been a mother. In another case the woman was forty-eight years of age, said the motion of the infant was so violent as to be intolerable, but the uterus was in the virgin condition. This case was much talked of, and is known to some of the readers of this journal. These and many other cases we might mention, clearly shew the necessity of being able to determine whether a woman be pregnant or in labour; and the question is of great importance, when a woman pleads pregnancy in stay of execution; for by a mistake both

the lives of the mother and foetus may be sacrificed. But when all the usual signs of pregnancy are present, especially the darkness of the areola, the size of the abdomen, the bruit du souffle of the placenta, the bruit du cœur, the altered state of the cervix uteri, there cannot, in our opinion, be the slightest doubt of the existence of pregnancy.

The last article in this section of the work before us, is one that has interested parents and families from time immemorial, though to some readers it may appear of little consequence. M. Velpeau asks, "Is it possible to recognise the sexes during pregnancy? Is it possible to create this or that sex according to the will? Influence of the seasons and prosperity on fecundation?" These questions we shall notice in a future article; and must now observe, that however insignificant or useless they may appear to superficial practitioners, it often happens that individuals are exceedingly interested as to the sex of offspring, when title and property are to be disposed of, and frequently consult their medical advisers on the subject.

—o—

On the Deaths of some Eminent Persons of Modern Times. By Sir Henry Halford, Bart., M.D. &c., &c. 8vo. Lond. 1835. pp. 40.

THIS is one of the most thoroughly contemptible productions we had ever the misfortune to peruse; it contains not a single case of the smallest interest, in a medical point of view, and is merely a prosy narration of the death of some famous persons who died much after the same fashion as their neighbours, and of some infamous persons who, whatever they *did* die of, *ought* to have died of a halter.

Among the latter may be numbered King Henry VIII. of blessed memory.

"That prince, when he ascended the throne, at the age of twenty, is said to have been one of the handsomest and most portly men of his time. In proof of his comely looks in early manhood, I may refer you to Holbein's pictures of him at Windsor, and more especially to that whole-length portrait of him at Belvoir Castle; and, as to his stature, I may argue from the remains of him which I have seen in his coffin, and from his favourite large arm-chair, which is still preserved in the corridor at Windsor Castle. As life advanced, however, he became corpulent, unwieldy, and gross in his habit, was covered with sores, and died of a dropsy at the age of fifty-six.

"Henry's state of health, in the decline of his life, made him a great dabbler in physic; and the King not only offered medical advice on all occasions which presented themselves, but made up the medicines himself, and administered them. We find in that curious magazine of materials for history, the British Museum, a volume containing a large collection of recipes for plasters, spasma draps (dipped plasters), ointments, waters, lotions, and decoctions, devised and made by the King himself and his physicians, applicable, perhaps, amongst other diseases, to that which had been imported, some twenty-five years before, from Naples; and, in Sir Henry Ellis's most interesting collection of Original Letters, we read one from Sir Bryan Tuke to Cardinal Wolsey, giving an account of an interview with the King, in which his Majesty prescribed for Sir Bryan, and sent also some excellent instructions to Cardinal Wolsey, how he might avoid the infection of the sweating sickness, and how he should treat the disease should it attack him."

His Majesty's skill in *surgery* should not have been omitted—his wives' heads, with their "poor dumb mouths," attested the boldness of his surgical genius, and also proclaimed him a monster worthy of the execration of all posterity.

Cardinal Wolsey, the minister and crony of the bluff monarch, "died of a broken heart, in fact, though the symptoms which afflicted him in the last days of his life, were those of a dysentery."

We agree with our author, that Wolsey was not such a bad fellow as some would have made him appear; he died almost a saint, and quite a prophet: he had no sooner uttered his last words, than "Incontinent the clock struck eight,
'The very hour himself foretold should be his last.'
Shakspeare.

The hour at which he knew, and had prophesied he should die, he gave up the ghost, and thus departed this life."

If the clock was as incontinent as his eminence had been, it was one of the naughtiest clocks that ever ticked. The most interesting pathological circumstance connected with the demise of the cardinal, appears to be, that he departed this present life by giving up the ghost—this is a very striking fact, although it does not entirely settle the question, "an corpus anima relinquat an animam corpus;" for authorities on this disputed point, see L. Christ. Frid. Garmann *De Miraculis Mortuorum*. Dresd. and Lips. 1709.

That very interesting female Queen Mary, died of dropey, which she at first mistook for pregnancy; so did Johanna Southcote. This princess, it appears, "inherited from Queen Catherine her mother, a weak constitution, and was always of feeble and unpromising health. When she arrived at mature age, the peculiarities of her sex were irregular and deficient; for which were prescribed bleeding and exercise on horseback." Good, now, sweet Sir Harry, tell us what are the peculiarities of the sex; for we hold that they be many and hard to understand—at least we never could make them out to our entire satisfaction.

Among other deaths, that of the truly eminent Jonathan Swift is commented on by Sir Henry. All we have to say is, that it is fortunate for the worthy baronet that the Dean is his subject, rather than he the Dean's; in the latter case, "The Deaths of some Eminent Persons" might possibly have been furnished with a commentary like that on "Dr. Gibbs' Version of the Psalms of David." But we must not occupy more space with the very sorry publication before us—its contents are devoid of utility or interest, and the badness of its style is sufficiently evinced by the few passages we have extracted.

—o—

DISEASES OF THE GENITO-URINARY ORGANS.

(Continued from p. 756.)

Diseases consequent to Blennorrhagia or Gonorrhœa.

Phymosis.—The term phymosis is applied to that disease, when the prepuce cannot be drawn back so as to uncover the glans penis. The disease may be congenital, or accidental, and the latter demands most attention on the present occasion.

The causes of accidental phymosis, are gonorrhœa, excoriation from this disease, from coition or want of cleanliness, and lastly from chancres or venereal sores on the glans penis, or on the under surface of the prepuce.

When the urethra is inflamed in gonorrhœa, the inflammation may extend to the glans, and cause it to swell to such a degree, as to distend the prepuce and induce phymosis. The dependent position of the penis favours the ingress of blood into the inflamed glans and prepuce, and necessarily retards its egress. It is for this reason that phymosis is so common to the working classes, who while labouring under gonorrhœa are obliged

to follow their usual employment. It is, however, a fact, that in many cases inflammation extending to the prepuce itself, and not of the glans, is the cause of phymosis. I have seen numerous cases of this kind, and am of opinion that they are more common than the former.

In some cases this inflammation of the prepuce is very slight, and the integuments scarcely discoloured; in other cases, we find them red, swollen, and the disease occupying the whole integuments of the penis. In these cases the skin is of a deep red or purple colour. We observe other examples, in which the prepuce is elongated over the glans to the extent of two or three inches, and terminated by a minor orifice. In some cases there is a hard narrow band passing round the fore-skin near the external opening.

Inflammatory phymosis may terminate in suppuration or gangrene, and in many cases the glans or whole of the penis to the pubes is destroyed by mortification. It has been long remarked that abscess very rarely occurs in the prepuce; though we sometimes observe it behind the suspensory ligament at the pubes. In consequence of the unyielding nature of this ligament, the entire penis becomes exceedingly tense, and indurated.

The integuments are of a dark red colour, which indicates the presence of matter underneath, though fluctuation can be rarely felt. The matter usually makes its way through the dorsum of the penis, in the thinnest part of the suspensory ligament. In some cases the abscess extends to the mons veneris or even above the pubes. In other examples this part may slough and form a foul ulcer.

When the tumefaction of the prepuce compresses the orifice of the urethra, so as to close this passage, the result will be complete retention of urine. In this case the urethra ulcerates unless speedily relieved, the urine is extravasated into the surrounding cellular tissue, producing the most extensive gangrene of the penis, scrotum, and adjacent parts.

In some cases of inflammatory phymosis, adhesion takes place between the prepuce and glans, and this union may remain permanent. Here then will be phymosis which may induce inflammation, gangrene, and death, at any period of life, but especially in old age.

In the latter period of life, the prepuce gradually contracts and forms phymosis, which may obstruct the orifice of the urethra, prevent the discharge of the urine, and this fluid will be forced between the glans and prepuce, give rise to inflammation, ulceration, or gangrene.

Infants are generally born with phymosis, but there is no remedy required, as supposed by the Jews, because the closest contraction will yield to occasionally drawing back the prepuce after bathing the part with warm milk and water. The glans will act as a wedge when the fore-skin is frequently drawn back

and the contracted prepuce will be dilated. There should however be no interference when the infant passes water freely, and more especially as touching the prepuce leads it to contract a very bad habit, and a source of great irritation. Circumcision or slitting the prepuce is only required in these cases in which the infant cannot evacuate the bladder; and under such circumstances the sooner the operation is performed the better.

Partial contraction of the prepuce spontaneously disappears in most cases at the age of puberty, or at the approach of manhood, when frequent erections of the penis distend the glans, and cause it to act like a wedge on the affected part. But when the contraction of the prepuce continues to be a serious obstacle to the performance of the generative function, an operation is required. This is performed in one of two ways—by slitting open the fore-skin upon a director, by a longitudinal incision, or by partially incising the fore-skin, then drawing it back as far as possible, and dividing its inner fold. This last method, which was proposed by the editor of this Journal, as stated in Mr. Cooper's Surgical Dictionary, 1831, causes less deformity than the former operation. M. Dupuytren proposed to divide the prepuce at the side of the frœnum. There is seldom any hæmorrhage by either operation; and I introduce both in this place, before describing the treatment of inflammatory phymosis.

This disease is to be treated on ordinary principles, though there are some modifications, as will appear by the following remarks.

Treatment.—In mild cases, inflammatory phymosis will yield to injections of tepid water beneath the fore-skin, taking care to keep the penis raised; to cold applications and evacuation of the bowels, with rest and low diet. It is most essential that the patient should remain on a sofa or in bed; keep the penis raised towards the abdomen, and thus favour the return of blood from it into the circulation. It is for this reason that judicious surgeons advise a patient with a broken leg, thigh, or arm, or inflammation of any of these dependent parts, to keep them raised so as to expedite the return of the blood through the veins towards the heart. If the patient can remain in the recumbent or laying position, he should support the penis on the pubes and towards the abdomen, with a proper bandage. He should also apply a cold lotion constantly, or as frequently as possible. The disease will not yield when the penis is left in its ordinary dependent position, as this favours the progress of the inflammation. But when the inflammation is intense and extensive, and threatens gangrene of the whole penis, the most active antiphlogistic measures are necessary. General blood-letting will be required; leeches to the affected parts, or punctures, may be made in them. The punctures

afford great relief, as they allow the escape of the serous part of the blood, which is often the cause of the tumefaction, and likewise of the blood itself.

Men of intemperate habits, who continue to work and drink as usual, and allow the penis to remain pendulous, suffer very severely from this disease. These are often broken down subjects, and will not bear depletion.

In these cases, when there is danger of gangrene, it will be necessary to slit the prepuce, and freely expose the glans. The loss of blood by this operation is highly advantageous, unless it be too profuse, which is seldom the case. Some object to incision of the prepuce, but such practice is proved to be valuable in diffuse inflammation of other parts, and repeated observation has convinced me of its value in the disease under consideration. I am certain it has prevented gangrene in many cases.

In bad habits or broken constitutions, it will be necessary to allow wine, porter, &c. as in other cases of threatened gangrene. Warm fomentations and poultices are also beneficial.

When gangrene has occurred, and inflammation has ceased, we should treat it on ordinary principles, and assist nature in throwing off the sloughs or dead parts.

The dilute nitric acid lotion, and fermented poultices, with solutions of the chlorides, are excellent remedies. The powers of the constitution should be preserved by quinine, wine, porter, and animal food, according to circumstances. But if inflammation exists beyond the dead parts, antiphlogistic remedies will be indispensable.

It sometimes happens that after the sloughs have separated, there will be profuse hæmorrhage. The best styptics are warm oil of turpentine, and a saturated solution of albumen, while compression is also applied.

When there is retention of urine caused by a contracted phymosis, incision is required. If extravasation of urine be allowed to take place, free incisions will be necessary, but a timely division of the prepuce will prevent this troublesome and dangerous disease.

In chronic phymosis, in which there is partial adhesions between the prepuce and glans, we should carefully separate them with a scalpel, and prevent their recurrence by interposing oiled lint between the parts. When there is complete adhesion between the prepuce and glans, so that a probe or director cannot be introduced between the coherent parts, an operation ought not to be performed, as it is exceedingly painful to the patient, and almost invariably unsuccessful. I have known it repeatedly to fail.

In those cases in which the prepuce is considerably elongated beyond the extremity of the penis, circumcision will be performed with benefit.

We seldom meet with such cases, if the

phymosis be treated judiciously at its commencement*.

Paraphymosis.—When the prepuce is retracted behind the glans penis, and cannot be drawn over this part, the disease is called paraphymosis. In this case the prepuce acts as a ligature behind the corona glandis, and hence the disease has been termed circumligatura.

The effect of this constriction is the prevention of the return of blood from the glans as well as from the portion of the prepuce anterior to the stricture; and the consequence will be, cedematous swelling and inflammation, followed very rapidly by gangrene.

Paraphymosis is often caused in a healthy person by drawing a tight prepuce behind the glans, or by sexual intercourse; but it is most commonly produced in incipient phymosis, by the patient being induced to draw back the foreskin, with a view of examining the glans. He finds that in consequence of the swelling of the latter, he is unable to replace the fore-skin, and he thus produces the disease under notice.

Paraphymosis is often induced by children and school-boys, who, in sport, draw back the prepuce, and cannot return it.

The indication of *treatment* is to restore the prepuce to its natural situation, and this is effected in one of three ways.

The first method is generally followed, though most injudicious. It is attempting to push the glans with the thumbs through the stricture, and at the same time endeavouring to draw the enlarged and contracted prepuce over it with the fingers. I have seen patients faint during the operation, and the surgeon fail at the same time. The objections to this operation are—first, the glans is enlarged and in its natural situation, then why push it back? secondly, its congested state offers an insurmountable impediment to forcing it through the narrow space formed by the stricture. The second plan is applying cold lotions and puncturing the cedematous prepuce; and the third is the best, which is the following:—

The scientific surgeon, recollecting that the glans receives its blood from the corpus spongiosum urethræ, compresses the enlarged glans between his fingers, so as to force the blood into its natural channel; he thus diminishes the size of the glans, and with the other hand very readily succeeds in drawing the prepuce over it. The patient scarcely suffers any pain, and the operation is generally successful. When the glans is diminished by the pressure, it ought to be

drawn a little forwards, when the prepuce will slip over it without any difficulty. When the prepuce is cedematous, it ought to be punctured with a lancet, to evacuate the serum, and thus diminish its size; and should there be inflammation, or great congestion of the glans, cold should be applied for a few minutes, before attempting the operation of reduction.

In chronic cases, or when there is inflammation present, we often fail by either of the methods now mentioned. In the latter case, leeches or scarifications may be necessary.

In all cases when dangerous symptoms are urgent, division of the stricture must be effected when other means have failed, or are impracticable. The skin of the penis is to be drawn towards the pubes, and an incision made through the strictured part. A slight incision is first made, a director is then passed under the stricture, and the part divided. When this division is effected, the prepuce will, in most cases, pass readily over the glans; but should there be any difficulty in accomplishing its passage, it may be left in its present position, as the removal of the stricture prevents all dangerous results. In fact, from the moment the stricture is divided, the symptoms begin to subside, and as soon as the inflammation and swelling disappear, the prepuce will glide spontaneously over the glans. I have known this occur in the worst cases, in which manual pressure was intolerable.

When paraphymosis is neglected, and the inflammation has subsided spontaneously, adhesions take place, there is a tumour behind the glans, sometimes of a size to prevent erection and copulation. I have met with three such cases, which were cured by operations.

Excoriations.—When the inner surface of the prepuce and glans are irritated by gonorrhœal discharge, they sometimes become excoriated. There may be several abrasions, accompanied by itching, redness, and a yellow secretion. The sores are superficial and irregular, and are sometimes of an oval or circular shape. They are easily distinguishable from venereal chancres, though some eminent authors deny the dissimilarity. The best mode of distinguishing between excoriations and venereal ulcers, is to refer to the time at which either appeared after sexual commerce. Chancres do not appear immediately after connexion, and they are generally circumscribed and defined, while excoriations are diffused.

There is, however, great difficulty in many cases in deciding on the nature of many sores which appear on the genitals, in consequence of the applications which patients make previously to applying for advice. The history of each case will, in general, enable us to form a correct opinion.

Treatment.—The indications of treatment are to regulate the bowels and keep the parts

* We see a great number of cases at the Free Hospital, which generally yield to the treatment above recommended, and have not observed one in which circumcision was necessary.—ED.

perfectly clean. [Solutions of acetate of lead, sulphates of lime and copper, black or yellow wash, frequently applied on lint, will speedily effect a cure in a great majority of cases.

There are many other morbid conditions excited by blenorragia, or gonorrhœa, which require consideration. The nervous connexion between all parts composing the genito-urinary organs, and the whole nerves of the body, accounts for the disorders excited by local disease of the urethra, testicle, prostate gland, bladder, ureters, and kidneys. The universal sympathy between all parts of the body will account for the excitement of diseases in remote parts.

There are, therefore, other diseases induced by urethritis, which must be noticed; these are chordee, bleeding from the urethra, irritable bladder, and mucous disease of the bladder.

Chordee.—This term is applied to a painful erection of the penis, during which the organ is drawn downwards, or laterally; and the patient feels as if cord were surrounding it. The cause of this disease is inflammation of the corpus spongiosum, and the pain is produced by dilatation of the vessels, induced by the influx of the blood preparatory to an erection. The disease is most troublesome at night, when the patient becomes warm in bed.

The *treatment* consists in the application of cold water or cold lotions, leeches, and fomentations to the affected part; at the same time administering hyoscyamus, camphor, opium, and conium internally; and if there be much ardor urinæ, or scalding, the medicines already prescribed for that complaint. When the disease becomes chronic, there is generally more or less induration of the penis, and this is best removed by the preparations of iodine, and the ung. hydr. camphr.; but some cases are incurable*.

Bleeding from the Urethra.—This sometimes occurs from painful erections, or after the introduction of instruments. When the hæmorrhage is considerable, a compress ought to be placed on the root of the penis, and secured by a roller brought round the loins, and passed between the thighs, so as to press the organ against the pubes. Others recommend cold lotions.

The urethra is congested or inflamed, and requires the same treatment as in acute urethritis. The patient should be confined to bed or to a sofa, and avoid all causes capable of irritating the generative organs. All vinous and spirituous liquors, walking, riding on horseback, or in a carriage, and dancing,

are injurious. Sexual commerce ought to be avoided.

Irritable Bladder.—Towards the last stage of gonorrhœa, there is often an urgent desire to empty the bladder, which may occur every ten minutes; the urine is voided in small quantities, and sometimes mixed with blood; this may give rise to the suspicion of stone in the bladder. It is of great importance to form an accurate diagnosis, between the one disease and the other, and this can be readily done. In irritable bladder there is generally no pain after the expulsion of the urine; whereas in stone, the pain will be usually felt. The pain is most violent in irritable bladder, when the organ is full, or contains urine, and sometimes the inflammation is followed by suppuration, and then there will be a discharge of purulent matter. This disease is one of the most painful incident to humanity, and is often induced in old people by the extension of urethritis to the mucous coat of the bladder, by the improper use of stimulating injections, or by the retention of urine, from motives of delicacy. The disease, if improperly treated, may speedily destroy life; and on dissection the mucous coat of the bladder will be found inflamed or ulcerated.

The indications of *treatment* are to alleviate the pain, and to prevent its return; these objects will be best effected by large doses of opium, by opiate suppositories, and by keeping a gum elastic catheter constantly in the bladder. A flexible instrument is generally preferred, and it should be secured in its place by a bandage carried round the thighs and loins; the instrument thus applied will afford immediate ease, by emptying the bladder, and by allowing the urine to escape as fast as it enters the organ; the bladder will thus be kept constantly empty; and there is no objection to this plan, even if there be ulceration, for by keeping the bladder quiet, cicatrization will be facilitated. The bowels should be opened by castor oil, the pubes and perinæum shaved, and a blister applied to either part. The free use of carbonate of soda, or liquor potassæ, will be very beneficial, by decomposing the urine, and freeing it from its irritating effects on the inflamed tissue. In some cases the disease will be followed in old persons by a copious mucous discharge, which was formerly denominated *catarrhus vesicæ*.

The quantity of mucus is often considerable, and the fluid is thick, tenacious, and of a pale yellow colour. It is caused by disease in the internal surface of the kidneys, ureters, and bladder.

The best remedies for this complaint are copaiba, uva ursi, pariera brava, with soda, liquor potassæ, and liquor calcis.

* We have been consulted in some cases, in which there was permanent lateral, and in others inferior curvature of penis, which very much impeded coition, and some of these patients were cured with iodine. Others were not relieved.—Ed.

**NON-ADMISSION OF PATIENTS INTO
THE METROPOLITAN HOSPITALS.**

WE beg the attention of our readers to a letter signed T. W. H. in the Times of last Saturday.

It contains two striking illustrations of the manner in which the poor of this metropolis are debarred from the advantages which public hospitals ought to extend to them, and left to suffer unaided, or to die neglected.

A patient, in a miserable state of disease, and whose case was acknowledged to be one requiring *immediate* attention, applied at Guy's Hospital on a Monday, and was told that Friday was the day for admitting *medical* cases *; the patient returned on Friday, and was again refused admittance because it was four minutes past the appointed hour.

The week before, a still more revolting case occurred at the same institution. A poor girl who had come all the way from Croydon for advice, and who applied for it on the right day—Friday, was put off till that day week, because she was twelve minutes after the regular hour: *within four days from that time she was dead.*

The coarsest humanity would sicken over such recitals! So, then, although disease and destitution occasion misery every day of the week, they are to meet with compassion only on one day; impending death is an evil to be averted at ten o'clock, but a matter of entire indifference at eleven. Suppose a man to be seized with acute inflammation of a vital organ, which if not arrested,

may prove fatal in forty-eight hours. His friends, if he have any, convey him to the hospital, and, if he have none, he crawls there as he best may, and craves admission. "My good friend," quoth the porter, "this is not the right day—take it coolly—you will be admitted in less than a week." Another is struck with apoplexy at eleven o'clock, and is straightway brought to the hospital. "He should have been struck an hour sooner, quoth the porter, "bring him again this day se'nnight." The unhappy men keep not the appointment; they have already been received into the bosom of their mother earth, by a mode of admission not regulated by times or seasons. If perchance a rude stone mark the place where such a *victim* of public charity lies buried, that stone is less the monument of a forgotten pauper, than of the barbarity of a nation calling itself civilised and humane!

A man with two days' life in him is in fine condition to wait a week for medical aid; a man in a state of coma is like to be an exact observer of regulations and of hours!

How is it that in a country which we believe, sincerely, and without partiality, to contain a greater aggregate of humane and generous feeling than any other on the face of the earth, the ends of charity can thus be frustrated, and the very decencies of humanity outraged? We cannot tell; but of this we are certain, that if a foreigner were to see nothing of England, but what passes, six days out of the seven, at the doors of our metropolitan hospitals, he would proclaim us, with seeming justice, as a nation either of savages or of idiots.

We are very glad to see the letter alluded to at the commencement of this article. We wish sincerely that well disposed persons would oftener express, in the public prints, the feelings which cannot but arise within them when circumstances bring them in contact with the regulations of our hospitals: for our

* This may aid us in drawing the line of demarcation between physic and surgery—*medical* cases are those which are admissible at Guy's Hospital on Friday.

own part, we shall never be remiss in seconding their representations—the subject is one which admits of no discrepancy of opinion among those endowed with common sense and common feeling; there are many points on which we may think wrong while advocating what we believe to be right; but on points of ordinary humanity, there is no fear of error—on these all men, *except the regulators of London hospitals*, think alike.

At this moment we know of only two institutions, in or near London, which have the smallest claim to be considered as hospitals in the true sense of the term; the one is the Free Hospital in Greville Street, Hatton Garden, and the other is the Seamen's Hospital, off Greenwich; at either of these a patient presenting himself at any hour of the day or night is admissible, if there be room for him. The former owes its existence to the spirited exertions of a few medical gentlemen, and principally of Mr. Marsden; the latter was instituted by the enlightened philanthropy of some gentlemen unconnected with medicine, and is, perhaps, less of a doctor's job, or a job of any kind, than any other of our medical charities. The surgeon resides on board the vessel. The medical officers are paid for their trouble, according to the means of the institution, and, as far as we are able to collect, discharge their duty in a manner highly creditable to themselves and beneficial to the objects of the charity.

With regard to the large metropolitan hospitals, we can only say what we have already said again and again—they *must* come under the superintendence of the legislature, and they *will*!

—o—

DUPUYTREN'S CLINIC.

Hernia.

CASE I.—*Inguinal Hernia, strangulated at the neck of the Sac—Operation—Enteritis—Death.*—A man of spare habit, about 58 years of age, came to the Hôtel Dieu, labouring under all the symptoms of strangulated hernia, such as hiccough, nausea, flatulence, bilious

and stercoraceous vomiting, and suppression of the alvine evacuations. This state of things had lasted for about twelve hours, and had been produced by an effort of the patient to get into bed. On this point M. Dupuytren made an important remark. Persons afflicted with hernia, he observed, are accustomed to wear a truss only during the day, and imagine they may leave it off at night without danger; whereas, according to my experience, in the majority of cases it is during the night that strangulation takes place. The effort of getting into bed, any effort or movement when there, efforts of a certain description especially, are so many causes which unceasingly threaten strangulation. We cannot, therefore, too earnestly advise persons afflicted with this malady to keep the truss applied day and night.

In the present case there was an inguinal hernia of large size, a considerable fold of intestine appearing to be engaged. But neither the external ring, nor the inguinal canal itself, formed the stricture; for the intestine could easily be made to pass up to the *internal* ring. The stricture, therefore, was at the neck of the sac. The hernia had not been strangulated above twelve hours; there was no appearance of immediate danger, and no remedial measures, such as general or local bleeding, baths, emollient or astringent applications, &c., had been employed. Nevertheless, the well-known difficulty of reducing hernias of this description, determined the surgeon to operate immediately.

An oblique incision was made over the tumour, in the direction of its long diameter. The different layers were successively divided, as well as two arteries, which were tied; the sac was raised up, and opened about its middle, a little serous fluid escaping. The intestine appeared of a reddish brown colour, but in a state sufficiently healthy to admit of its return. As had been expected, the quantity of intestine was large—eight inches being engaged. The stricture was divided, not with a *concave* probe-pointed bistoury, as is so generally recommended, but with a *straight* probe-pointed bistoury, for want of a bistoury cutting on its *convex* edge. A *concave* bistoury, according to M. Dupuytren, is liable to very serious objections. Besides that it cuts with greater difficulty, and rather by pressing than by sawing, we cannot fail to perceive that the most concave part of the instrument being that which corresponds to the neck of the sac, the curve of the instrument is very likely to wound some part of the intestines contained in the cavity of the abdomen, especially where a free division is necessary. With a *straight* bistoury, on the other hand, and better still with a *convex* one, the division is much more easy. It is made rather by drawing than by pressing; and the instrument may be carried much farther on without risk of doing mischief.

The *convexity* of the instrument corresponding to the stricture, the slightest motion is sufficient. As to the direction in which the division ought to be made, M. Dupuytren does not hesitate, in all cases of inguinal hernia, to divide directly *upwards*, in a direction parallel to the *linea alba*. By this means, he observes, we always avoid the epigastric artery, and we get rid of the numberless difficulties which render the operator uncertain as to whether he should divide *inwards* or *outwards*.

The mass of intestine being considerable, and filled with gas, M. Dupuytren (according to the method he is accustomed to adopt) pressed it gently between the palms of his hands. By this means the air was forced from the inferior portion of the tumour into that part of the intestine remaining within the abdomen. The size of the hernia was thus diminished, and its reduction became more easy. When this latter step had been accomplished, a bandage was applied; but union by the first intention was not attempted. M. Dupuytren recommended that the patient should be bled in an hour; again in the evening, if necessary; and even a third time during the night, if symptoms of peritonitis should arise. The first bleeding was performed; the others were not. Whether this omission favoured the development of inflammation, or whether a fatal result would have occurred notwithstanding, violent symptoms of enteritis supervened, and the patient died two days after the operation, in spite of local depletion, baths, and fomentations. On opening the body, effusion of sero-sanguineous matter was found in both the iliac fossæ. The external surface of the intestines presented at intervals large spots of a dark brown colour. It was a part of the small intestines which had formed the hernia. Internally, the mucous membrane was very highly inflamed.

CASE II.—Inguinal Hernia strangulated at the neck of the Sac—Operation—Cure.—A young man about twenty years of age, of a strong constitution, had been afflicted for a long time with inguinal hernia of the right side: the patient happening to make a false step, this hernia became strangulated. He was immediately attacked with colic, nausea, and hiccough; then with vomiting and suppression of the stools. Bleeding and a bath were employed without relief, and the patient was brought into the operating theatre fifteen hours after the strangulation. A tumour was seen in the right groin; and the same symptoms as in the preceding case, indicated strangulation at the neck of the sac. The operation was immediately performed with great facility. Two arteries were divided, the four ends of which were tied directly. The intestine, which was of a light brown colour, was reduced without difficulty. Immediate union was not attempted.

No accident followed the operation. The abdominal tension and pain disappeared, together with the nausea and vomiting. The alvine evacuations were re-established, the wound proceeded rapidly towards a cure, and, ten days after the operation, the patient was free from all danger, and ready to be discharged.

CASE III.—Strangulated Crural Hernia—Operation—Union by the first intention—Rapid cure.—A woman, about forty years of age, came into the Hôtel Dieu with all the symptoms above enumerated of strangulated hernia—hiccough, nausea, vomiting, &c. For several years she has been troubled with crural hernia, which she had occasionally confined with a truss, but which became strangulated, the evening before, in consequence of an effort to lift a burden. Examination revealed a crural hernia, not very painful, turned up over Poupart's ligament; and covered, consequently, by the skin, cellular tissue, superficial fascia, and some lymphatic glands. Attempts at reduction had been made without effect. M. Dupuytren remarked, that the turning upwards of the hernia, over Poupart's ligament, rendered a different mode of applying the taxis necessary. The first efforts ought not to be made from below upwards, in the direction of the crural canal, but from above downwards; always bearing in mind the curved direction of the canal. The surgeon decided on operating immediately.

By the first incision the skin, a little subjacent cellular tissue, and the superficial fascia were divided. A lymphatic gland of considerable size was then brought into view; and as it was situated directly over the tumour, M. Dupuytren did not hesitate to divide it through the middle, although aware that this practice involves the risk of consecutive fistula. The hernial sac was then perceived, and was opened at its lower part; a little reddish-coloured serosity escaped, and the hernia was uncovered. The incision into the sac was enlarged with scissors, first longitudinally upwards, and then to each side in a crucial form. The hernia was of a very simple description, being formed of a knuckle of small intestine, which although of a brownish red colour, had sufficient tenacity to admit of being returned into the abdomen. This was done immediately after the division of the stricture, which was made directly upwards, in a direction parallel to the *linea alba*. It is thus M. Dupuytren divides the stricture in all cases of crural hernia in the female, and always without danger, owing to the absence of the spermatic artery. The rule will not hold good in the male subject; for there the existence of the artery in question obliges us to divide the stricture in another direction; and this direction, according to M. Dupuytren, is from below upwards, and from within outwards. The incision will

then be parallel to the course of the spermatic vessels, which are thus sure to be avoided; but if there be no danger of wounding the spermatic artery, when the strangulation exists at the *inferior* orifice of the crural canal, injury of that artery is to be feared when the strangulation occurs at the neck of the sac, on the *superior* orifice of the canal; for then the division has to be made at a greater depth. In this case, would it not be better (as we once saw practised by M. Dupuytren himself), instead of dividing freely at *one* point, to incise slightly at two or three *different* points. These incisions, which might be less than two lines in extent each, would be equal to a single incision of much greater length, and would furnish sufficient space, with less danger of encountering the vessels.

In the present case immediate union was attempted; and, in spite of the division of the lymphatic gland, in a few days the cicatrization was perfect, and the cure complete. This brilliant success should induce M. Dupuytren to have recourse more frequently, in operations for hernia, to union by the first intention. When this plan is adopted, the sac in general does not inflame more than is necessary to produce adhesion, and it is rare for this mild degree of inflammation to be communicated to the peritoneum. On the other hand, when immediate union is not adopted, the contact of the sac with the air, and with the dressings, must necessarily give rise to a degree of inflammation sufficiently active to produce suppuration, and to affect the peritoneum; and this, no doubt, is one of the principal and most frequent causes of the peritonitis, which carries off so great a number of patients after the operation for hernia. When a portion of intestine is highly inflamed, its return into the abdomen is in general sufficient to remove the inflammation. The soothing contact of the surrounding parts furnishes the best poultice; and why should it not be the same with the hernial sac? To prevent all foreign contact, and restore it to its natural relations, are the most likely means of effecting a cure.

—o—

Foreign Medicine.

M. Rostan's Clinical Remarks on Diseases of the Nervous Centres.

(Continued from p. 752.)

THE disorders above mentioned are not the only phenomena of meningitis. Sometimes, especially in adults, it occasions delirium—perversion of the mental functions; but it is not to be denied that such disorder depends on the extension of inflammation to the cortical substance of the convolutions, or at least on a sympathetic affection of this gray stratum. It is on this subject particularly that the opinion of M. Delays appears to be

founded on positive data; the smallest anatomical knowledge enables us to judge of the necessary connexion between disorders seated in the pia mater, and derangement of function in the cortical substance; this is not to be regarded as an hypothesis, but received with the credit attached to a well established fact. The delirium varies infinitely in its characters; it is, however, more generally furious and noisy than silent; it is general or exclusive, continued or intermittent: it is seldom present at the very commencement of the disease.

In the present state of science it is impossible to determine whether its characters have any uniform relation to the seat of the disease. Coma occurs frequently in the decline of the malady, but hardly ever at the time of its invasion—a fact which militates against the existence of primary acute hydrocephalus, which Dance has lately endeavoured to re-establish. In studying meningitis, it is not sufficient to confine our investigation to the phenomena by which it is directly indicated; the state of the other functions must also be attended to; and it is to the elucidation of the indirect phenomena of this disease that M. Rostan directs his attention. The tongue is usually large, of a rosy colour, and sufficiently moist; the thirst is not urgent; there is loss of appetite, as in almost all inflammatory affections. If the mouth be dry, and the tongue red at the margin, the existence of some complication is indicated. Vomiting occurs chiefly in the first stage, with or without pain in the epigastric region; this symptom, however, is not to be considered as arising from inflammation of the stomach; according to M. Rostan, the vomiting is a consequence of the functional disturbance of the brain, and altogether independent of the state of the stomach. In other respects the digestive functions are not deranged; the belly is neither tense nor painful; constipation, however, almost always exists.

M. Guersant has established that meningitis is a frequent consequence of gastro-enteritis; M. Rostan doubts the truth of this proposition, and can only account for the discrepancy of opinion between M. Guersant and himself, from the circumstance of his own observations having been made principally on adults, while those of M. Guersant were confined to children.

At the commencement of the disease the pulse is full and frequent, in a few days it becomes slower, and finally, when death seems to be approaching, it is again accelerated, but small and more or less irregular. Occasionally the face is flushed, and the conjunctivæ injected. The blood drawn from a vein is frequently covered with an inflammatory crust; the respiration is natural or moaning, and sometimes accompanied with sighing. In some cases the patient utters loud and shrill cries, which suddenly cease, and are repeated at intervals, but which do not seem to be connected with any

particular feeling of distress. Some authors have attached considerable importance to this sign, which M. Coindet has denominated *cri hydrencéphalique*.

The heat is sometimes considerable over the entire surface, at others it is unequally distributed, and alternates with chills. Patients very often complain of flushes of heat ascending to the face, which is for the moment suffused with a vivid colour. Sweats occasionally break out, which are not attended with any remarkable result.

It is not sufficient thus to analyse the more or less important symptoms of meningitis; they must be collected and grouped, and their relations brought together in a picture whose *ensemble* may be comprehended by the student.

In this manner M. Rostan has described meningitis, which may be divided into three stages, each characterized by well marked phenomena. The first stage, which has been aptly denominated that of *excitement*, generally commences with rigor, succeeded by febrile re-action more or less distinct; pain in the head then supervenes, with peculiar brightness of the eyes, increased sensibility to light, morbid acuteness of hearing, agitation and jactitation; convulsions do not as yet occur. With these symptoms are conjoined more or less heat of the surface, thirst, and vomiting. The countenance indicates pain and anxiety; there is an unusual contraction of the eyelids and lips, communicating a caricatured expression to the face, which aids the diagnosis.

In the second stage, called that of *perturbation*, delirium supervenes; there is sometimes a tardiness in answering questions, and a peculiar snappishness in the mode of speaking. The function of motivity is disordered, as indicated by irregularity of muscular action, convulsions, and other symptoms already alluded to. The ordinary duration of this stage is one or two days.

In the third stage, denominated that of *oppression*, or *collapse*, all the phenomena of excitation and perturbation cease; the patient continues for a longer or shorter time in a state of drowsiness or faintness; the organs of animal life appear to be oppressed by a direct and powerful influence. The phenomena of sensibility are more or less diminished; the muscles yield without resistance to the weight of the limbs, which renders the position analogous to that observed in adynamic fevers. At this time the pulse is thread-like, irregular, unequal, and often almost imperceptible; the extremities are cold, and the skin is covered with a gelid clammy sweat—this is a sign of approaching death.

(To be continued.)

THE MEDICAL PROFESSION AS IT IS,
AND AS IT OUGHT TO BE.

To George James Guthrie, Esq.

DEAR SIR—The following observations not only interest each individual of the medical profession, but refer to circumstances which implicate the well-being of society at large.

In making them, you cannot suppose that any feelings of personal hostility towards you influence my breast; for, as proof to the contrary, I have as an individual experienced repeated acts of friendship from you, as well as the most gentlemanly and impartial conduct, both from yourself and the other members of the Board of Examiners of the College of Surgeons, in conducting the examinations of pupils. Moreover, I esteem you as a man possessing no ordinary degree of talent either as a lecturer or a practical surgeon. My present object is to allude to some of the statements advanced by you before the parliamentary committee of inquiry, in reference to some of the base monopolies existing in the profession, suppressing merit, for the good of the few to the injury of the many. As a lecturer to a medical class of no small pretensions either as to number or ability, I deem it a duty incumbent upon me to express my thoughts on these points.

In the first place, sir, as it regards the future constitution of the College of Surgeons, you boldly advise that it should remain as it is (quoting your own words), “a self-perpetuating body,” a sort of a close-borough corporation, as you, I believe did not deny, when hard pressed by Mr. Warburton upon this point. You strenuously objected to the term “self-elected” corporation; but at the same time stated that “the members of the College have no voice in the election of the council” or governing body; “that the old existing members of the council elect a new one;” and, moreover, that the Board of Examiners (ten in number) are elected out of the council according to seniority; and that the new members of the council are elected by the members of the council themselves. Now, sir, with due deference to you, I really think that this mode of election entitles it to the appellations above mentioned.

You assert that the present mode in which the members of the council are elected “is the fairest and the best;” and the only alteration which you propose in the governing body of the College is, that *the meeting of the council should be open* to the “medical commonalty;” which boon, you said, “the members at large would sooner receive than the right of election!!!”

After having stated your objections against certain various plans of election which have been proposed to the council, at different times, you say, “If the council are elected by the whole body of members, all the ob-

jections already stated against the last-named proposals will hold good ;" which, in order to show the inadvertent contradictory nature of your evidence in this respect, I will if you please, briefly mention : they are the following :—" The general body would not be satisfied ; there would be very elderly men chosen, some seventy or eighty years of age ; we should not know where to find the electors, whether in London or elsewhere ; it would cause a general canvass, and lead to electing teachers in hospitals and lecturers only." You then added, that " if the whole body were electors, perhaps the *youngest* surgeon might be chosen. Hospital surgeons would be more frequently elected than they are now ; the profession would become ' a placarding body,' *would be all at daggers drawn* ; open canvass would be attended with a great deal of inconvenience ; the profession would become a political body, and very troublesome."

Why, my dear sir, do you not know that the profession *must* be a political body in a certain sense ? and that every association is, whether belonging to profession or trade, so far as it regards the internal regulations of their own matters of business ?

The assertion, that " they would be all at daggers drawn," is a compliment to the commonalty of the profession, to be sure, which puts us below the par of a ten pound householder. Is it to be supposed that when a meeting for electing or balloting a member is duly advertised in the leading journals, that all who choose, could not meet at the College of Surgeons for that purpose, like rational beings ? Do you not know, sir, that it is monopoly, injustice, and disaffection which begets discord and tumult ? and that if the medical community could have exercised their own just rights, and had individually a vote, there could be no disaffection nor cause for reform or inquiry ? For the real object of reform is to render just rights and privileges to all, thereby satisfying them.

How you could have been so mistaken as to have said that " the members in general would sooner have the privilege of all the meetings of the council being open to them, than the right of election" seems inexplicable, unless it is that in consequence of intimate association, the mental vision of the *medical* aristocracy is as much deranged as that of the aristocracy of the community at large—that they both see things through their own dim and fallacious medium, and are but little acquainted with the actual wants and opinions of the enlightened " commonalty."

You would not admit surgeons who practise pharmacy to be members of the council, nor even to be electors, because you state they are not qualified for the higher branches of the profession—their time is so engaged in pharmacy, that they have not time to practise surgery. But I would ask, my dear sir, do the

majority of general respectable medical practitioners occupy much of their time in actually compounding medicines ? Do they not leave that charge and drudgery to their assistants and apprentices ? And even supposing that they did compound some of their medicines with their own hands, would that take up more time than the employment of those means whereby most hospital surgeons not only gain their appointments, but insinuate themselves into practice afterwards, viz. family and political connexions, money influence, or gaining the private friendship and support of the governors of charities and their families, through the instrumentality of card, dinner, and ball parties ? This is the way in which public appointments are obtained in England—not by laborious professional study night and day, and well tried professional merits, as you have unsuccessfully attempted to insinuate.

Again, let me ask you, sir, did not the illustrious Abernethy administer medicines to his patients with his own hands ? And, have not pure surgeons as many medical cases as general practitioners ? For it is a fact acknowledged by all pure surgeons, that the bulk of their practice consists of medical cases ? All these facts tend to prove that no invidious line of distinction should be drawn between pure surgeons, commonly so called, and general practitioners—that their election should depend upon absolute merit, which must be determined by some public test, conducted by competent judges.

I remain, my dear Sir,

Yours very obediently,

G. D. DERMOT.

Hospital Reports.

ST. GEORGE'S HOSPITAL.

Case of Epulis.

ANN —, aged thirty-eight, about thirteen years since, after having had several diseased teeth, which were not extracted, began to have a swelling of the gum of the lower jaw, which underwent a gradual enlargement until within the last few months, during which time its growth has been much more rapid. At the present time it occupies the whole of one side of the gum, from the dens sapientiae, which is in a state of decay, to the canine tooth of the opposite side. The tumour is hard and insensible, nor does it occasion any other inconvenience than that which is the effect of its bulk. It contains, upon its external surface, the stumps of several teeth, decayed down to the gum—indeed, the remains of all the teeth indicated, except two which have been extracted. Its size is rather difficult to estimate, but its anterior position protrudes so much as to be very visible on

speaking; its surface is irregularly lobulated, rising to a greater height at the front, where the decayed stumps of teeth in the upper jaw allow it to attain a greater bulk.

Mr. Walker performed the following operation for the removal of the tumour:—An incision was made along the base of the lower jaw, from a little anterior to the margin of the left masseter muscle to the angle of the jaw on the opposite side; from this another incision was carried upwards, leaving, however, the margin of the lip undivided. The flaps thus formed were then dissected off the bone, and reflected upwards. With a small key-hole saw an incision was then made between the lateral incisor and canine tooth in front, and between the last molar and dens sapientiæ behind; these were now connected by an incision extending below the base of the tumour; a groove having thus been made in the bone, a pair of cutting forceps were employed, by which the whole diseased mass was at once removed. The surface of bone thus left, presented some slight irregularities, which were afterwards taken away, as was also the stump of the dens sapientiæ. The surface was then touched with the actual cautery. The edges of the external wound were then brought together by sutures.

Upon making a section of the tumour, it was found to consist of a hard dense texture. It appeared to spring exclusively from the alveoli of the teeth, the texture of the jaw itself appearing to be entirely free from any disease.

No constitutional disturbance followed the operation, and in a few days the edges of the external wound had firmly united.

WESTMINSTER HOSPITAL.

Anthrax.

JOHN CARTER, aged forty, a hackney-coachman, was admitted into Henry Hoare's ward, June 9th, under the care of Sir Anthony Carlisle. He is a man of a plethoric habit, having generally lived very freely, and has frequently indulged in the use of spirits to excess. During the last month he has felt languid and poorly, his appetite became impaired, and latterly he has had febrile symptoms. A week previous to his admission, swelling and inflammation first shewed themselves on the back, which were attended with pain of a hot, burning-like character.

The inflammation spread from three distinct centres, leading to as many irregularly circular, and elevated, but flattened tumours. Two of these were seated high up on the back, between the two scapulæ, whilst the other was lower down, near the inferior angle of the left scapula. The two larger of these tumours possessed a diameter of about two inches, and the smaller one that of an inch and a half; they had the peculiar brawny

feel pathognomic of anthrax. The size of the tumours, and the severity of the symptoms, were equally increasing up to the date of his admission, when crucial incisions were made into each of the tumours, which gave him great relief. A large poultice of linseed meal was directed to be applied, and he was ordered to take the Mistura Salin. Effervescent.

12th.—*Rx.* Hyd. submur. gr. vj;
Opii pulv. gr. j. M. ft. Pil.
h. s. s.

14th.—One of the carbuncles being very much inflamed and painful, was again incised to-day, and he is ordered to take the following:—

Rx. Confect. aromat.,
Ammon Carb. ā 3 ij;
Mist. camphoræ, ʒ viii. M.
Capt. cochl. ij, ter quotidie.

15th.—The incision has given great relief. Tongue covered with a whitish fur; great thirst; he drinks freely of toast-water; pulse eighty-four, feeble.

18th.—Much better; tongue only slightly furred. As the bowels have not been relieved lately, he is ordered to take a common aperient draught.

23rd.—Much better; the inflammation has almost entirely subsided, and the supuration nearly ceased. The poultices have been discontinued, and the sores are now dressed with adhesive plaister, and they appear disposed to heal. Pulse, sixty, full, but not strong; is sitting up to-day.

30th.—During the last week the patient has made a gradual and satisfactory improvement, and to-day is considered so well as to be discharged as cured.

THE RAPIDITY OF THOUGHT.

ALL popular and settled notions, however unfounded, like prejudices early imbibed, are with difficulty eradicated. Among these may be instanced the dictum of the astonishing rapidity of Thought, which is almost proverbial, and generally believed: even Mr. Tooke, Vol. I., p. 28, conforms to this established maxim: "Words have been called winged: and they well deserve that name, when their abbreviations are compared with the progress which speech could make without these inventions; but when compared with the *rapidity of thought*, they have not the smallest claim to that title." By calculation, the progress of light from the sun and other luminaries is said to be ascertained; and likewise the rate at which sound travels: but hitherto no contrivance has been fabricated to estimate the rapidity of thought. If the succession of our thoughts should be more rapid than they can be distinctly apprehended, confusion must ensue, and their rapidity would render them useless. Our perceptions are regulated by the same law. If the prismatic colours be painted on a surface which is revolved with great rapidity, the individual colours will not be apparent. The succession of sounds to a definite number, may be severally distinguished, in a certain interval: but if the succession be increased beyond the power of discrimination, they will impress the ear as one uniform sound. The same principle must regulate our thoughts, whether they be composed of ideas or words, or, if it be possible, of both jumbled together. It does not appear that our thoughts for any useful purpose, which must imply their communication to others, or for a record in written characters, can be more rapid than the intelligible pronunciation of the words themselves, and which,

when delivered in quick succession, leave the shorthand-writer behind.—*Dr. Haslam on Thought.*

Case illustrative of the Effect of Frictions with Veratria Ointment in Palpitation, communicated by William Porter, Esq., Surgeon, Gower-street.

A LADY, about twenty-eight years of age, has suffered from a dropsical affection for about eighteen months, accompanied with a considerable degree of palpitation of the heart and irregularity of the pulse, and these symptoms appeared to be connected with irregular menstruation, from which the patient had suffered for some time. The lower extremities were cedematous, and there was difficulty of respiration and general nervous excitement. In the treatment of the disease various measures were employed without much benefit, until about two months ago, when the cedematous state of the extremities was much relieved by the use of diuretics and drastic purgatives; the palpitation, however, continued the same as before. As this latter symptom was peculiarly annoying to the patient, the attempt was made to remove it by means of an ointment made with twenty grains of veratria to one drachm of lard, and a small part of this was ordered to be rubbed over the region of the heart for ten minutes night and morning. After the second or third friction the palpitation disappeared along with the irregularity in the pulse; this took place about eight weeks ago, and although the patient is still unwell, it has not returned.—*Turnbull on the Ranunculaceæ.*

SELECT LECTURES,

FROM

M. BROUSSAIS'

*Course of General Pathology and Therapeutics;
translated and revised*

By JAMES MANBY GULLY, M.D.

LECTURE VIII.

THE prognosis of rheumatism has reference to its degree. I can certify to you, that when recent, and accompanied with a certain degree of heat, it may be arrested by the same means that are effectual in any other inflammation. I have cured hundreds of cases by leeching and cupping; the latter succeeds well in the flat muscles, but, in thick muscles, leeches are preferable, because they are capable of withdrawing blood from a greater distance. To place the two means in comparative juxtaposition, and enable you to form a judgment of them, I will quote the case of a man of seventy-two years of age, lately in my service, who fell on his right hip, and suffered from a muscular inflammation; this was first treated with cupping and poultices, which did not give the slightest relief; whereas a free application of leeches, on the following day, brought the patient round immediately—a warning fact to those who affect to despise the remedial agency of leeches. And, if it please those individuals, I would maintain, that when the inflammation is recent, though not phlegmonous, local bleedings are most strikingly influential: though it is but fair to state, that they do not succeed when the disease is chronic, the fact being, that in the latter case the blood leaves the part in proportion as it proceeds to atrophy, and as the vessels become obliterated, thus presenting no appropriate case for leeching. But are we on this account to violently stimulate the patient, to set him on fire, or expose him to the reverberations of extreme heat, like spitted game? Not at all; for you will thereby bestow on him the gift of some visceral inflammation. Were it possible to communicate to him an uniform and

sustained heat, such as exists in hot climates, well and good; he would speedily be cured. This any one will maintain who has observed the progress of the disease in those climates, though it is impossible to obtain such evidence in northern regions. Many of our rheumatic patients go to warm latitudes and get well, return to cold ones and relapse. Heat, therefore, is the agent more especially appropriate in the treatment of the disease in question. But, because external heat cures, would you infer that it is necessary to heat your patients internally—to give them stimulants, sudorific decoctions, tincture of guaiacum, &c.? This would be all very well, if we were sure that the stimulation of the viscera would not remain predominant, but would always produce sweating. Suppose that you thereby succeeded in giving some relief, have you not, during the winter, the almost incessant action of cold, and can you promise to resist the cooling influence of a medium like our's by means of sudorifics? If so, you will be mistaken; neither against rheumatism, nor against gout, are there any specific remedies taken from the list of drugs. You must act upon the skin, or, giving your remedies a different direction, act so as not to endanger your patients' life by presenting them with a chronic gastritis. I repeat it, I have had rheumatic patients under my care who did well by being kept warm, by using frictions, and taking emollient or gelatinous baths, to which aromatics were added, or which were charged with sulphurous and gaseous matters; after which the surface was covered with cotton clothing, which kept up the transpiration and diminished the general suffering. If the pains were excessive, I gave them narcotics, having a care not to harm the stomach. I once applied this treatment to a general officer, who went on well with it, but thought it too tardy in progress, telling me that he once met with a person who cured rheumatism by a mixture of sudorifics and purgatives. He took this mixture, which gave him a gastritis and hypertrophy of the heart, subsequent to which a pulmonary congestion came on, and he died.

To talk of withdrawing a rheumatic humour that has been concentrated on the viscera, is mere nonsense, and moreover leads to the compromise of your patient's life. Persons thus treated come to you with some acute affection, the cause of which you do not detect, but only the consequent mischiefs; you behold an ataxic fever, a dothi-nentery, an apoplexy, the serious nature of which is in striking contrast with the innocuous character of the primitive disease; you wonder how inflammation has come to be so fiercely developed in the viscera—yet, in the commencement, there was nothing more than a rheumatism! This should make you feel that no disease whatever is inconsequent or to be neglected, and that it is by approximating things small with great that you are to become real medical men, and not by writing forty or fifty accounts of the most serious disorders, having no care for the minor ones, for the precious reason that they are not worth the trouble.

To sum up; when recent and slight, rheumatism is removable by leeches; when of longer standing, it is not so easily got rid of. But at what epoch does it cease to be thus removable? This it is hard to answer; to judge on the question you must possess a fact and habit of observation, which I could not impart to you in one nor even in a hundred lectures; nothing but good clinical instruction can supply it.

When the disease is chronic and the parts become cold, a local heat must be maintained; warm baths, slightly exciting poultices, and vapour baths, must be employed, with narcotics internally, if there be great pain; a nutritious diet should be ordered sufficient to keep up the circulation, but not so stimulating as to induce phlegmasiæ; and, above all, care should be had not to torment the visceral apparatus by medicines. The freshly drawn skins of newly killed animals, warm sand and milk baths, &c. all act by maintaining a gentle external heat, which opens the skin and calms the irritation. Nature effects the rest. Fortunately the warm weather comes in aid after a few months, and the patients come round. As regards internal affections, the same theory holds as in gout. If the pains are unattended by phlegmasia, sedatives are given: if they are actual phlegmasiæ, you attack them with antiphlogistics; if there is transfer or metastasis internally, you establish blisters or other revocations on the part that has been deprived of its energy.

Neuralgiæ.—Under the influence of cold, irritation is sometimes observed to predominate in the external nervous branches and cords, and you have then a kind of nervous rheumatism. Certain nerves are more subject to it than others. How does it occur? Not more mysteriously than in the preceding tissues. The peculiar pulp of the nerves is enveloped in a gelatinous, cellulo-fibrous tissue, denominated neurilema, the structure

of which is nearly resembling that of the aponeuroses and other fibrous tissues, as shown by Bichât. The impress of cold being made on this enveloping tissue, begets in it an irritative movement, which may become an actual inflammation; there is then an external neuritis, and this sooner or later implicates the central nervous substance. It is frequently complicated with rheumatic irritation, but may exist without it. We will first consider it in its isolated character, and shall then be able better to conceive of it in its complicated condition.

Sensitive persons who have suffered from cold, particularly of the feet and hands, often have lancinating pains along the limbs, pains that are the preludes of neuritis. A medical man readily recognizes them: I have several times felt them, and could not mistake them again. If one can have such pains from the impress of cold, you need not be astonished that the irritation of which they are the evidence is raised to the level of a phlegmasia, becomes predominant in the nerves, and gives rise to nervous rheumatism. This is more particularly observed in the thigh, and then has the name of sciatica; the seat of it is easily pointed out, inasmuch as it follows the track of the nerve. Pressure with the finger causes a prolongation of the pain in it, and a kind of electric movement along its course; at the same time the muscles contract. Varieties in the pain may obtain according as the main point of irritation is higher or lower, according as it affects the internal or external, the superficial or deep-seated nervous fibres. When sciaticæ are very inflammatory the pains are agonizing; the muscular contractions aggravate them and cause them to pass through the nerves like electric sparks, particularly if the nerves are in communication with the visceral nerves; the slightest movement is intolerable, and the spasms may extend to the brain. If the disease is not overcome, muscular irritation is superadded and becomes inveterate, the limbs become bent, contracted, and atrophied. Sometimes the sensibility and phlegmasia are so concentrated in the most painful parts that gangrenous eschars form. These phenomena are more usually observed in the thighs and hips; but the brachial nerves are also liable to them, and the phlegmasia that possesses them may be complicated with that of the muscles. When the inflammation is acute, there is heat and gorging in connexion with the seat of the disease. If remedies are not applied, it very rarely ceases of itself; the same happens in the upper as in the lower limbs—the nerves become disorganized, the muscles retracted, and suppurations and eschars may form.

Neuralgiæ of the face are of two kinds; one involving the eye and forehead, in which there are convulsive movements of the eyelids, acute pains in the nervous twigs of the ophthalmic branch of the suborbital and superior maxillary; the other affecting the in-

ferior maxillary branch, its dental and facial twigs, and accompanied with the same kind of pains and contractions, of varied violence, of the muscles of the same side of the face.

In all these cases, but especially in the former, the irritation may be communicated to the nervous centres, and endanger life.

What does dissection show, and what is our prognostic in these affections? Dissection discovers inflamed nerves, red or black, according to the degree and duration of the inflammation; disorganized nerves, sometimes exhibiting solutions of continuity in the branches and cords, but particularly in the large trunks. In a less inflammatory shade, we meet with infiltrations of gelatinous and albuminous matter, a kind of ganglions that have become developed, and are, as it were, incrustated with earthy matters—in short, we meet with all the disorders of sub-inflammation. Sometimes, in consequence of the violence of the phlegmasia, a phlegmonous abscess forms, in which the nerve is comprehended and disorganized. These alterations, the varieties of which are numerous, and not described here as in a treatise on pathological anatomy, lead to a miserable and often excruciating suffering. This may suffice for the prognosis.

In the treatment, leeches stand first. I am sorry for those who do not patronize them, but it is no less certain that they reduce this inflammation both in the leg and in the arm and face. I exhibit proofs of this on all possible occasions, and such are very frequent in my military practice. Disorderly privates, that have been exposed to an icy wind for several hours together, are often brought to me in a neuralgic state, with such violent pains and contractions as to render it impossible to touch or shake them in the least without causing intense pain. Now, I speedily cure these with the so much slandered leeches; but there should be no chariness of them; fifty, sixty, eighty should be applied at once, and repeated if needed; a small number produces no effect. We then employ emollient poultices and powerfully narcotic ointments, and in two or three days the disease will have disappeared. Should you be very nice with it, and, instead of this energetic treatment, combat it with antispasmodics, in conformity with the vague precepts of a by-gone pathology, you will see it aggravated, and perhaps propagated over the economy, and then, not having been able to subdue it in its simple condition, what will you do now that it is complicated?

Neuralgia depending on some external violence, as a blow, a fall, an effort, intense heat from the close proximity of a furnace or fire, is to be similarly treated. If, after employing these means to the proper extent, you have not entirely succeeded, you have still revulsives, rubefacient ointments, blisters, and particularly moxas, which should be repeated, without burning through the

entire thickness of the skin; but do not be in too great a hurry to employ them, for you may retard or even altogether obviate the cure. I have often completed cures already half effected by leeches, by means of acetate of morphia used in the endermic method over the course of the nerve or on the most painful portion of it.

All these means failing, we fall into empiricism, and give narcotic preparations, emetic and sudorific mixtures, Meglin's pills, or unknown formulæ. But whilst yielding to the wishes of the patient in administering these various remedies, we must never lose sight of the organ in which they are to be deposited, the stomach; for it may thereby become inflamed or contract a predominating nervous irritation. In fact, stimulating treatment not only creates gastritis, but neuroses of the stomach as well, that are obstinate in kind and serious in character. In such case, the only refuge is in a warm climate.

A last resource is found in the section of the nerve; you may do it in superciliary, suborbital, or maxillary regions; but can you cut across the ischiatic, the brachial, the median, &c.? Assuredly not; the most that you can do is to take away any ganglion or tumour that compresses the nerves in question. Here, then, we must be content with local bleedings, revulsives, sedatives, change of climate, and certain remedies attended with more or less danger, and therefore to be used with the utmost caution.

Regarding neuralgiæ that are owing to the suppression of some hæmorrhage, the menses or piles, to the cessation of an external suppuration or secretory irritation, of which I have not spoken, the only point they exhibit in addition to those mentioned is the indication of revocative means, such as leeches to the anus or vulva, sinapisms or blisters on the seat of some dartre, or of some suppressed suppuration. This rule of action applies in all cases where a greater irritation has succeeded to a lesser one.

Lymphatic Inflammation of the Legs.—This disease is also developed after the impression of cold, which is its chief though not its sole cause, for it may be induced by forced exercise or contusions. Its mechanism resembles that of the preceding affections. It is an irritation that seizes on the lymphatic vessels and ganglions, leads them to inflammation and gives rise to a congestion and painful condition of the whole of one thigh or of both, effects that follow the more certainly if the skin is in a state of perspiration at the time the cold acts upon it. This is the case with lying-in females, who are more especially subject to it. When cold seizes them after delivery, and when a transfer of action from the uterus to the mammae is going on, which transfer is always accompanied with copious sweats, they may be attacked with this affection, which among the English is called *phlegmasia alba dolens*.

One or more red lines are observed along the internal part of the thigh; a series of smaller ganglions is felt, and the cellular tissue is tumefied. If the phlegmasia does not predominate, there is a tense œdema unyielding to the hand, and excessively painful from the quantity of nerves that accompany the ganglions and vessels; the irritation is communicated to the heart, and there is a certain degree of fever. This irritation may be established internally, and give rise to a visceral congestion and phlegmasia that becomes predominant, and is attended with great danger. The external phlegmasia is in itself a serious matter demanding immediate arrestation, for in a very short time it is apt to cause extensive and numerous abscesses, purulent collections and absorption of pus, succeeded by hectic fever, provided death has not taken place during the acute stage; thus, there is the local danger and the danger of visceral congestions. The disease is not, however, so rapid in its progress; after a few days, the pain may abate and an engorgement and subinflammatory state remain, approaching to elephantiasis and tending to the degeneration of the lymphatic tissues.

What treatment should we employ? Leeches again. They only withdraw a blood mixed with serum, but they nevertheless produce a rapid disgorging, followed by resolution. True, we thereby miss the opportunity of relating some long tales and beautiful dissections; but is not the cure worth them all? And this is more certain, as we have been careful speedily to attack the first points of irritation; for inflammation, like a fire, has always a starting point, and must be attacked at an early period, if we hope to stay its progress. After leeches you have compression, which, prudently employed, and at the fit time, may be greatly advantageous. But should a decidedly chronic state declare itself in spite of these means, or because they have not been employed, the case puts on a more serious aspect. At present I shall not enter on this point, but reserve it for some other time.

Erysipelas of new-born Infants.—It depends on the same causes, and is developed in the same manner as the preceding disease. Some have forbidden such children to be bled, but they are wrong; two or three leeches may be advantageously applied to the congested points; nor is it in this particular case that their utility is exhibited. Children often come into the world with a decided inflammatory tendency. A monograph has lately been written on this subject, as if it were something new, though it is a long standing one in the physiological doctrine, which, long ago, maintained that children are often born with all kinds of phlegmasiæ, acute or chronic, apparent or non-apparent. When observed, they should be combatted by antiphlogistics, as in adults, proportioning the means to the degree of

activity and the powers of the little individuals; for there is in them, in regard to vital resistance and the power of supporting losses of blood, differences analogous to those remarked in persons more advanced in age.

We have beheld inflammation in the external parts, in the skin, in the subcutaneous cellular tissue, the articulations, the muscular and aponeurotic tissue, and the nervous cords of the limbs, particularly in the larger ones. One fact must have struck you, that the fever is always in a direct ratio with the external inflammation. In fact you have seen, that a slight inflammation causes no fever, that a greater induces it; that when the inflammation that has excited the fever has been reduced by local means, the fever ceases; that if any cause reproduces this inflammation, and gives it a fresh impetus, the fever re-appears. In peripatetic inflammations, such as those of the articulations and muscles, you have seen the fever appear with the local inflammation, and disappear with it. Together with the fever, you have always observed lassitude, a derangement of the functions of the stomach, an alteration of the principal secretions, the sweat, the sebaceous matter of the skin, the urine, and the mucus of the tongue. You may have been able to judge by the disorder of the appetite, that the secretions of the digestive canal are also deranged—a fact that receives additional confirmation from the declaration of the patient that he has sometimes a bilious taste in sometimes a clammy condition of the mouth, when irritation existed in the stomach, and that he has nothing of the kind when that irritation disappeared. We have also spoken of glandular lymphatic inflammations, and shown that they ought not to be taken from the general rule—that they depend, as do the others, on an irritation applied to the exterior of the body; that, in like manner, they occasion fever and disordered secretions, and that these phenomena disappear with them.

Such are the leading facts that would strike you in this somewhat abridged, but sufficiently explicit relation that I gave you of the phenomena of external inflammations. On one point I laid particular stress—that the danger here is in a ratio of the rapidity and extent of the inflammations, because the internal disorder is always proportioned to them; and on this other point—that the visceral inflammation supervening on them may become the predominant affection, and compromise life. This is a standard proposition, and may be adduced as the leading and most important truth of our medical epoch.

As regards chronicity, you have seen that when the inflammatory state was extinct a less active irritation often remained, which does not pass rapidly towards suppuratory

disorganization, but which tends to denaturalize the nutrition of the parts, and that then the disease was constituted of a sub-inflammation. These details I shall reproduce under the head of sub-inflammation, and shall endeavour to prove that these irritations should be considered in the sub-inflammatory as well as in the inflammatory state.

I told you, with reference to the treatment, that whenever the physician comes in time to circumscribe the inflammation, and attack its two fundamental elements, congestion and pain, he puts a stop to the morbid scene, and has nothing to fear from the propagation of the irritation to the different parts of the body, and therefore nothing to fear for the life of his patient; but that if there existed in the individual affected with an external phlegmasia, a disposition to an internal one, or if he already had one, the former aids the development or aggravation of the latter, and the patient may be carried off, notwithstanding every care. This question, however, I shall more fully enter upon when we come to the account of internal phlegmasia, in order to arrive at which more gradually, we now proceed to the consideration of the inflammations of the mucous apertures, in which inflammation is more nearly situated to the viscera, and more generally affects them. Indeed, it is sometimes difficult to say whether these inflammations, as well as more external ones, do not primarily spring from the viscera; but so soon as you ascertain that the febrile disorder and derangement of the functions have appeared subsequent to them, the distinction is thereby established, and you enter upon the question we are now upon.

I have made no mention of the external secondary inflammations, such as small pox, scarlatina, measles, &c., because they are only episodes of some internal inflammation that always precedes them, and you ought never to confound with them the cases of external primitive inflammations that are accompanied with a predisposition to visceral irritations, or with already formed internal phlegmasiæ; this would be taking the effect for the cause, or a simple coincidence for a result.

We now, therefore, proceed to the inflammations that are seated in the origins of the mucous membranes; this will lead us to those of the viscera. And first, of the inflammations of the genito-urinary mucous membrane.

Urethritis.—In placing urethritis in this category of inflammations, I only speak of that which is not specific, inasmuch as I carefully exclude such phlegmasiæ from the descriptions I give. I only enter upon the pure and simple inflammation of the mucous membrane of the urethra, which may be either acute or chronic, and in this respect

is similarly characterized with other inflammations.

The causes of this disease are excessive excitations of the urethral gland, both externally and internally—those caused by the venereal action and masturbation for instance. To these a third cause may be added, the action of bougies and irritating injections in the urethra; I see no others that can be adduced. To say that urethritis consequent on coition is the effect of the absorption of a virus during the act, is advancing what cannot be proved; for some women affected with vaginal inflammation give urethritis to certain individuals, and do not give it to others; and again, some women, who have neither vaginitis nor urethritis, nevertheless give the latter to men: this is an undeniable fact.

Urethritis is more particularly apt to occur in youth, a period of life when the mucous membranes are more irritable, and the abuses of coition and masturbation are freely indulged in. It is well known that vaginal phlegmasiæ, even such as are scarcely felt by the woman, may yet communicate urethral inflammation. As regards those that are owing to the introduction of irritating injections into the urethra, and which may be artificially produced in animals by injections of chlorine, soda, or irritating salts, they are seen in man after similar modifications, after stimulating injections employed as remedies in some disease of the urethra or bladder. I am acquainted with a person who was sent last year to Barges, and was recommended to inject the waters of the place; the consequence was, that he contracted a violent urethritis. It may also be produced by the mechanical irritation of a bougie or sound. You will perhaps say that this kind of urethritis has not so regular a progress as that which depends on excess in coition, but there is no proof of this; sometimes they are regular in progress, at others not: I have seen many that were produced by masturbation, perfectly regular in their progress. As there is much darkness on the subject, you must stay by what is the actual case, and not seek to establish impossible distinctions.

The characters of urethritis are in the first place the four general ones of tumefaction, redness, heat, and pain. It sometimes begins in the prepuce and gland, and is propagated along the urethra to the fossa navicularis; in such cases, an itching sensation with increase of venereal appetite is often experienced two or three days before anything is felt in the urethra itself.

On examining the prepuce and gland you find a mucous and purulent oozing with the four inflammatory characters. At other times the inflammation commences in the urethral canal, without any previous appearance at the gland; this depends on the manner in which the urethritis has been contracted. The irritation once established

propagated along the canal to its membranous portion, where it ordinarily stays, though it may extend further, and even into the bladder. Nervous or enervating phenomena are first experienced, painful sensation of the penis, a desire for coition, and then disgust of it, tension and hardness of the urethra, excessive sensibility of the mucous membrane, preventing the excretion of the urine, constriction of the bulb, and frequently in the commencement, constipation.

We will first take urethritis in its greatest severity; for it has, like all diseases, numerous shades, and is exhibited with as many aspects as there are individuals of varied sensibilities; it even appears in different degrees in the same individual when he has been several times attacked with it. If he is robust, sanguineous, and previously exempt from the inflammation, and has got it by some great irritation, he has it in its extreme violence; if he has it again the year after, it is less inflammatory; and if he has the luck to contract it every two or three years, it is gradually moderated and finally ceases to be acute. You may if you please make so many entities of these different shades. In the highest degree there is dysuria and even ischuria; it is an indubitable fact, that in excessive urethritis the kidneys almost cease entirely to secrete urine, and this should teach us that there is nothing to fear from the fulness of the bladder imagined by some. Moreover, as the general functional activity is increased, an absorption of the aqueous parts of the urine takes place. The patients in vain endeavour to make water: they either dare not or cannot. When the spongy part of the urethra becomes hard and tense, from the irritation of the mucous membrane, the erections are extremely painful, the urethra is no longer distensible, and the penis is curved downwards, constituting *cordee*. The disease having arrived at this degree, the irritation may be disseminated so as to produce fever, which however, is moderate, as the inflamed surface is small. Pay all attention to this material fact: the fever is proportionate with the extent of the inflammation, a minute phlegmasia produces no fever, a stronger one a moderate degree of fever, and a severe one a great degree of it. In this instance we have frequent pulse, the tongue is covered with mucosities, the secretions are disordered, the patient has pains of the loins, and gives evidence of commencing gastric irritation. After a variable number of days, according to the treatment, this excitation yields; mucus begins to flow, and becomes more and more opaque up to the twelfth or fifteenth day, when it is altogether so, and the disease has the characters of catarrh. Gradually the urethritis diminishes, and if not combatted, terminates by resolution in thirty to forty days; a minute finishing discharge remains, and persists for a variable period, becomes trans-

parent, and is completely dissipated. If the inflammation is not great, and the difficulty of passing water but slight, with only a small degree of redness, and minute mucous concretions at the extremity of the urethra, the discharge may continue for a longer period.

LECTURES
ON THE
PHYSICAL EDUCATION AND DISEASES OF INFANTS,
FROM BIRTH TO PUBERTY.

BY DR. RYAN,

Delivered at the Medical School, Westminster Dispensary, Gerrard Street, Soho;

Session 1834-35.

LECTURE XLIV.

*Diseases of the Digestive Organs, continued—
Congenital Diseases of the Stomach—Inflammations—Vices of Conformation, and Intra-uterine Diseases of the Intestinal Canal.*

GENTLEMEN—We have next to consider inflammations of the stomach, and vices of conformation, as well as the congenital diseases of the intestinal canal, and the remaining part of the digestive organs.

Inflammations of the Stomach.—Gastritis or inflammation of the stomach is a very common disease of new-born infants, and of those that are very young. The mucous membrane is the part first affected, but when inflamed, it presents a variety of forms, which may be divided, like those of those of the mouth and throat. 1. Erythematous gastritis; 2. Gastritis, with alteration of secretion (*muguet*); 3. Follicular gastritis; 4. Gastritis, with disorganization of tissue.

1. *Erythematous Gastritis.*—Erythematous inflammation of the stomach presents itself in a ramiform or capilliform injection, in red patches of various sizes, in irregular lines, or in numerous red spots, which may be distinct or confluent. These different appearances may or may not be accompanied with tumefaction and friability of the mucous membrane. The mucosities of the stomach are sometimes thick, and more abundant than in the ordinary state; but this symptom is not constant. The seat of the ramiform redness is in the vessels of the stomach, that of the capilliform in the ramifications of the capillaries; that of the patches or spots or the lines, and red points in the proper tissue of the mucous membrane, and, as M. Leuret has well observed, in the papillæ or villosities of that membrane, which may be sometimes slightly tumefied. Gastritis may however exist without any swelling of the villosities.

It is important to state that the ramiform inflammation is the slightest of all, and that all the others are most intense.

All these inflammations may exist at the same time, or may be observed separately, and are often the precursors of profound disorganization or transformation of tissue.

We should distinguish the different forms of gastritis from passive congestions, and to accomplish this, we should recollect the seat of the redness and the fulness or vacuity of the vessels of the abdomen. Congestions are most apparent in the most dependent part of the stomach, and there is a similar condition in the vessels of the digestive tube, in the great abdominal vessels, and the right cavities of the heart. Inflammation or active redness exists independently of these conditions, and is often accompanied by tumefaction or friability of the mucous membrane.

Erythematous gastritis is generally accompanied by vomiting, either as soon as drinks have been swallowed, or in some time afterwards. There is generally pain on pressing the epigastrium, though this symptom may be absent; and what is still more remarkable, there may be but occasional vomiting, and no febrile symptoms whatever. It is therefore very difficult to distinguish erythematic gastritis during life, and in many cases dissection alone reveals it. The disease may be acute or chronic, and succeeded by ulceration, gangrene, or ramollissement or softening of the mucous membrane.

Enteritis, according to M. Billard, is the commonest complication with gastritis, for in a hundred and fifty cases of inflammation of the digestive tube, inferior to the diaphragm, or, in other words, of the stomach and intestines, there were ninety cases of gastro-enteritis, fifty of enteritis without gastritis, and only ten cases of gastritis without enteritis. We may fairly conclude from this calculation, that in cases of enteritis there is often at the same time gastritis. The diagnosis is therefore difficult, but the treatment for gastritis and enteritis is fortunately the same. This I shall describe immediately, when I shall have given the pathology of the other forms of congenital gastritis.

II. Gastritis with alteration of Secretion, or Muguet of the Stomach.—I have stated, when speaking of stomatitis or inflammation of the mouth, accompanied by change of secretion, that this form of inflammation was peculiar to the mucous membrane. I also stated that it might present itself in the mucous membrane of the mouth, throat, œsophagus, stomach, intestines, and all portions of the intestinal and other mucous membranes. This form of inflammation is, however, more rare in the stomach than in the mouth or œsophagus; for M. Billard informs us, that in 214 cases of muguet, which he examined in 1826, at the infirmary of the Foundling Hospital of Paris, he only saw three examples of the disease in the stomach, and two in the intestinal tube; and

he inquires whether the contact of the air on the inflamed mucous membrane of the mouth might account for the frequency of the disease in that part? He does not, however, attempt to answer the question*. He gives the histories of three cases of the disease in the stomach in which the morbid appearances were exactly similar to those in the mouth, which I described on a former occasion.

III. Follicular Gastritis.—This form of disease is similar to that of the follicles of the mucous membrane of the mouth and œsophagus. The follicles of the stomach are isolated and not in clusters, as in the mouth, œsophagus, or small intestines.

When the follicles of the stomach are inflamed, they appear elevated in the form of small, white, round, granulations, which terminate in blackish points, and these are their external orifices. As the inflammation advances, they terminate in ulceration or some other disorganization.

M. Billard met with fifteen cases of this disease; eight of the infants were from four to six days old, the rest were from eight to ten, and one was aged three weeks.

There was no vomiting, no fever, but great debility; and there was another infant who vomited a sanguinolent and dark fluid.

IV. Gastritis with Disorganization of Tissue.—The most frequent disorganizations of the stomach, consequent to gastritis are, gangrene and gelatiniform ramollissement or softening.

Gangrene of the Stomach.—This disease is rare in infants at the breast. MM. Denis and Billard have however described it.

Gelatiniform Ramollissement.—This disease was first accurately described by Professor Cruveilhier, and was often seen by M. Baron at the Foundling Hospital of Paris. The disease consists in the reduction of the mucous membrane into a sort of thick, soft pulp, like jelly, and the parietes of the stomach or its coats are so thin and fragile, that the least traction or pressure perforates them.

This state is accompanied by symptoms of intense inflammation. It is in the most dependent part of the stomach, and is supposed by Billard to be aggravated by the deposition of serous fluid in the coats of the organ at this part. He holds that perforations may occur in this position, which may be followed by sudden death, and that the disease may appear in very young infants,

* This able pathologist seemed to be tainted with the exploded notion, that the influence of the air on wounds, ulcers, and cavities was most injurious. The strictures of John Bell, of Thomson, in his work on Inflammation, which are recorded in their works, and in Cooper's Dictionary, totally disprove this opinion.

dom necessary, —
unless when enteritis is also present, and
even in this disease they must be used
sparingly and with caution. Two or three
leeches applied to the epigastrium or ab-

diately before birth is much less
tends to the jejunum, and is diminished in
the ileum. The jejunum presents marks of
the valvulae conniventes—the villusities are

marked; we often find isolated muciparous follicles in the jejunum, sometimes as large as the head of a pin, and almost always whitish: the follicular plexuses are slightly prominent, and also whitish, and sometimes punctuated with black, as observed in adults. The black spots are most common in the extremity of the ileum; the ileo-cæcal valve is prominent, and the aperture which it surrounds is very strait. In the greatest number of infants a crow's quill will scarcely pass through the aperture, and this opening strongly opposes the passage of fæcal matter or gases from the large into the small intestines. We may convince ourselves of this fact by passing water from the small into the large intestines, and from the latter into the former; the fluid readily passes from above downwards, but there is an insurmountable obstacle to its return from below upwards. The cæcum and large intestines do not present the characters which distinguish those of the adult.

The mucous membrane of the intestinal tube gradually changes its colour after birth; it acquires a milky whiteness, and remains as if covered with short hairs for some time. During the whole of the first year, the inner surface of the tube is remarkable for this appearance, and for an abundant secretion of mucus.

The contents of the intestinal tube of an infant at birth vary in their colour and consistence. We usually find, in the duodenum and jejunum, thick, whitish mucosities adhering to the sides of the intestine, sometimes in circumscribed patches, and at other times in diffused layers. These matters are generally yellow, and probably coloured by the bile; but there are often small greenish masses, which are found in the intestines long after the expulsion of the meconium. They have been observed in an infant eight days old; they are not irritating, as the part of the intestine with which they are in contact is not inflamed. We also often find, near the ileo-cæcal valve, in the infant about to be born, an accumulation of yellow frothy fluid; the large intestine being filled with meconium, or the dark green fluid which is speedily evacuated after birth in the majority of instances. Such are the natural appearances of the internal surface of the intestine and its contents; but the variations from them are numerous.

When we remove the contents of the intestines in a nascent or new-born infant, we find a layer of thick mucosity adhering to the internal surface of the canal, and which on account of its thickness and consistence forms a kind of covering over the mucous membrane. When this covering is raised with the nail, it appears to an inattentive observer to be the mucous membrane. This layer is often expelled by purgatives when administered to new-born infants, and some practitioners have termed it a *saburra*. It is this substance that is expelled in flakes,

and mixed with the alvine motions of some new-born infants. The bile sometimes colours it in the duodenum, and when we remove it, we observe the mucous membrane in a healthy state beneath it.

The meconium tinges the internal surface of the intestinal tube to a greater or less extent, of a green colour; and it often happens that this substance, when expelled, is mixed with the mucosity just described.

When the meconium is liquid it is rapidly expelled in most cases, and the surface of the colon presents irregular patches of a green and white colour. These may be removed with the back of a scalpel, and then the mucous membrane will be found of its natural whitish colour.

As soon as the new-born infant receives food, the intestinal contents are varied in colour, and the phenomena of digestion are those of the after periods of life.

There is great importance attached to the evacuation of the meconium by nurses, and they exhibit various aperients to new-born infants for the purpose, which will be noticed when describing the medical management of new-born infants.

Malformations of the Intestinal Canal.—It has been found that a greater or less portion of the intestinal canal has been absent in acephalous fœtuses. In some cases there was only a portion of the small and large intestine; in others the large intestine alone remained. The intestinal tube is also liable to many other primitive malformations—to division, obliteration, dilatation, and contraction, in some part of its extent.

The division of the intestinal canal has been observed in different parts of its course, but particularly in the small intestine.

Scafer, of Wurzburg, has given a history of cases of this kind, which he divides into three classes:—1. The intestinal canal is contracted in many points; 2. It is divided in several parts by mucous membrane; 3. It is divided in many parts, and each is separated from the other*. M. Billard has related a case of intestinal division, and it appears, from all that has been written on the disease, that infants affected with it only survive a day or two. Nevertheless, they seem well developed externally, but do not pass meconium or urine; they sometimes vomit a brown fluid, and, after death, the intestine is found to have terminated in a cul-de-sac in one or many parts†. In other cases the small intestines were found adherent to each other, or to the gall-bladder; and the rectum may be imperforate, as I formerly stated. This last portion of the

* Journ. Complement. du Dict. des Sciences Med. t. xxiv.

† M. Billard relates some cases of this kind, which deserve perusal.—*Traite des Maladies Enfants*, &c., 1834.

intestine has opened into the bladder or vagina; but these malformations I have fully noticed already, when describing congenital malformations of the outlets of the body.

Congestions of the Intestinal Canal.—The intestinal tube may be congested in the nascent or new-born infant, in the same manner as the stomach, which has been already described. It may present three appearances, as in the former part: the ramiform, capilliform, and patches of larger or smaller size. M. Billard observed twenty-five cases of passive congestions of the intestinal canal in infants that died some hours or days after birth, and without hæmorrhage; in fifteen of which, all the external characters of apoplexy of new-born infants were apparent. The symptoms relative to the digestive tube were none or nearly none, and the lungs and heart were congested as well as the intestinal tube. These passive congestions often give rise to intestinal hæmorrhage; and this merits serious attention.

Intestinal Hæmorrhages.—A frequent result of intestinal congestion is hæmorrhage. In fifteen cases noticed by Billard, there were eight infants between one and six days old, four from six to eight, and three from ten to eighteen. Six of the infants were males and nine females. The greatest number were remarkable for general plethora, and congestion of the integuments; others were pale and feeble, as after severe hæmorrhage. In all, the great vessels of the liver, spleen, lungs, and heart, were considerably gorged with blood; in nine, the foramen ovale and ductus arteriosus were obliterated, or on the point of being so. In all, the brain and spinal marrow, with their coverings, were strongly injected; and in all there was more or less red and dark blood, in clots, in different parts of the intestinal convolutions.

Such are the vices of conformation and diseases of the intestinal canal, including the small and large intestines of infants born at the full time, and of those who died shortly after birth. At our next meeting I shall describe intestinal diseases, as they present themselves at or after birth.

—o—

M. VIREY ON THE GENERATION OF ANIMALS AND PLANTS.

(Continued from page 768.)

Conditions necessary for Fecundation or Conception.—The intercourse of the two sexes is necessary for generation; and this is a law to which nature has subjected man and many animals. Nevertheless, there are examples on record which prove that an intimate union of the sexes is not necessary. A woman may become pregnant without immediate congress, by absorbing the seminal

fluid, applied to the orifice of the external genitals.

The slightest approach of the sexes, in which there is a seminal emission, may effect impregnation. All modern physiologists admit this doctrine, though, in former times, many German writers were ridiculed for this opinion. Plempius, Degraaf, Schurig, cited many examples of pregnancy which occurred in consequence of the application of the spermatic fluid to the genital orifice. Johnson published a work, entitled *Lucina sine Concubitu*, for the purpose of establishing the possibility of pregnancy without copulation. Averrhoes and Skenckius related cases of women who became pregnant on entering a bath in which the seminal fluid had been effused. Tarvernier states, that the Persian women sought the water of baths in which men had bathed, as an efficacious remedy for sterility. Fables still more extraordinary are recorded of women who were impregnated by the force of the imagination, by the winds, stars, and aerial spirits; and of these the present century afforded us an example, in another country, in Joanna Southcote. These fables are totally unworthy of belief.

It appears that, to render the act of reproduction as perfect as possible, it is necessary, independently of a good constitution, adult age, and the integrity of the genital organs, that man and woman should be determined upon it. If the whole mind is not absorbed by the act of sexual union, the offspring will be feeble and delicate, as we observe infants of those who make excessive mental or corporeal exertion. The sons of illustrious men are almost unworthy of their parents; while we observe, on the contrary, that most of those who become celebrated by character, genius, or valour, have been the fruit of an ardent love, and had parents distinguished for physical power. It is equally true, that great men are not the offspring of great minds, but of ardent love*.

General Causes of Fecundity and Sterility.—"It is necessary for a fruitful marriage, says M. Virey, "that there should be a certain harmony between the sexes, both moral and physical, and this is manifested in the sympathies of instinct, which, independently of beauty, makes us prefer one person to another. The sexes secretly wish their

* Sterne, though no great physiologist, has, in his first chapter, happily illustrated this point: "I wish either my father or my mother, or indeed both of them, as they were in duty both equally bound to it, had minded what they were about when they had begat me; had they duly considered what they were then doing, &c. I should have made a quite different figure in the world."

union by a natural impulse, which cannot be explained, and which, in a crowded society, renders us more attentive to one person than all the rest; and nature inspires us better in this respect than reason.

"This harmony consists less in similitude of temperamen, tage, &c. than in diversity; for if we remark, a violent bilious man prefers a mild and modest companion; whilst a passionate, impetuous woman, finds most charms in a moderate, tranquil man; so that one may be tempered by the other, whether they be too cold or too hot." It is well known that some married persons fail to have a family, who are fruitful after a second union.

When the characters are very different, they cannot enter in the state of harmony, as a frigid or ardent individual, until age or habit renders them more suited to each other: thus married persons have passed fifteen or twenty years without infants, notwithstanding their most anxious desires. Abraham and Sarah, and Jacob and Rachel, are examples mentioned in the Bible.

When there is antipathy, disgust, hatred, or passion, conception seldom happens; though some of these obstacles may exist at first, as in women who pretended to be forcibly violated, but who finally acquiesced in pleasure, and became pregnant; and it is not as yet determined whether impregnation can be effected when a real hatred exists. There are, however, many examples recorded of married and unmarried women who were impregnated when in a profound sleep, as mentioned in the books on Medical Jurisprudence, and recently by Dr. Gooch (*Outlines of Midwifery*, 1832), and Dr. Kennedy (*Elements of Obstetric Auscultation*, 1834). In such cases there could not be much voluptuousness, though amorous dreams might occupy the mind; but there was at the time no repugnance, for the former, or some degree of it, appears indispensable to the generation of a new being. It may be said with truth, that that which commences with hatred finishes with love, when the transport of pleasure ravishes the will.

Marc is of opinion that the moral causes of sterility in both sexes are, a fear to procreate, too vivid a desire to have children, an antipathy or incompatibility of humour between the sexes, negligence, apathy of husbands to their wives, the diseases and inconveniences of their wives, violent passions, and immorality or infidelity. He estimates the proportion of sterile to fecund women at 10 in 1000; Hedin, a Swedish minister, 1 in 10; Franck, at 6 or 7 in 3 or 400. The fear of procreation arises from the effects of indigence and inability to support offspring, or, in the upper ranks, from the vanity of women, who imagine that conception, and its consequences, will diminish or destroy their charms, or deprive them of devoting their time to those frivo-

lous pleasures which the rights of maternity demand. Reserve and frigidity, during the approach of the sexes, is a cause of sterility*.

—o—

UNIVERSAL CODE OF GENERATION.

PART I.—GENERATION OF PLANTS.

FROM the preceding facts it is evident that plants are entitled to be classed among organic or living beings. The reproduction of living beings cannot take place unless by the co-operation of two orders, male and female, which compose each species. The word species means individuals which perfectly resemble each other, more or less, and are capable of themselves, by a reciprocal intercourse, to reproduce other beings with the same distinctive characters as their own; and this from one generation to the other. The species, according to Buffon, is an abstract and general term, nothing of which exists but in considering its nature in a succession of time, and in the constant destruction and reproduction of beings. It is that of comparing nature in the present with that of past times, and existing with defunct individuals, by which we have an idea of what we call species; and the comparison of the number and the resemblance of individuals is but an accessory idea, and often independent of the first; for the ass resembles the horse more than the spaniel the

* Fecundity is greater with some than with others. Haller knew families who had sixteen, twenty, twenty-eight, and thirty children. A friend of mine knew a lady of title, who is still fine and youthful looking, who had twenty-seven children. A patient of mine, at St. John's Hospital, had thirty-two; and a woman, aged seventy, appeared at the Police Office, Bow-street, in May last, who stated that she was the mother of forty children, and that her daughter had twins three or four times. The magistrate unphilosophically stopt her narration, as he thought he had heard enough of her fecundity.

M. De Stael asked Napoleon who was the greatest woman in France. He answered—"She who has had most children." Dr. Blundell seems to be of opinion, that fertility depends more on the female than the male sex. He mentions an example of two sisters, who bore three children each at a birth; and of a member of the profession who, in advanced life, namely, eighty years of age, had four children, which Dr. B. is disposed to attribute more to the fecundity of the wife than the husband. Hahneman, the father of homœopathy, near eighty, has just married a Parisian lady, aged thirty-six. These and other cases show the possibility of the truth of charges of violation against very old men.—ED.

hound, nevertheless these are of the same species, whilst these produce together individuals which can reproduce other beings, but the ass and the horse are different species, for they cannot produce but hybrid and infecund individuals.

We must not confound the species with the varieties or races, which only consist of accidental differences among individuals of the same species. Thus, the white and red rose, the simple or the double, &c. are only varieties of the same species; the English, Dutch, French, and Arabian horses are only varieties of the same species, and so are all the different dogs of the same race. In like manner, all men who people the earth do not form but one species, all are human beings, capable of engendering with others of whatever nations, and producing offspring with the moral and physical characters of the human race. Nevertheless, the human race, like vegetables and animals, offers a certain number of varieties, as the European, Caucassian, Mongolian, Hyperborean, American, and Negro.

The different species of living beings are composed of two classes, which are essentially different from each other by their physical organizations: and these are the male and the female sex. This distinction of individuals of the same species arises from the difference of structure, function, and secretion of the parts destined for reproduction: the female contains in her ovaries the elements of the new beings, while the male is destined to vivify these principles with a fecundating fluid called sperm—spermatic fluid, in animals, and pollen in vegetables—without the action of which the female will find it impossible to produce a new being. The organs subservient to generation are called the reproductive, sexual, or genital. Nature does not afford a single example of reproduction without this double organization, without an action more or less immediate of the sexual organs of the male on those of the female, or upon some production which escaped from the womb of the latter, as in the example of the frog, which does not impregnate the ova or eggs of the female until they are expelled from her body. We may, therefore, define generation a function by which certain principles emanate from a female individual which are fecundated by certain other fluids furnished by the male, which transform it into a new living being like those from which they take their origin; and these are capable in their turn of procreating other beings, similar to themselves.

But the processes which nature employs for the continuation and eternization of beings are very different in all individuals which compose the vast kingdom of animated nature. Notwithstanding their perfect analogy, there exists a difference in man, the other animals, and in vegetables.

Though I propose in this work but to no-

tice the generation of the human species, I cannot but introduce a brief description of the reproductive function in beings which nature has placed in a subordinate rank. This will enable me to proceed from the simple to the compound, and finally to conceive the complicated mechanism of this admirable and important function in man.

It has been already stated that there are male and female organs in animals, destined for reproduction, and there are similar organs in vegetables. With the exception of a very small number of plants, all vegetables offer on the same stalk both male and female organs of reproduction, an admirable provision of nature, which thus furnishes the means of generation to the plant compelled to develope, increase, and die in the sun, whilst animals have a muscular system, that enables them to move from place to place and search out each other. The flower is the part of the plant which contains the sexual organs. These are sometimes united, and the union is called hermaphrodite.

The flower, the most tender, beautiful, and remarkable, on account of its form and variegated colours, is generally composed of four principal parts, of which two are essential to generation—the stamen and the pistil; two others which exist for ornament and protection against external bodies—the calix and corolla. Such is the arrangement of all these parts in proceeding from the exterior to the interior.

The calix is that part which surrounds the flower, which varies in colour, consistence, and the number of pieces which compose it, all of which are united at the base. It may consist of one, two, or three pieces, and those are called phyllæ.

The corolla is placed within the calix, and forms the inner envelope of the stamen and pistil. Linnæus ingeniously compared this to the nuptial bed, or the theatre of the amour of plants. It varies in form and colour, and like the calix consists of one or more pieces.

The stamen, or the male sexual organ, is the third part of a flower, which proceeds immediately from the corolla, and its use is to fecundate the pistil or female organ, which is placed in the centre of the flower. This organ is composed of the filet and anther. The filet is not always present, as it is not indispensable to fecundation, as on its summit is the anther, without which fecundation cannot happen.

The anther consists of a fine membranous sac in a double cavity, in the interior of which is a very fine powder called pollen. The anther is compared to the glans or head of the male organ, and the filet to the body of the same organ. The pollen consists of very fine grains, in the centre of which there is a subtle fluid possessing a similar odour to the semen of the male: it is that of fecundation, by its action on the pistil.

Most flowers have several stamens, and

fewer pistils, so that we may fairly conclude that plants are generally polyandrous, that is to say, there are many husbands for one female, as among certain animals, and the human species in certain eastern nations.

Linnæus based his beautiful classification of plants on the number of stamens, or vegetable husbands. Thus his first class is monandria, one stamen—his second diandria, two stamens—and so on to the eleventh class, dodecandria, from eleven to nineteen stamens; the twelfth, icosandria, from twenty to a hundred stamens; the thirteenth, polyandri, from twenty to a hundred stamens, inserted at the tube of the calix, which is often united with the ovary; the fourteenth class, didynamia (two powers), four stamens, two of which are longer than the others; the fifteenth class, tetradynamia (four powers), six stamens, four of which surpass the other two in size.

The stamens, or male organs, may unite in different bundles; which led the illustrious Swede to add four other classes. Sixteenth, monodelphia, one further, when all the stamens are united into one. Seventeenth class, diadelphia, two brothers; eighteenth class, polyadelphia, many brothers; nineteenth class, syngenesia, simultaneous generation, when many stamens are united by the anthers, and not by the file, so as to form a tube which is traversed freely by the style of the pistil. The twentieth class, gynandria, which signifies woman and man, the male and the female, in which the stamens are attached to the pistils.

In fine, there are plants in which the sexual organs are not in the same flower, and these are divided into three classes. Twenty-first class, monoecia, one house or family; twenty-second, dioecia, two families; twenty-third class, polygamia, hermaphrodites, in which the male and female organs are united or unisexual. Lastly, there is the twenty-fourth class, in which the sexual organs escape detection with the eye, and these are called cryptogamia, hidden marriages. The female organs of plants are the following: the pistil is the centre of the flower, and is the female organ; it is composed of the ovary, the style, and the stigma. The ovary, derived from the word ovum or egg, because this contains small grains, germs, ovules, or rudiments, is the inferior part of the pistil, which is supported by the receptacle or base of the calix. When incised or cut across, it contains ovules or eggs. The stigma is the superior part of the pistil, which transmits to the ovary the pollen or fecundating powder shed on the surface of the stamens.

The style, which does not always exist in all plants, is a thread-like process situated between the ovary and stigma, whose use is to transmit to the first the fecundating powder—though the stamens or male organs are much more numerous than the pistils or female organs: but in some plants the latter

exceed the former in number. The number of pistils has served Linnæus for a division of a certain number of these classes into orders.

First order—monogynia—one pistil. Second order—digynia. Third order—trigynia. Fourth order—tetragynia—four pistils.

Functions of a Flower, or Amours of Plants.—Having succinctly described the reproductive organs of plants, let us now direct our attention to the mechanism of these functions, which have for their object the reproduction of the species.

The celebrated Linnæus first gave the physiology of the reproduction of plants. The flower forms the theatre of their amours: the calix is considered the nuptial bed; the corolla the curtains; the anthers are the testicles; the pollen the fecundating fluid; the stigma of the pistil the external genital aperture; the style the vagina, or the conductor of the prolific seed; the ovary the womb; the reciprocal action of the stamen on the pistil, the copulation or consummation of the sexual intercourse.

It is only at the period of floration, or the development of the flower, that the marvellous unions or marriages of flowers are celebrated. The sexual organs of male and female exhale a spermatic odour, while they become more irritable, and even acquire a degree of action visible to the naked eye. Then the functions of generation commence, and are six in number. 1. Sexual approach; 2. Dehiscence or ejaculation; 3. Absorption of the prolific fluid by the female; 4. Fecundation; 5. Gestation; and 6. Dissemination or expulsion of the fruit from the ovary.

I. Sexual approach, Copulation—Coition.—When the flower is developed and perfected, the sexual organs act on each other; the male organ (anther) directs its head towards the stigma (genital fissure), so as to shed on its surface the pollen or prolific fluid. In some hermaphrodite flowers which have ten stamens, as the fraxinella, ruta, &c. each approaches the female organ, and having shed its seed, resumes its original position, to give way to the nine others, which alternately perform the same function. In some flowers the corolla contracts, so as to bring the stamens nearer the pistils, and in aquatic plants the flowers elevate themselves above the surface of the water, copulation is effected, and then they plunge again into the water and develope in that fluid. Linnæus observed, that when the stamens were longer than the pistils the flowers were vertical, when the pistils were longer than the stamens the flowers were inverted, when both were equal the flowers were pendent. In this manner sexual approach was facilitated, and insemination effected in all hermaphrodite flowers.

II. Dehiscence or Ejaculation.—The pollen of plants contains the fecundating powder, and consists of a number of small sacs, invisible to the naked eye, in which a fluid

exists, which is analogous to the spermatie liquor in man and animals. The rupture of these sacs, to allow the escape of the pollen, is termed dehiscence, and is similar to the emission of seed in man and animals.

The surface of the stigma (genital fissure in animals) presents a number of apertures, communicating with the ovary, or directly, or by the filiform (thread-like) process called style, and which we call the vagina in woman and other animals. The ovary of plants, like the uterus in animals, possesses a power of absorption or suction of the fluid, which it communicates to the ovule or germ. It is this action by which the ovary draws to itself either the seed, or the vapour arising from it, *aura seminalis*, and which action is termed pollinic absorption in plants and impregnation in animals.

The history of human generation informs us that the womb absorbs or sucks in with avidity the male fluid, and that impregnation follows the slightest penetration of the virile member.

The stigmata of flowers, like the organs of most women and animals, in the season of amours, are bedewed with more or less humidity, acquire more heat, and even become odorous. This organ in the sensitive plant, tulip, &c. becomes congested and contractile, not only after the application of the fecundating powder, but when submitted to any kind of stimulation. The arum of Italy develops so much heat under the same circumstances, as to be appreciable by the thermometer. We see the female organ in the crown imperial, the board of St. Anthony, &c. depress itself towards the male organ, which it surpasses in length. We even observe tremblings in the *parnassus de marais*, when it receives the exciting impression of the fecundating fluid. Eranté has beautifully described these phenomena in his delightful work—*De Connubiis Florum**.

III. *Fecundation, Impregnation of the Germ, Conception.*—The seminal fluid of the pollen having been transplanted to the ovules or germs in the ovary, these rudiments acquire a new mode of vitality; they rapidly increase, and are transformed into real grains, which are capable of giving birth to a new vegetable being, whilst they are placed in a situation the most favourable for germination. Such is fecundation in plants; and it does not differ from what we term conception in women and other female animals.

When fecundation is effected, both male and female organs, except the ovary, decay and die, as nature has accomplished her object and left the elements of future generations for development. These organs can

no longer contribute to the perpetual renovation of the species. "Reproduction," says Merat, "is the end of all the cares of nature, for which she has prepared the most brilliant apparatus. The act being finished, all enter into repose, all fade, all vanish. Retard fecundation, impede it by any means, and the flower preserves the freshness of its calix for a long time."

IV. *Development of the Ovules, Gestation, Pregnancy.*—The ovule remains a certain period, as in animals, until it develops and is transformed into grains capable of giving birth to new individual vegetables. We shall see, in studying the fruit, the processes employed by nature to effect this object.

V. *Dissemination, Dehiscence, Parturition.*—These terms are synonymous, and mean the escape of the grain from the fruit, and are analogous to parturition in women or animals.

a. *Analysis of the Fruit.*—The fruit is nothing else but the ovary arrived at perfect maturity. It is composed of two principal parts—the pericarp and the grain.

The pericarp is that part of the fruit which contains the grains. It is composed of three other parts. 1. The epicarpe or external membrane, which covers the fruit externally; 2. The sarcocarpe or pulpy part of the fruit, which is situated immediately under the epicarpe; 3. The endocarpe is the membrane which lines the internal cavity of the fruit, and which is in direct contact with the grains. It is easy to understand this description by examining an apple.

There is also a communication between the seed and the pericarpe, in some instances, which is termed trophosperma. We see this in the pod of a garden pea. The seed is covered by a membrane, named episperme. There is also a small prolongation from the trophosperme to the grain; which is termed podosperme, which means the foot or root of the seed, and it establishes a means of communication between the ovules and the pericarpe. It is through this prolongation that the ovules receive the nourishment necessary for their transformation into grains, like the umbilical cord in women and animals. The small cicatrix on the grain is called umbilicus, as in man, and it results from the podosperme or umbilical cord with this part of the fruit. The examination of a pea affords a perfect idea of all these parts.

Means which Nature employs to disseminate Plants on the Surface of the Globe, and to prevent the Extinction of the Species.—The chief of these means is dehiscence (parturition of a plant), which consists in the rupture of the pericarpe to allow the escape of the seeds. This operation, as in animals, does not take place until the germs have acquired all their maturity. Then the grains endeavour to escape, rupture the connexions which retain them in the pericarpe, and escape on the surface of the earth to produce new beings, as without this all vegetables would disappear on the surface of the

* ————— *Dat pronubia signum*

placentæ;
Ova tument, guadet flos femina prole futura.

globe. Nature employs a number of means for the propagation of plants in the different parts of the earth, and to prevent the extinction of the species: as the mode of dehiscence of certain fruits, the promptitude of germination in a great number of grains, the power which others possess of remaining incorruptible for a great length of time, the winds and the waters, which transmit them to a great distance, the animals which swallow them entire, and lastly, their great fecundity. A few illustrations may be given of each of these causes, as all of them afford peculiarities which are extremely curious to those desirous of examining and observing the propagation of vegetables.

b.—Dehiscence or Dissemination.—There are some fruits whose pericarpe, at the period of maturity, opens with such rapidity, that the grains are projected with an elastic force to a very considerable distance, and sometimes with a great noise. We observe this in the willow, the fraxinella, &c.

Promptitude of Germination.—There is a vast number of plants which germinate with astonishing rapidity, some even in the short period of three days.

c. Incorruptibility.—Most grains, except the oleagenous, remain incorruptible for a long time; some have remained forty, fifty, a hundred, and even a thousand years. Some have been found between the bandages of Egyptian mummies, which retained their power of germination. Mr. Houlton mentioned a fact of this kind in his lectures on botany, delivered before the Medicobotanical Society of London.

Winds and Waters.—A vast number of grains are so light that they may be transported to great distances by the winds. Others float in the air, and, according to some botanists, have been transmitted from one country to another, and even from one continent to another. Thus it is said that the erigeron of Canada was transported by the winds from North America to Europe. In the same manner it is stated that rivers, torrents, the waters of the ocean, transport seeds to a great distance, from one island to another, and from one continent to another. The corva of the Maldivé islands is said to be conveyed by the ocean to the Sechelles. The coasts of Norway present fruits which were transported by the same means from America.

d. Animals.—Man and animals contribute very much to the emigration of plants. They swallow many seeds without masticating them, and deposit them with their excrements in various situations, where they germinate. Many other seeds are also conveyed in the exterior of animals, as in their hair.

e. The great Fecundity of Plants.—The fecundity of plants in general, and many in particular, is really astonishing, and explains the facility of their reproduction, and their rapid multiplication. Thus, to cite a few

examples, a single poppy seed produces 30,000 grains, and a tobacco seed 40,000. Many other examples will be found in the account of fecundity.

VI. Amours of Plants in which the Male and Female Organs are not united in the same Flower.—There are certain plants in twenty-first, second, and twenty-third classes of Linnæus, whose flowers have male or female organs only. Monoic plants have sometimes the sexual organs placed at a greater or less distance on the same branch. Some, on the contrary, have the male flowers on one branch and female on another, as in all the dioic plants. The winds transport the pollen to the female organs, and bees, butterflies, and other winged insects, in flying from flower to flower.

Nature, ever wise in purpose, has placed male and female plants sufficiently near to each other that they may easily celebrate their amours by the wings of the wind.

Proofs of Sexes and Amours in Plants.—The theory of the reproduction of plants is far from being the fruit of the imagination, and it can only appear so to those who have never contemplated the brilliant spectacle of animated nature. It is proved by daily observation, which it is in every one's power to make. Multiplied experiments have proved that the rudiments of grain contained in the ovary cannot be developed but by the action of the fecundating pollen of the male on the female. The most illiterate floriculturist can attest this fact.

Lectures on Diseases of the Urinary Organs.

By Sir B. C. Brodie, Bart. V. P. R. S. &c.
Second Edition. 8vo. pp. 329. Longman and Co.

The Anatomy and Diseases of the Neck of the Bladder and of the Urethra, being the substance of the Lectures delivered in the Theatre of the Royal College of Surgeons, and in the Westminster Hospital. By G. J. Guthrie, F.R.S. &c. 8vo. pp. 284. Burgess and Hill.

THE authors of the productions whose titles are at the head of these remarks, hold the first rank as operative surgeons, and justly enjoy a very high character wherever surgery is cultivated.

Both have contributed important original works to the republic of medical literature. They now appear before the medical world as illustrators of a most important class of diseases—those of the genito-urinary organs. It is however to be regretted that they have

treated the subject too superficially and imperfectly ; and have added very little to what is already known. The profession had reason to expect much more from two of our hospital surgeons, who are also most extensively engaged in private practice. Nevertheless, they have scarcely advanced a single practical suggestion that has not been already made by their contemporaries in foreign countries ; and moreover, they have neglected to state many improvements suggested by our continental neighbours. Truth and justice compel us to offer this remark ; and it is confirmed by the recent strictures of foreign surgeons. Some of our impartial contemporaries can see nothing but super-excellence in English surgery—that of every other nation is bad compared with it ; in fact, “ nothing good can come from Nazereth.” Such sentiments will be palatable to those influenced by national prejudice, who are unacquainted with the actual state of science abroad, and very partially acquainted with that at home. Flattery is a delicious essence, and is generally swallowed with avidity, no matter how freely applied.

But observation in different countries has however thoroughly convinced ourselves, that there are able and great physicians and surgeons abroad as well as at home, and that talent is not confined to any. We are led to make these remarks after our comparison of the works before us with those of other nations, and after a full conviction, from an impartial examination, that our countrymen, so far from excelling, are not even equal to some foreign authors who have described the same class of diseases. Some of our slippery and toad-eating contemporaries have to their honour lately abused by wholesale all foreign surgery, though they generally contrive to fill a large portion of their own pages with the said inferior article. Thus stand their principles and practice. Now, if foreign medicine and surgery be so very inferior to British, why are the pages of our periodicals literally crammed with it ? We leave our opponents to answer this question. We shall not even allude at present to the motives which have led to such unjust and unmerited censure of foreign medicine, though we deeply regret that such a blot should stain the pages of British medicine.

While we honestly admit the improvements made by our foreign contemporaries, we also

maintain and uphold those of our own countrymen ; though every one acquainted with the actual state of science at home and abroad must acknowledge if he speak the truth, that the profession in this country, as a body, has not kept pace with the progress of science. Thus, neither of the eminent authors of the works before us have spoken of lithotrity as it merits, nor neither has formed a just estimate of Arnott's and Ducamp's plan of cauterization of strictures. Again, on perusing the work of Sir B. Brodie, one would suppose that he and his predecessors at St. George's Hospital were the only individuals in the world who had treated of urinary diseases. He scarcely mentions the name of a foreign writer, nor even of his metropolitan contemporaries, so that his readers must be satisfied with his own opinions. This is a charge that may be as justly made against most of our hospital physicians and surgeons ; in fact they endeavour to make students believe that there is no such hospital on the face of the globe as that to which they belong ; whether St. Bartholomew's, Guy's, St. George's, the Middlesex, the Westminster, the London, or North London. Every one of these is an hospital of wonders, and so are the Dublin and Edinburgh. This hospital puffing is carried to a most disgusting extent, but the present students very properly appreciate it. This puffing of “ shop ” must cease, for students and practitioners are now too enlightened to imagine that the scientific treatment of disease is superior in any particular institution. We are borne out in this statement by referring to the practice recommended by both writers whose works have given rise to our criticism. Sir B. Brodie states in his first sentence, “ It is my intention to communicate to you the results of my experience as to the diseases of the urinary organs, and the treatment which is required for their relief.” The author confines himself to his own experience, which is extensive, but he nearly omits all allusion to that of others, both national and foreign. Now we must contend that no public lecturer, however eminent, can discharge the important duty of teaching, without referring to the labours of his predecessors and contemporaries ; and he who does so, falls far short in communicating the necessary information. It is of course very instructive to students to hear the experience

of a lecturer, but they want something more—they want a full account of all that is known on the subject.

But when a teacher publishes his lectures, they come before the whole profession, who have a right to expect the fullest information. Now here our author has fairly disappointed them. His account of the pathology of stricture is meagre, and wholly unworthy of an individual of his acquirements and eminence. Here it is:—

“Strictures of the male Urethra.—A mechanical obstruction to the flow of urine through the male urethra may arise in various ways. There may be an enlargement of the prostate gland, by which one extremity of the urethra is surrounded; an abscess in the perinæum, or one of the mucous follicles, may be inflamed, and converted into a solid tumour; and any one of these, as well as some other causes, may operate so as to produce the effect which I have mentioned.

“The most common cause of difficult micturition is, however, a contraction or stricture of the urethra itself, and this disease requires our first consideration.”

Now, surely no student could form a just idea of the origin and cause of strictures from this description; he could not refer to urethritis as a cause, as he does not find gonorrhœa mentioned, nor is he informed of the commencement, progress, different forms and situations of strictures. These are serious omissions; and can only be accounted for by supposing that the author thought it enough to detail the results of his own experience. He introduces some ordinary cases of retention of urine from stricture, and describes his own methods of treatment, in which we find nothing novel. Interspersed among the histories of the cases are remarks on the form and pathology of stricture, which ought to have followed each other in regular order.

The symptoms are tolerably well described, but by no means so minutely as they might have been; and then follows an account of retention of urine, rupture of the bladder and urethra, infiltration of urine, sloughing, &c., abscess of the prostate gland, inflammation of the bladder and surrounding parts, and lastly, disease of the kidneys.

The next subject treated of is, the diagnosis of stricture of the urethra. This point is very accurately elucidated. Then comes the retention of urine from stricture.

In the cure of stricture Sir B. prefers a

gum elastic catheter with a stilet, to a metallic one, so strongly recommended by Sir Astley Cooper. He observes, “I should premise that the disease is not to be cured by medicine.” It would therefore appear, that cures effected with iodine in Germany are not believed by Sir Benjamin, nor does he once even allude to them. He expatiates on the advantages of the different kinds of bougies, and does not recommend the flexible metallic ones. He prefers a gum elastic catheter with a strong iron stilet, which is to be worn in the bladder for three or four days if possible, then withdrawn, and replaced by a much larger one. The patient should remain in bed or on a sofa; and we are further informed that a cure may be effected in the course of ten days, of a very contracted stricture. We have however repeatedly met with cases which did not yield so speedily.

Our author thinks the dilator of Mr. Arnott, made of varnished silk and filled with air by a syringe, as well as the steel one, unnecessary, whenever a bougie can be passed. He tells us that he rarely uses a caustic bougie with nitrate of silver; and he describes the objectionable and dangerous caustic bougie of Sir E. Home, while he is silent on the improvements of Arnott and Ducamp. We scarcely think it possible that Sir B. Brodie has not seen Ducamp’s instrument, and if he has, why pass it over in silence? It enables the surgeon to apply a caustic to the stricture only, and does not cauterise the whole urethra, like the barbarous armed bougie of British surgeons. We should be sorry to learn that our author has not seen this unobjectionable instrument, and we regret that he has not mentioned it or employed it. We hope he will do so before he publishes another edition, and never again talk of the dangerous caustic bougie of his patron and friend Sir E. Home.

Our author next notices diseases of the bladder and prostate gland, urinary and renal calculi, and lithotomy. We have already stated that he is silent on lithotrity. The reader, however, will be amply repaid for the perusal of these articles.

In conclusion we have to observe, that this work, though abounding with many instructive cases, is a most imperfect treatise on the diseases of the urinary organs, and far inferior to Chopart’s, by Sabatier, to Ducamp’s,

Appassat's, Phillips', and many others on diseases of the urethra.

It is a familiar treatise, which may be perused by the general as well as the medical reader. In delivering our opinion, we are actuated by a love of truth and science. We are no fawners on hospital physicians and surgeons: they shall hear our real and honest opinion of their productions. If they feel annoyed we cannot help it; but their toadies and hangers on will always apply a proper quantity of the delicious essence called flattery, which will soothe the irritation we have excited.

The second work at the head of these remarks need scarcely be noticed by us, as its contents have already appeared in this Journal. The author confines himself to the anatomy and diseases of the neck of the bladder and urethra, and these he has ably elucidated. He entertains some new opinions on the structure and diseases of the parts of which he treats, among which he contends that diseases of the middle lobe of the prostate gland is of rare occurrence, and generally supposed to exist when the real disease is in the neck of the bladder. He condemns the universal proscription of caustic, and hopes that the instrument of Lallemand, which is an improvement of Ducamp's, may finally be used in this country. His description of it is not however so clear as it might be, but those who wish to inspect it, will find an excellent delineation of it in Mr. Phillips' Treatise on the Urethra and its Diseases, especially stricture. This is a work which every surgeon ought to have in his possession. We are bound to state that there is a vast deal of practical information in Mr. Guthrie's work, which deserves careful study. The work is entitled to a place in every surgical library. In fine, we cannot but observe that the prejudices in this country against caustic bougies arise from their dangerous effects on the urethra, by burning most unnecessarily the whole of the canal, exciting spasm, and profuse hæmorrhage. These evils cannot happen from Ducamp's instrument. The caustic is concealed in a tube, and touches only the stricture. It effects a cure after three or four applications, and is now generally employed on the continent of Europe. It is highly lauded by the French, German, and Italian surgeons, and is very much employed by Mr.

Costello, Mr. Benjamin Phillips, and other British practitioners. We have also used it ourselves, and consider it a great improvement. It is infinitely safer than the caustic or armed bougie of this country.

In concluding our notice of the works before us, we have to observe, that both are instructive on the subjects of which they respectively treat; but these are only a portion of the diseases of the genito-urinary organs; and therefore we object to either as treatises—indeed the latter is not offered as such. We still want a complete Treatise on the Diseases of the Genito-Urinary Organs.

—o—

An Essay on the Nature of Diseases. By A. Green, LL.B. 12mo. pp. 52. London: 1835. Simpkin, Marshall, and Co.

ON perusing the title of this tract we were startled, wiped our spectacles, and read it again, when, to our amazement, we saw that the author had attempted to explain the nature of all diseases in a brochure, which one could carry in his waistcoat pocket. Pathology reduced to fifty 12mo pages! quoth we; well, this author must be a remarkably clever individual to write, *de omnibus rebus medicis, et quibusdam aliis* in such narrow limits. The shadows of the ponderous tomes of Andral, Hope, Craigie, and others passed before our mental view; and we could not help exclaiming, what labour have the authors of these volumes undertaken unnecessarily! Here is Dr. Green, LL.B., who has cut the gordian knot, and reduced pathology into a nut-shell.

Astonished at this unequalled and extraordinary achievement, we naturally hastened to peruse the pathological *multum in parvo*; but we found it in the state of the mountains of old—

Parturiunt montes, et nascitur ridiculus mus.

The progeny of Dr. Green is of kindred with that of the mountains; he has given birth to the hypothesis, that all diseases are caused by animalcules. He has not, however, offered the slightest proof in support of this opinion, and all his notions are based on mere assertions.

A great deal of indulgence ought to be shewn to a doctor of civil law, when he chooses to dabble in physic; and as we

abound with the milk of human kindness, we treat our author with our wonted urbanity. We do not nor cannot agree with him; but we award him credit for incubating such an offspring, and such an unintelligible hypothesis of the nature of all diseases.

As we progressed in his discoveries, we often imagined that the mantle of St. John Long, or Hahneman, or Ramadge, or Eady, or Goss and Co., had descended on his shoulders: but we discovered that he was not interested in curing consumption, or cancer, or syphilis, though he considered all of these and every other disease caused by animalcules. There was nothing of the no-cure no-pay system professed by him—he did not proclaim cancer or consumption curable, and fill his pockets under false pretences; neither did he profess to cure a parish or a city with the hundred thousandth part of a grain of bread crumb or magnesia, nor does he profess to cure incurable diseases. No! he does not belong to the genus: knaves and humbugs, the species of which acquire ill-gotten wealth by imposing on a credulous public, by professing to cure incurable diseases, or by basely imposing on the weakness of human nature, when overwhelmed with dangerous or fatal disease.

Dr. Green is evidently a man of principle; he is no miraculous curer. The notions, however, of our author, are second-hand, as Linnaeus and others have anticipated him. The proposition, that animalcules are the causes of all diseases is not new, neither is it true. Thus to imagine that animalcules are the cause of all continued and intermittent fevers, all contagious diseases, syphilis, plague, hydrophobia, small-pox, measles, hooping-cough, scarlatina, scurvy, iritis, calculus or stone in the bladder, ossification of the arteries, scirrhosity (qy. scirrhus) of glands, mesenteric disease, white swelling of the knee joint, gout, rheumatism, nervous diseases, cancer, caries of the teeth, &c. &c.; appears to us not only untenable, but perfect nonsense.

The author talks of curing consumption by inducing inflammation of the lungs, a method also praised by Dr. Ramadge in his "Consumption Curable." Ordinary practitioners are so stupid as to suppose, that inflammation of the lungs exasperates con-

sumption and accelerates death. This is the general, almost the universal opinion of the profession in all countries, but no doubt they are mistaken, as such eminent men as Green and Ramadge defend the opposite plan of treatment.

Dr. Green has, however, accumulated many assertions in support of his hypothesis. "*De gustibus nihil disputandum*," or as Sterne has translated it, there is no disputing about hobby horses; and we agree with Shandy, that our author has a right to ride his as he pleases. This little work will interest almost every general reader.

—o—

MANUAL OF OPERATIVE MEDICINE, BY M. MALGAIGNE.

FREELY TRANSLATED AND CONDENSED

BY GREVILLE JONES, Esq.

Lecturer on Anatomy and Physiology.

CHAPTER III.—OF THE LIGATURE OF MASSES,

KNOWN to the ancients for the removal of peduncular tumours, and in the operation for certain fistulæ; perfected and varied by Levret, advised by Arabetz for amputation, treated as a means of more general application by Mayor. This operation consists in constricting parts, either to divide them slowly, or to suspend the circulation and procure their separation by gangrene. The nature of the ligature has varied—silk, thread, pack-thread, or metallic thread, either of lead or silver; all these substances may be useful. The essential point is that the ligature should be smooth and strong. If it be of silk or thread, it should be rubbed with soap, to make it glide more easily.

There are three general rules with regard to the application of the ligature, which refer however only to those unions which are exposed to view. Such as are situated in deep cavities require especial methods, which we shall describe hereafter. The rules in question are—1, to choose a ligature sufficiently strong for the parts it is intended to embrace; 2, to embrace only a moderate thickness of tissue; 3, not to comprise the skin in the ligature. This should be cut and dissected away first, except when the peduncle is very narrow, or the skin ulcerated or diseased. We may tie also, without previous section, tumours of the mouth, fungi, polypi, &c.

When there is only a moderate thickness of the tissues to be divided, it may be surrounded with a ligature, and tied in any manner that may be judged expedient. When a conical tumour with a broad base is to be tied, and the thread slips towards the apex, it may be retained on the base either with

the fingers or by implanting in the bone the hooks of a pair of tenaculum-forceps*, until the stricture is effected.

When the peduncle is too large, a needle should be passed across it, armed with a double thread. The two portions of the thread are to be separated, and each peduncle tied separately.

When the base is extremely large, it may be requisite to tie it in several portions. For this purpose two large curved blunt-pointed needles may be threaded with the same thread passed through the tumour at separate points. Then the ends may be cut, turned round the tumour, and tied, or the same manœuvre may be effected by one needle only; it is requisite that after the needle has traversed the tumour from right to left, it should re-traverse it from left to right. The passage of the needles requires some caution. We should proceed slowly, guiding the needle at its entrance with the right forefinger, and assist its exit with the left forefinger. If the base touches on important organs, instead of passing the needles beneath the tumour they should traverse its substance. They should always be inserted on the most dangerous side, and brought out on the side where there is less to fear. With these precautions the vessels roll before the blunt point of the needles, and are very seldom wounded. If at any time hæmorrhage supervenes, the needle may be left in the wound as a plug, and a strong ligature applied behind it, and the tumour which gives rise to the bleeding strangulated.

The stricture effected by a ligature may be *definitive* or *progressive*. In the first we make with the two ends of a ligature, the first part of a knot, as tight as possible. An assistant secures this with the finger, while we add a second tie. After some days the incipient division of the tissues renders the ligature relaxed, and it becomes necessary to renew it twice, thrice, or four times. This procedure applies only to very small tumours†.

In the progressive stricture the surgeon is master of the ligature, to relax or tighten without changing it. It is effected by different modes of procedure, which vary only in respect to the instruments employed.

In one method the first tie is made with a bow, so that it may be tightened at will—the degree of stricture being represented by the force exerted by the surgeon's hands. The knot-tyers (*serre nœuds*) of Levret, Desault, &c. belong to this method, since they have no other use except to permit the ligature to be tied far from the handle, when that is placed in a deep situation. In a se-

cond method a *metallic* ligature is used. The ends are twisted to the requisite degree, and the torsion increased at intervals of a few days.

The third method is the *knot-tyer of Graefe*, imitated from the tourniquet of Petit. This is a steel rod perforated at its extremity by a hole, through which are passed the two halves of the noose previously applied. At the other extremity is a screw, which, when turned, moves a moveable nut, to which the ends of the ligature are firmly attached; a simple turn of the screw is sufficient to diminish or increase the stricture.

A fourth procedure is by the *knot-tyer of Roderic, modified by Mayor*. The *serre nœud* of Roderic is composed of small balls of wood, bone, horn, or ivory, two or three lines in diameter, traversed by a central canal. A greater or less number of them are added across their canal, the two ends of the ligature are passed so that they become strung like a necklace, and represent a moveable tube. The last is pierced with two holes, in order that when the ligature has cut into the constricted parts, it may not permit the little balls to escape; and the last has a similar disposition, in order that the knot of the ligature may be tied on the interval between the two holes.

M. Mayor complains that this tube is too flexible, and subject to turn and twist in every direction, when forcible constriction is applied. He therefore only employs the little balls for half the extent of the *serre nœud*, and he completes it by a metallic tube. To the end of this a small axle is fixed, which is imitated from the tourniquet of Percy. The two arms of the ligature are attached to this axle; and it may be conceived how, by giving this one or more turns, the constriction may be carried as far as necessary. Moreover, M. Mayor has rendered the extremity of the last ball almost a sharp edge, in order that it may play its part in cutting through the tissues.

Estimate of the value of these Methods.—If we wish to divide merely a lamina of skin, as in some fistulæ, the two first methods are preferable. If an energetic constriction be necessary, recourse may be had to the two others; but (without reference to the use of the balls, which may be had either way) the screw of Graefe appears to us easier to manage, simpler, and more powerful, than the tourniquet of Mayor.

The first effects of constriction are in general painful; afterwards the parts lose by degrees their sensibility with their life. If it is a part which we insulate entirely from the body in proportion as we tie the ligature, we see the part swell and acquire a livid tint. Other symptoms depend on the nature of the tissues. When the section is made slowly, the formation of the cicatrix commonly occupies a corresponding period. The following precautions are to be observed:—
1. To tie with precaution and slowness, ob-

* Pince à erigne.

† The incessant stricture adopted by Levret and Pelletan is mentioned, but with the confession that the instruments used cannot be depended upon.—T.

serving the effect upon the living parts, and also upon the ligature, which we must take care not to break. 2. If the tissue be soft, lax, and easily torn, complete strangulation must be avoided; too prompt a division may be followed by effusion of blood; the ligature should be tightened once or twice every day. 3. If the tissues be hard and difficult to penetrate, the first attempt at constriction should be carried as far as possible without breaking the ligature, and our efforts should be repeated twice a day. 4. If local inflammation, or uneasy nervous symptoms, come on, it is better not to increase the constriction, but even to relax it somewhat, until such accidents have ceased. 5. If at any time those accidents should be so alarming as to demand the prompt removal of the ligature, or even of the diseased part, instead of relaxing the thread, it is better to tighten it extremely, and excise the tumour on this side of it with a cutting instrument. Then we may tie with ease all the divided arteries, increasing or relaxing by turns the compression, in the same way as we would use a tourniquet in amputation of the limbs.

CHAPTER IV.—METHODS APPROPRIATED TO HINDERING THE EFFUSION OF BLOOD; OR, SURGICAL HEMOSTATICS.

Hæmorrhages are the most formidable accidents which are complicated with or follow operations. It is then of importance to know how to prevent them before operating, how to suspend them while operations are going on, and how to repress them definitively afterwards.

SECT. I. Methods employed previous to operating.—There are two methods of preventing hæmorrhage—compression of the arterial trunks, or their previous ligature. But the latter is a very complicated operation, and will be treated of hereafter.

Compression has for its object to flatten the artery, and thus, for the moment, efface its calibre. Hence, in order that compression should be exact, the necessity for these conditions: 1. that the artery should not be too deeply seated; 2. that it should rest upon a solid bony surface. When these conditions are absent, the whole limb must be compressed.

1. There are six modes of compression in general:—

1. *With the Fingers.*—We first find the artery, which is recognised by its pulsations, and choose the point at which we will compress it, and then apply the thumb or fingers on the vessel, observing the following rules:—1. The pressure ought to be made in a direction perpendicular to the osseous plane on which the artery rests. 2. If the thumb be made use of, it is to be applied across the vessel, and pressed downwards, as in using a seal. If the other fingers be made use of, an horizontal plane is formed by the union of their soft extremities. They are ar-

ranged along the course of the artery, so that the pressure is made by the four fingers together, while the thumb, placed on the opposite side of the limb, or on some salient point, furnishes a point d'appui. 3. The pressure ought to be as light as possible, sufficient only to efface the calibre of the artery—a very important rule, which cannot be broken without fatiguing oneself horribly, and even exposing oneself to relax the pressure; the fingers benumbed, and, as it were, paralyzed, no longer feeling the position nor the size of the artery. 4. The assistant who makes the compression ought to be placed so that he can see the operation without inconvenience to the operator, and without being inconvenienced himself. 5. If the fingers become tired during a long operation, the corresponding fingers of the other hand may be placed above them. If that does not suffice, a second assistant may press on the fingers of the first, or even may take his place, by compressing the vessel immediately above his fingers. 6. If, in consequence of any movement of the fingers, or of the patient, the obliteration of the vessel ceases, it is requisite promptly and firmly, instead of increasing the effort of compression, to re-establish it upon the axis of the vessel, and perpendicularly to the osseous plane, as before. 7. Compression ought to be continued until the application of definitive hæmostatic methods has taken place. If, at any time, the operator requires a jet of blood, to enable him to recognise the mouths of the vessels, the assistant has only to raise lightly the fingers, without quitting the artery, and re-apply them immediately.

2. *Pressure with a Pad.*—A pad, or merely a bandage rolled tightly, is placed upon the course of the vessel, and the fingers are pressed upon it. This has all the inconveniences of the former method of procedure, with the additional disadvantage of employing an instrument which does not feel the artery.

The pad, mounted on a handle, and applied as a seal, saves any fatigue; but it is liable to become displaced, and is calculated only for the subclavian artery, or perhaps the abdominal aorta.

3. *Pressure with the Garrot.*—This instrument is composed of a pad, a band, a plate of horn or tortoiseshell, and a small stick of horn or wood, furnished with a string at one end of it. The pad is placed on the artery, the plate on the opposite side of the limb. They are retained in their situations by the band, which is passed twice round the limb, and then tied in a knot on the plate. The little stick is pushed as far as its middle between this knot and the plate, and by turning it round, the band may be twisted on itself, so as to cause constriction of the whole limb on the bone, especially where the pad is situated. An assistant may hold the stick in its place, or it may be retained there by

tying its string to the band. This is one of the best means of compression. Its use, however, is confined to the middle parts of the limbs, and it has been objected to on account of its causing injury to the skin and preventing the retraction of the muscles. We have employed it much in Poland without finding it produce contusion of the skin. But we have met with the following inconveniences. It is difficult to relax and renew the compression quickly, when we wish by a spurt of blood to detect the mouths of the arteries; and its pressure being general, is exerted on the veins, so that the return of blood is prevented, a venous hæmorrhage from the stump ensues, ceasing however, when the garrot is quite taken away.

4. *Pressure by the Tourniquet of Petit.*—This is formed of two square plates, somewhat arched, the upper of which may be raised or depressed, by a screw fixed to the lower one. Under the concave surface of the latter is placed a small cushion covered with chamois leather. A free pad and a band affixed to the plates complete the apparatus. The plates being in opposition, the cushion attached to the lower one is placed on the course of the artery, the free pad on the opposite side of the limb, which is surrounded by the band moderately tightened; then the screw is turned, which by removing the two plates presses the lower one against the artery, and thus establishes sure and efficacious compression. The compressing cushion ought to be large enough to render its application over the artery easy, and to hinder the instrument from rocking over to one side. *Dupuytren* employed a troublesome and expensive instrument, which consisted chiefly in the substitution of a steel plate, curved so as to form two thirds of a circle, and divided in the middle in such a way that its two halves rode on each other, for the band of *Petit's* tourniquet*.

5. *Pressure by the Ligature en masse.*—This has been before described.

II. We shall now point out the *special methods of compression* applicable to particular arteries. The anatomical details which are wanting in this place will be found in the article on the ligature of arteries.

1. *Arteries of the Neck, Face, or Cranium.*—*The common Carotid.*—Easily felt under the skin, chiefly at its upper part, and resting on an osseous plane, it may be compressed with the fingers acting perpendicularly to the horizon. But this pressure is painful, on account of the neighbourhood of the trachea and larynx, and is rarely had recourse to.

The External Maxillary.—The easiest artery

in the body to compress; it may be compressed with one finger upon the edge of the lower jaw-bone, in front of the insertion of the masseter muscle.

The Temporal Artery.—In front of the external ear, two lines from the front of the tragus, its perpendicular compression is very easy. All the other arteries of this region escape pressure, or are so small that it is useless. If a wound of the arteries of the skull should give rise to hæmorrhage, it would be much more rational to compress the wound itself, than the small arterial trunks, on account of their numerous anastomoses.

2. *Arteries of the Upper Extremity.*—*The Subclavian Artery.*—*Camper* proposed to compress this with the thumb on the first rib in the omo-clavicular hollow. But on account of the rising of the clavicle the thumb cannot penetrate sufficiently deep, and moreover, this compression would be very fatiguing. It is usual, therefore, to have recourse to a pad attached to a handle. But the security of the pressure here being subordinate to the movements of the clavicle and shoulder, is not to be depended on; and it is nearly given up. We believe, nevertheless, without trusting to it entirely, that it is useful to have recourse to it only as a supplementary means.

The Axillary Artery under the Clavicle.—*Dalh* proposed to compress this artery on the second or third rib. The fingers not being able to effect this, on account of the thickness of the muscles, he invented a particular tourniquet. This compression, difficult and uncertain, is justly abandoned*. *The same in the Axilla.* The artery is easily flattened against the head of the humerus. The pressure is made with the four fingers, either alone or furnished with a pad. It should be remembered that the artery is situated at the union of the anterior with the middle third of the axilla.

The Humeral Artery.—Immediately under the skin, and coasting the inner edge of the biceps, it may be compressed throughout its whole extent with the thumb and four fingers, or with any kind of tourniquet. Care must be taken to make the pressure in a perpendicular direction. *The Radial Artery* is easily compressed at the inferior third of the arm, between the radius and tendon of the palmaris longus, in the situation where the pulse is felt. It is rarely employed. *The Ulnar Artery* may be commanded by pressing the flexor ulnaris against the ulna. This is less employed than the operation just mentioned. *The Collateral Digital Arteries* may be compressed in their whole length at the union of their anterior surfaces with their sides.

* The object of this was of course to exert pressure upon the course of the artery, and the opposite part of the limb, without compressing all its surface.—T.

* One cannot help feeling much surprised at this observation. Cannot any one command the pulse of his own wrist by pressing the subclavian artery on the rib?—T.

3. Arteries of the Trunk.—The Abdominal Artery.—This may be compressed with success upon the lumbar vertebræ, chiefly in thin subjects, by placing them in such a position as to relax the abdominal muscles, and pressing them strongly with the thumb or fingers, or (what is still better) with a pad applied transversely over the course of the artery. We may thus correct uterine hæmorrhages, or gain time to tie the iliac arteries, when injured.

The Dorsalis Penis.—This is easily compressible at the base of the penis, with the fore finger placed below and the thumb pressing from above.

4. Arteries of the Inferior Extremity.—The External Iliac.—It is compressible through the walls of the abdomen, against the edge of the upper opening of the pelvis. The pressure should be directed somewhat obliquely outwards; but it should only be employed when we are unable to compress the vessel lower down. The *femoral artery* may be compressed on the pubis by the thumb, alone or furnished with a pad, against the ilio-pectineal eminence. It should be remembered that this eminence is inclined forwards and downwards at a variable angle. Hence the pressure should fall somewhat obliquely on the artery downwards and backwards, forming with the horizon an angle of 45 deg. The compressor of M. Dupuytren may also be employed, and even the tourniquet of Petit, with some precautions. Compression on the pubis is sure, easy, and much employed. The same artery may be compressed *as far as the lower third of the limb*, by pressing it against the femur with the fingers, tourniquet, compressor, &c. Care should be taken that whatever means we use should flatten the artery against the bone. The *popliteal artery* may be compressed opposite the articulation, with the fingers or tourniquet; the latter is preferable, on account of the mass of cellular tissue which surrounds the artery. The pressure should be directed from behind forwards. But it is seldom employed in this situation.

SECT. II. HEMOSTATIC PROCEDURES DURING THE OPERATION.

During an operation we have to contend with arterial and venous hæmorrhage. We employ—1. *Direct compression*, which consists in applying the fingers on the mouths of all bleeding vessels, until we proceed to the arterial trunk, or until the operation is finished. 2. By *indirect pressure*, used chiefly in flap operations; here the flap is compressed between the thumb and finger. 3. By *ligature*, which is the same as the method used after the operation, except when, before operating, the great vessels are secured—a mode by which all hæmorrhage is effectually prevented. Pressure during an operation is usually entrusted to assistants.

These methods are applicable to veins as

well as arteries. But we must add that venous hæmorrhages arise from two important causes. 1st. A mechanical impediment to the return of blood towards the heart, as when we use the tourniquet; but hæmorrhage from this cause is immediately stopped when we remove the instrument. 2nd. Violent struggles of the patient, which hinder the passage of blood through the lungs, and cause it to flow back into the venæ cavæ and their branches. This happens especially in operations performed about the neck. It is to be remedied by making the patient inspire deeply, and cease from struggling. Frequently two deep inspirations have proved sufficient to arrest an hæmorrhage which had appeared irrestrainable.

SECT. III. HEMOSTATIC METHODS OF PROCEEDING AFTER OPERATIONS.

Blood may flow after an operation, from the capillary vessels, from the veins, or from the arteries.

I. Capillary Hæmorrhages.—The capillary vessels usually cease to bleed soon after the division, in consequence of the pressure exerted upon them by the retraction of the tissues in which they lie. But in some subjects, whether owing to idiosyncrasy or some morbid diathesis, the blood continues to exude; and, frequently after the hæmorrhage has ceased, and the dressings have been applied for some hours, it will re-appear.

When this occurs, the dressings, if they have been already applied, must be removed; the wound is to be sponged with cold water, which should be squeezed out at some height above it. The bleeding surface should then be left exposed to the air for from half an hour to five or six hours. In the interim we may examine if any uneasiness be produced by the position of the limb, or if any plethora exists which may require bleeding.

Exposure to the air failing, recourse is to be had to the various kinds of styptics known under the names of refrigerants, absorbents, and astringents. The first consist of cold water, wet compresses, ice, evaporating lotions of alcohol and water, or ether and water, or, the most powerful we are acquainted with, powdered camphor placed between two wet rags, and moistened as fast as it evaporates. The second of charpie, sponge, the agaric of the oak—which is to be preferred—or of cobweb, still more powerful; or of substances in the pulverized state, as powdered gum arabic, the fibrine of the blood dried and powdered, or resin. These powders are dusted on the wound, or upon balls of charpie. The astringent styptics are used in powder, as alum; or, in a liquid state, as solutions of sulphate of iron, of sulphate of copper, of alum, of nitrate of silver, vinegar and water, lemon juice, Rabel's water, and the more recent, and at present secret compositions, of Talrich, Binelli, &c.

Caustics have been applied to restrain this

sort of hæmorrhage, only in two instances; the nitrate of silver has been used for leech bites; and the sulphuric acid, applied through a speculum to the neck of the womb, after the excision of that part.

The actual cautery must be submitted to more rigorous rules. Experience shows, 1st. That when the iron is half hot, either from having been permitted to cool, or from being quenched by blood, it adheres to the eschar and brings it away, and the blood continues to flow; 2ndly. That the same adhesion between the cautery and the eschar takes place when the former is applied too long to the wound; 3rdly. That when the eschar is thin it falls off very soon, and the hæmorrhage recommences. Hence these essential conditions—that the cautery should be of a white heat, applied quickly, removed before its redness has gone off; that the surface of the wound should be perfectly cleansed of blood and other fluids at the time the application is made; and that the eschar should be sufficiently thick. If, therefore, the first cautery should only have operated superficially, we may apply a second, observing the same rules*.

—
Erratum in our last Number.

At page 733, sect. 1, 2nd column, 23rd line from top, after “ammoniocal pomatum” add an asterisk, as all the note from the words “This preparation” refer to this part; and, in the note, *for* Cyndrett, *read* Gondret, and *for* laves, *read* leaves.

—o—
MEDICAL BOTANY.

IN illustrating the important subject of Medical Botany, we select the most important articles, in alphabetical order, and follow the plan of our best writers on *Materia Medica*. We this week give a plate of the *Aloe Socotorina*, with the natural history and medicinal uses of that valuable medicine.

Plate 2.—*ALOE SOCOTORINA*.

This species is a native of the Cape of Good Hope. It is allowed by De Candolle to yield the best aloes; and Thunberg, upon whose authority this is stated, tells us, that the Hottentots cut off the leaves and arrange them so that the lower serves as a gutter to conduct the juice into a calabash, which is then brought near a fire, and the liquor reduced to one-half. It is prepared at all seasons; but after the rains, the leaves, which in general yield little juice, furnish it more abundantly, but of a weaker quality, and containing less extract.

* I insert these remarks because they are in the original, but I do not believe that any French surgeon at present would apply the actual cautery to a capillary hæmorrhage.—T.

The leaves of every species are collected and bruised, with the addition of water. The expressed pulp is then boiled in water, and the filtered and decanted decoction mixed with the expressed juice. The whole is then heated, which separates the parenchyme. It is again filtered, boiled down to a proper consistence, and poured into coolers while still warm. The upper layer is separated, as being of the first quality, or, as he calls it, *aloes citrin*; the middle layer is the hepatic, or *aloes jaune*; while the bottom is the caballin, or *aloes noir*. We do not, however, think that the genuine sorts can be procured in this way, which would not account for the great difference in smell and taste. It may, however, furnish varieties, sold each under the names of that genuine variety which it resembles in appearance.

Socotorine aloes, which is the most esteemed, is brought, wrapped in skins, from the island of Socotora in the Indian Ocean. It is dark coloured, of a glossy clear surface, and in some degree pellucid; in masses of a yellowish-red colour, with a purple cast; fracture unequal; easily pulverizable; when reduced to powder of a bright golden colour. It is hard and friable in the winter, somewhat plastic in summer, and growing soft between the fingers. Its taste is bitter and disagreeable, though accompanied with some aromatic flavour; the smell is not very unpleasant, and somewhat resembles that of myrrh. It does not produce hæmorrhoidal affections so readily as Barbadoes aloes.

Med. use.—Aloes in doses of two grains or less, is a stomachic, and with this intention is an ingredient of the various *Pilule ante cibum*. In larger doses it acts as a purgative, but its operation is tardy, first manifesting itself eight or twelve hours after it has been taken. It is therefore frequently given at bedtime. It also acts in a small dose, and hence is conveniently given in pills, which obviates the bitter taste. Wedekind thinks that its primary action is not upon the intestines, but upon the liver; and hence it is to be used whenever we wish to increase the secretion of bile, and correct the atony of the liver. It is particularly useful to persons who lead a sedentary life.

Aloes is a bitter stimulating purgative, exerting its action chiefly on the rectum. In doses of from 5 to 15 grains it empties the large intestines, without making the stools thin; and likewise warms the habit, quickens the circulation, and promotes the uterine and hæmorrhoidal fluxes. If given in so large a dose as to purge effectually, it often occasions an irritation about the anus, and sometimes a discharge of blood.

It is frequently employed in cases of suppression of the menses, or of the hæmorrhoidal discharge; but it is particularly serviceable in habitual costiveness, to persons of a phlegmatic temperament and sedentary life,

and where the stomach is oppressed and weakened. For its use in typhus fever, scarlatina, cynanche maligna, marasmus, chlorosis, hæmatemesis, chorea, hysteria, and tetanus, Dr. Hamilton's excellent work on Purgatives may be consulted. Aloes is also used as an anthelmintic, both given internally and applied to the abdomen in the form of a plaster. Dissolved in alcohol, it is employed to check hæmorrhagies in recent wounds, and as a detergent in ulcers.

From its warmth and activity it is accused of causing colic pain, bloody stools, and other hæmorrhagies, and has been proscribed in persons of a plethoric, nervous and dry habit of body, in pregnant women, and in fevers and inflammations generally, yet it is often given in these with advantage.

Aloes is administered either,

a. Alone, or

b. In composition : with purgatives, as soap, scammony, colocynth, rhubarb ; with aromatics, as canella ; with bitters, as gentian ; with tonics, as iron, myrrh ; with fetids, as assafœtida.

It is exhibited in the form of

a. Powder ; too nauseous for general use.

b. Pill ; the most convenient form.

c. Solution in water, wine, or diluted alcohol.

Dose.—The effect of aloes is by no means proportioned to its dose, so that a few grains operate nearly as well as several times the number. Five, ten, or fifteen grains may be given in a single dose as a purgative, but against a costive habit two or three grains daily will generally suffice. Corresponding quantities may be given in solution, and the action is more speedy. Some foreign therapeutists assert, but connected with a hypothesis as to its mode of action, that aloes has absolutely no effect when thrown into the rectum as a clyster.

The London Medical

AND

Surgical Journal.

Saturday, July 25th, 1835.

—

NOTHING OF A LEADER.

THE use of leaders, we conceive, is to lead people by the nose ; but the difficulty is to find *strings*, for the journalist who had *hands* enough to do the public this service had need to be an infinitely improved development of Briareus : we are accordingly often

obliged to spin long *yarns* out of rather deficient materials. We are at the present moment in this embarrassing predicament ; we have nothing to say. Things are really monstrous dull !

Warburton's reform is out of breath, and is lying down to rest itself, and the parliamentary evidence has become a drug—every body is dead of it. We have reduced all inimical journals to fragments, and chaunted their dirge—like Faust's devils

Wir tragen

Die trümmern in's nichts hinüber,

Und klagen

Ueber die verlorne schöne.

or, as A. Hayward Esq. judiciously renders it—

We bear away

The wrecks into nothingness,

And wail over

The beauty that is lost.

Our numerous friends and correspondents are all either deceased or struck modest—at least we hear nothing of them. In short we are fairly aground waiting for the tide.

—“fere sicco subductæ litore puppes”
(puppies).

Were it not for a delightful facility which we possess of writing about nothing, the Original London Medical and Surgical Journal would this week be leaderless—thereby occasioning a breach in nature.

We first acquired this knack in order to confute the twaddle of *ex nihilo nihil*, when we were engaged in composing a new system of the universe ; but we have since found it of excellent service on more occasions than one.

The substantialists may talk how they like, but *oudenology*, so we shall name it, is a very important branch of science—without its aid, some of the most celebrated medical works of the day would collapse into atoms !

—o—

WE are not sorry to find that Mr. Andrews has been elected President of the College of Surgeons. The conduct of

this gentleman, as surgeon to the London Hospital, has evinced a straightforwardness, and aversion to humbug, which inclines us to hope that the influence with which his new office may invest him, will be exerted for the correction of abuses, and the good of the profession.

We would exhort him on his inauguration, as the King is exhorted when he is crowned, to take good care of the people committed to his charge—that is of the *subordinates*—he need not to trouble his head about the council, who know very well how to take care of themselves.

By his *charge*, also, we beg him to understand, we do not mean the charge of two-and-twenty pounds sterling for a diploma—the latter is in no danger of being neglected.

—o—

We understand that the reading room about to be opened for the use of the members of the College of Surgeons is to be lined with iron, as a safeguard against fire—a judicious precaution. We have heard it hinted that the senate have been moved to this by the apprehension, that the members may come in the evening in a state of ebriety, and with cigars in their mouths, thus placing the edifice in danger from the “devouring element”—for our own part we think the college is in more danger of being devoured by the council itself, than by anything else. While on the subject of metals, we may suggest that the *council chamber* might, with considerable propriety, be lined with *brass*—it would not be expensive, as the council are well known to be very rich in that commodity.

—o—

THE EVILS OF DISPENSARIES DEVELOPED.

To the Editor of the London Medical and Surgical Journal.

SIR—The ability and ardour with which you advocate the interests of the medical profession, entitle you to the general confidence

thereof; and being thus impressed, I address you under the conviction that you will neither turn a deaf or fastidious ear towards an object at once important to humanity and medical men, as both have suffered to an incredible extent, by false views and selfishness, to be hereafter detailed. Let me here call your attention to the dispensary system—a system frequently injurious to the poor, as at these institutions the needy are deluded by hopes of relief, not to be obtained thereat, and medicine is thereby degraded and injured. Under any state of the profession, these establishments must be highly injurious; but in its present depressed condition, they inflict much evil on the medical man and his family. In proof of this proposition, let me here call your attention to the immense sums raised by voluntary subscription within the circle claimed by the College of Physicians as their province of inspection, and we shall then see the great injury inflicted by these institutions. If we state the sum annually raised to secure medical exertions, within the circle just adverted to, at one hundred thousand pounds, such a calculation will be under the mark, but of which revenue the medical man receives not one fraction; and what is still more extraordinary, these gratuitous exertions on the side of the physicians and surgeons, instead of contributing towards the advancement of their professional fame, are often injurious to it. This is not surprising to those who know the vast numbers who subscribe to these institutions on selfish motives, and who also, on similar principles, mingle in the management of the affairs of a parish, as from these two sources, namely—gratuitous medical assistance, and the poor rate—they are enabled to secure the payment of rents by their tenants, which would not otherwise be obtained. The dispensaries perform the duties of the parish surgeon to a great extent, and therefore no medical man should be allowed to unite the offices of a dispensary and parish medical officer, for reasons that are obvious. The dispensaries, as at present constituted, are an absolute nuisance, and, as observed, singularly injurious to the poor, because not admitting them to immediate relief when labouring under disease; and these institutions also assuredly subtract from the just claims and respectability of medical men who are regularly educated. Your exertions and admonitions have produced the most beneficial effects, in many ways, to the cause of humanity—but these admonitions, so clearly and fervently demonstrating the incalculable mischiefs arising out of such institutions to medical men and their families, have not been duly attended to. A meeting, therefore, of the profession on the subject of dispensaries, would be of admirable utility at the present juncture, as it would bring this system, so vile, in many of its parts, under the eye of the profession, and the nation at large. The receiving rooms of

Hospitals and dispensaries, into which diseases of a highly contagious nature are daily admitted, become the sources of direful evil to the community, because from thence, as from a centre, infectious maladies of a most inveterate character are diffused over every part of the nation where they exist, and thus they become the sources of great expense and tragical events, as the consequence of domestics conveying these fatal diseases to the highest circles. The history of dispensaries, from which medical men, as well as the poor, suffer most severely, would excite the astonishment and indignation of every generous mind, as the medicines dispensed thereat are often of bad quality, and generally carelessly compounded—seldom does it happen that the prescriptions of the physician or surgeon are made up as prescribed. In defiance of all your exhortations, these institutions, lamentable to behold, still continue to be sought after by medical men, to their own degradation. Those frequenting dispensaries for relief may be divided into three classes. Firstly, those actually poor; secondly, the dependents and servants of wealthy and noble personages; thirdly, those who take an improper advantage, under varied pretexts, of those institutions, rather than pay for medical assistance. In placing the above imperfect outline under your consideration, there is certainly nothing in its character which ought to induce medical men to gratuitously devote their capital—which their professional talents are to be considered—to such institutions, because on every principle of justice they ought to be rewarded for their services. Indeed, it is the duty of the governors, if honest men, to insist on such a measure being adopted—the paupers ought to be paid for by the parish, which arrangement would be useful to some member of the profession—the rich ought to pay for the medical assistance given to their friends, dependents, and servants, and the industrious man should contribute according to his means, for the relief given to him, when labouring under disease. Does the lawyer or the clergyman give assistance gratuitously to either poor or rich? Does the grocer, the baker, the brewer, the butcher, apply his goods to the support of those institutions? Certainly not; because they are well aware that if they were to do so, they would be considered as disgracefully inattentive to the interests of their families, if not maniacs. Medical men are at once the foundation and sources of utility of these institutions, so that they are to be regarded as labouring to their own injury, as the patients cured thereat yield no remuneration for the services conferred on them. It is truly lamentable to observe people of wealth assuming the mask of liberality, generosity, and charity, by subscribing to these institutions under the ostensible pretence of serving the poor, when in reality they have no other object in view, but that of benefitting themselves

by obtaining medical assistance for their relations, servants, and dependents, for whose relief they ought to pay; and in not doing so, they subject themselves to the imputation of hypocrisy and extreme meanness. Dukes, duchesses, marquises, earls, marchionesses, barons, lords, ladies, baronets, and men of wealth, pass before the eyes of medical men at these institutions, as portrayed through their valets, butlers, poor relations, dependants, and ladies' maids. It is a duty which medical men owe to themselves and their families, to insist, at the expiration of each year, on a certain portion of the funds of these institutions being devoted to their remuneration, instead of accumulating in the hands of bankers, and being often applied to unworthy purposes; and should a demand so reasonable be refused by the governors, the medical men should instantly resign their situations, and commence an establishment under their own guidance and authority. By such an arrangement at their own abodes, medical men would be enabled to accommodate their charges to the circumstances of their patients, and thereby become the friends of industry and independence of mind; and by thus divesting themselves of undue selfishness, they would be regarded with gratitude and esteem by rich and poor.—I have the honour to be, Sir, your obedient humble servant,

INDUSTRIÆ AMICUS.

July 20th, 1835.

—o—

Summary of Orfila's Observations on the changes which occur in the Tissues of Dead Bodies after Interment. Appended to Sédillot's Manuel de Médecine Légale. Translated from the French, for this Journal.

(Continued from p. 760.)

THE various colorations of the gastro-enteric mucous membrane exist in middle-aged as well as in old persons, though they are less numerous in the former. If the individual has died suddenly during the process of digestion, of a disease not affecting the intestinal canal, the inner coat of the stomach is usually of a rose colour, while that of the intestines is gray, ash-coloured, or white, with or without yellow patches. The coloration of the inner surface of the alimentary tube may, on the other hand, be deeper and more varied, if death has not occurred during digestion, and has not been sudden, although the disease has not been of a nature to alter directly the tissues of the stomach and intestines.

We will conclude this rapid sketch of the different states in which the intestinal canal may be found previous to inhumation, by some remarks on the cadaveric lividities of this canal. It is well known that red, livid, or black spots, large and irregular, resembling those seen on the skin of dead bodies

are not unfrequently found under the serous membrane in the tissue of the part: these patches occupy the part of the digestive tube which was most dependent when the body grew cold; they arise merely from the stagnation of the blood and its accumulation in the capillaries, and are not to be regarded as traces of inflammation. The two following observations will place this fact beyond a doubt.

1. On opening the abdomen of a person who died suddenly of apoplexy, and who, a short time before, was in perfect health, it was found that all the convolutions of the intestines which occupied a superior position, as also the portion of the stomach that was visible, were remarkably pale: no redness was perceptible, except in the most depending part of each convolution, and the venous congestion was nowhere so great as in the portion of the ilium contained within the pelvis. The mucous membranes of the stomach and bladder were red at their most depending part. *The body had remained in the supine position: the dissection was made twenty-four hours after death.*

2. The body of a young soldier, who had died of acute pneumonia after a short illness, was placed on its belly immediately after death, and kept in this position till the dissection, which took place on the following day. The cadaveric lividities of the skin appeared on the face, chest, belly, and anterior part of the limbs; those portions of the stomach and small intestine which were in contact with the parietes of the abdomen presented the tints of rose, red, and violet, usually observed in the intestinal convolutions which occupy the pelvis and the sides of the vertebral column, while the latter parts and the posterior portion of the stomach and bladder were exceedingly pale. (Trousseau, *Dissertation Inaugurale*. Paris, 1825).

Let us now proceed to describe the different states of the alimentary canal which we have observed in bodies disinterred a longer or a shorter time after inhumation. What has been already stated demonstrates the difficulty, not to say the impossibility, of determining that the colorations, and even the ramollissemens, of which we are about to speak, have arisen after inhumation, because we know that they occur in dead bodies before they are interred: we shall also confine ourselves to a description of what we have seen, without pretending to establish, with reference at least to the stomach and intestines, what may be the necessary effect of long inhumation.

The mucous membrane of the *mouth, velum palati*, and *tongue*, are at first green and evidently softened; the colour progressively deepens till it becomes black: all these parts dry up, and at the expiration of some months we find, in the place of the tongue, nothing but a very thin and dry membranous appendage.

In the early periods the lining membrane of the *œsophagus* was of a green colour, more or less intense, especially at its upper part; for, at the lower, it pretty soon assumed a reddish colour: sometimes, also, the green of the upper portion were spotted with red and violet. In some old persons we have found, in the interior of this musculo-membranous canal, a number of small varicose tumours, filled with black fluid blood; this was evidently not a cadaveric change, but a morbid lesion. At a more advanced period, the *œsophagus* became browner and browner, and was destroyed in the same manner as the stomach, of which we are about to speak.

Stomach.—This viscus generally contained only a very small quantity of fluid. At first its mucous membrane was yellowish, of a rosy colour, grayish, blueish gray, or bottle green; occasionally these tints were spotted with red and violet; near the pylorus it usually presented a blueish patch of larger or smaller size, more deeply coloured than the rest. Later than this, it was raised at certain points by bubbles of gas of the size of a pin's head, or something larger. By this time it had acquired a rosy colour, which afterwards changed to a violet red, and it was lined with a thin coating of a bistre, or diluted mud coloured liquid.

At a still more advanced period it was of a whitish gray, with numerous blue spots, but without any appearance of redness; the stomach having already become considerably softened, underwent a rapid change, and soon after only part of it was to be found, resembling a portion of a hollow cylinder: it was next reduced to a dry laminated mass, separable into coralliform filaments; and finally into a black humid matter, like the grease of a cart wheel, covered here and there with small globules of white or greenish mould, and with patches much resembling the lichens found on the trunks of old trees. Several months after inhumation, the three coats of the stomach might still be separated; the muscular and serous, did not always present the same colours as the mucous; at first they were generally of a grayish or yellowish tint, then rosy, and lastly grayish: the parts of the serous membrane in contact with the liver and spleen, were occasionally reddish, especially at an early period.

Intestines.—The intestines were at first of a gray colour; sometimes slightly reddish externally, and grayish internally; in some cases, however, the mucous coat was rosy or violet coloured in certain parts, and yellowish where it was tinged with excrementitious matter. Later than this the intestines diminished in thickness; they began to dry up and adhere to each other, they then became brown and still further desiccated, and their parietes were gradually more and more incorporated, so that they could hardly be disunited: they thus formed a mass closely

applied to the vertebral column; the fecal matter was for a long time distinguishable; finally the intestines underwent the same changes, and the same destruction as the stomach.

We will inquire elsewhere whether the changes induced by putrefaction in the intestinal canal, are liable to be confounded with the effects of inflammation; suffice it to observe, at present, that long after death, when all traces of the thoracic viscera have disappeared, some cylindrical portions of the intestinal tube are generally to be found, in the cavity of which it might be possible to detect the remains of a poisonous substance.

Epiploa.—The epiploa and the mesentery at first become of a rosy or gray colour, and are softened; soon after they lose their flexibility, and have a tendency to be converted into adipocere: after this they remain for a long time without undergoing any remarkable alteration.

Liver.—The changes in the liver commence with softening and the conversion of its colour to a deeper brown. The peritoneal covering is easily detached, and is soon partially destroyed. In a few weeks the natural structure of the liver can no longer be recognised; the two substances of which it is composed are no longer to be detected; but the great vessels are still easily distinguishable, and are often lined internally with a sanies of a deep wine-lee colour. At a later period, sandy granulations of phosphate of lime are found on the surface of the liver, and in some instances soft white granulations, evidently composed of adipocere, are discovered in the interior of the vessels. Still later, the liver is reduced to a flattened mass, about half an inch thick, of a blackish brown colour, slightly desiccated, and which, on being incised, is divisible into layers, between which there is a solid, brown, bituminous-looking matter; this mass, flattening more and more, finally becomes black, coralliform, and separable with the smallest effort. Sometimes, instead of undergoing this desiccation, the liver is converted into a soft blackish matter, resembling the grease of a cart wheel—a kind of *bouillie*—in the midst of which a yellow matter, of a fatty appearance, is discovered.

Gall Bladder.—This organ is found to preserve its natural appearance at a time when the liver has undergone considerable changes; it is empty, or contains bile of a thick consistence, and olive green colour.

Spleen.—This very soon becomes soft, and easily lacerable; it grows more and more brown, and its natural texture is speedily lost: soon after it is reduced to a blackish pulp, like the grease of a wheel, or the mud of a gutter, and this impregnates the neighbouring parts, and communicates its colour

to them. Finally, it often becomes quite fluid, resembling decomposed blood, and is no longer to be recognised but by its situation.

Pancreas.—The earliest change undergone by this organ is softening, it then becomes of a grayer colour, and is eventually transformed into a pulp, at first grayish, but gradually assuming more and more of a brown.

Urinary Organs.—The kidneys do not soften so quickly as the spleen; they, however, soon lose their consistence, and their investing membrane is easily detached. The pelvis and infundibula are easily to be recognised after the cortical and tubular substance have ceased to be distinguishable. Finally, these organs are converted into a brownish pulp, and disappear.

The bladder undergoes no remarkable alteration for several weeks; sometimes, however, air is disengaged under the mucous coat. At a more advanced period it contracts, and exhibits nearly the same changes as the intestines: traces of the latter, however, are often found when the bladder has entirely disappeared; this arises from its vicinity to the anus.

Genital Organs.—At an early period these organs, though softened, preserved their shape; the corpora cavernosa soon became collapsed. Later than this the penis is flattened, resembles an eel skin, and has quite lost its natural appearance. The scrotum, which at first is sometimes excessively distended with air, gradually dries up; the testicles diminish in volume, acquire a wine-colour, and are transformed into fat. Still later, the penis resembles a tube of a firm consistence, whose parietes are in contact, and being separated, give it the form of a hollow cylinder. By this time the scrotum and testicles are replaced by a soft, brown, moist substance, presenting here and there membranous layers, and covered with a viscous blackish envelope, and by many worms. At a still later period the destruction of the genital organs is complete, and the sex can no longer be distinguished by inspecting them, although the pubis is still covered with hair, which is matted together with the foliated and carbonaceous mass to which the soft parts have been reduced. In the female, the external organs of generation after being softened, are converted into a shapeless foliated mass, by which the sex can no longer be discriminated. The uterus also becomes soft; it is flattened, and so altered in its form, that by the end of a few months it is only recognized by its situation. The fallopian tubes and the ovaries disappear pretty early; the broad ligaments offer greater resistance to putrefaction, and assume a grayish colour.

(To be continued).

Hospital Reports.

ST. GEORGE'S HOSPITAL.

*Fatty Tumours; Removal of Two by Operation;
Clinical Observations on.*

SIR BENJAMIN BRODIE lately removed two fatty tumours, one of them from a male, and the other from a female patient, both of which were seated over the shoulder.

After the patients had left the operating theatre, Sir B. Brodie observed that there were several distinct kinds of fatty tumours, and of the first form he should mention, both those now removed were examples. They consist of collections of fat not precisely like that of the healthy adipose tissue, but of a finer and more delicately granular kind, and enveloped in a strong capsule of membrane, which forms distinct cavities for different portions of the fat, so as to give the tumours lobulated appearance*. The contained fat adheres closely to the parietes of its capsule, but the latter possesses but a lax connexion with the surrounding skin and other structures, through the medium of a delicate cellular tissue. This is the case particularly during the early period of the growth of the tumour, and pervades its entire surface, except at one point, where the principal nutritious vessels of the tumour enter. This form of fatty tumour I believe only to occur in such parts as naturally possess a quantity of healthy fat; thus I have never known it occur in the penis, scrotum, or prepuce, whilst it is common about the neck.

Occasionally I have known this variety of tumour to be ascribed to an injury; thus in two cases they were noticed to commence after blows on the part, and when first discovered were not larger than walnuts, but gradually increased to a very considerable size. These tumours do not occasion any pain, nor other inconvenience, save that arising from their bulk. They ought, however, when large, to be removed by the knife, as they are liable to undergo changes highly detrimental to health. Thus they may become the seat of inflammatory action, an abscess may form in their centre, discharging pus mingled with an oily fluid, which often operates as a severe drain on the constitutional powers, and proves a source of great general irritation. In other cases, I have known them undergo a malignant degeneration, and assume the character of medullary sarcoma, which may again become a bleeding fungating ulcer.

The only effectual mode of treatment is to remove them with the knife, which is readily accomplished in the following manner:—An incision should be made through the integuments into the substance of the tumour, and then the line of separation be-

tween the skin and the capsule made out; and by commencing at this point, the tumour may almost be turned out by the finger and thumb, or by the handle of the scalpel, requiring only the actual use of the knife at the point where the vessels enter. A little bleeding will occur on their division, and it is generally advisable to employ a ligature or two. Care should be taken to remove the whole of the disease, which is readily effected by conducting the dissection externally to the cyst. Should, however, a nodule or two remain after the removal of the mass of tumour, they must be taken away, or the tumour is very liable to return. This, you would observe, I found necessary in the operation which I just performed.

In the next form of fatty tumour, the structure of which it is composed does not differ much from the surrounding healthy and normal adipose tissue, and as it is not contained in a regular capsule, the line of demarcation between the tumour and the fat in which it is formed is scarcely distinguishable. The fat of which such tumours are composed, is, however, on the whole, somewhat denser, and of closer texture than healthy fat†. I have seen one case in which a tumour of this kind involved very extensively the neck and shoulders, producing great deformity, and from this cause, unfitting the patient for his employment, as servant in a gentleman's family. In a case of this description, the use of the knife is out of the question, and I, therefore, gave a trial to the internal use of the liquor potassæ, and I was greatly gratified by the tumour entirely disappearing under its use. In another case, after the tumour had partly yielded to the liquor potassæ, without any general emaciation having been produced, I changed the remedy for the iodine, then first coming into notice; but under its employment, the patient became emaciated, and the tumour became larger, rather than the contrary; I therefore left it off, and returned to the potassa, which was speedily successful in ridding the patient of the disease. I regard this variety of the tumour to be completely under the control of this remedy, given in large doses; as, for instance, one drachm three times a day. I find beer a very good vehicle for its administration.

There is another form of fatty tumour, not obtaining a large size, but which is found to occupy every part of the body, in such numbers as to preclude the idea of extirpation. These, likewise, yield to the use of the caustic alkali, and are thus entirely got rid of. In one case of this kind, I requested Mr. Cutler to remove one of the tumours, and it was found to consist of a harder and more granular tissue than healthy adipose.

The fourth and last form of fatty tumour with which I am acquainted, is very uncommon.

* The encysted steatomatous tumour of Abernethy.

† The adipose sarcoma of Abernethy.—

mon; in extensive practice it may perhaps be met with once in fifteen or twenty years; its peculiarity consists in being of a regular conical or ovoid form, and in being complicated by the presence of an adventitious serous cyst, which surrounds the tumour just as the tunica vaginalis does the testicle. The only remedy for this variety of tumour, I believe to be extirpation.

NORTH LONDON HOSPITAL.

*Clinical Remarks on a Case of Irritable Stump.
Amputation by Mr. Liston.*

GENTLEMEN—The changes which occur in a stump are the following:—It shrinks more or less, there being absorption of the muscle; and, frequently, when the bone is not well covered, or only covered by a thin pellicle of skin, it becomes quite conical, from the same process going on; the vessels become smaller, impervious, and like cords. In order to allow the integument to move well over the bones, nature often forms the cellular tissue into a bursa mucosa. These are the changes taking place when the bone is well covered, when otherwise, necrosis may occur; indeed, in badly performed operations, it often happens that sequestra of three or four inches are found. I need scarcely say such a circumstance is not creditable to the surgeon who performed the operation. The extremities of the nerves do not, however, shrink in this way, but they frequently enlarge, sometimes to a very great extent, causing intense pain and irritation. I once performed the operation of amputating a stump on a man who had three times before submitted to the knife, but who suffered from these neuralgic pains, arising from the pressure of the nerve against the bone: this was the case with the man, Daly, whom I operated on the other day; but in addition to this pressure, the bone had become adherent to the cicatrix. The history of the case is interesting. He was admitted June 30th; about four years since his hand was severely lacerated by a stone falling on it. He was immediately removed to one of the hospitals, which he left in about four months after, with his hand in a very bad state. He had subsequently been under the care of several surgeons, the last of whom amputated the limb about three years and a half ago; the stump was a long time in healing, and since then he has suffered at all the vicissitudes of the weather; his pains were so great on his admission, that he begged the stump might be immediately removed: he was unable to follow his employment: he was deprived of natural rest; and his health had consequently been much impaired. I performed the operation in the following manner:—I formed a flap of sufficient size on the dorsum of the fore-arm, by commencing an incision over the edge of the ulna, and carrying it downwards, and then upwards, so as to make it terminate

over the edge of the radius, at the opposite point to where the incision was commenced on the inner side; I then passed the knife across the anterior aspect of the arm, from the termination of the last incision to where it had commenced, and by cutting from within outwards formed a flap corresponding to the other; to prevent the nerve from again becoming troublesome after the wound had healed, I removed about an inch more of the median nerve than was taken away with the stump; it was then dressed with our common isinglass dressing, having employed a single suture; since that time he has been going on very well; we have, however, had occasion to give him a few purgatives and diaphoretics to keep down a slight tendency to inflammation. The stump is now nearly healed, he complains of no pain, and talks about going out. I think the flap operation superior to all others. I believe it gives a much better covering to the bone; the wounds are generally very healthy, heal quick, and are clean. Previous to performing this operation, I had considered it possible that the patient might have been relieved by simply removing the enlarged extremity of the median nerve; had it been a well formed stump, I think I should have tried such a proceeding, though there is always danger in exposing the bone; but in this instance, as the stump was so badly formed, and so thinly covered by integument, I made up my mind to improve the stump, as well as relieve the man of his pains. You will be called on to perform operations of this kind under various circumstances; sometimes the stump may be left so long as to be seriously inconvenient to the patient: if it be a leg, and he uses a machine, the stump may come into contact with his clothes, and be very troublesome: you will then have to shorten it. Badly performed operations, also, sometimes produce the necessity for this proceeding. I once removed a stump in which the tibia was left some inches longer than the fibula. It is not always requisite for you to go through all the steps of the operation; it occasionally happens that you can remove a portion of the bone and improve the stump, by making an incision on the inner side, and drawing aside the flap.

—
Chronic Rheumatism, treated with Hydriodate of Potash.

RACHAEL MITCHELL, aged thirty-two, was admitted May 26, under the care of Dr. Elioton. About eighteen months ago she caught cold, and has since then suffered considerably with rheumatic pains in the joints, at every change of weather. There is no swelling or heat of the parts affected.

Rx. Hyd. potassæ, gr. iijss;
Aq. puræ, 3j, ter die.

June 4th.—The pains of the joints are better, but she has had a little sickness and headache.

20th.—Has been taking the medicine in gradually increased doses since last report. She now takes seven grains and a half of the hydriodate three times a day. She is improving rapidly, the pains being almost gone.

23d.—Discharged, well.

Dr. E. has employed the hydriodate in another case—that of an old woman, who had suffered for twelve months with a severe rheumatic pain in her neck. She took the hydriodate for six weeks, and was completely relieved.

Amenorrhœa.

The following formula has been used in the North London Hospital by Dr. Elliston, in cases of amenorrhœa, with the most decided success.

Rx. Ol. Tereb. ʒss.
Decoct avenæ, lbj.

Ft. enema quotidie.

It is well to mention, that a small quantity of blood was taken from the arm in each case. The injection in one case produced menstrual discharge in four days, though it had been absent four months. In another case the patient was relieved in seven days. Dr. E. has employed it in one instance without any benefit.

ROYAL COLLEGE OF SURGEONS.

—

Mr. Andrews has been elected President, and Sir Astley Cooper and Sir Anthony Carlisle were elected Vice Presidents for the ensuing year.

—o—

STIMULANTS OF GREAT MEN.

—

It is interesting to notice the different articles which have been taken, by eminent men, as stimulants to the mental faculties. It is interesting, as showing how diametrically opposite means may produce the same effect in various systems; and it is interesting, as showing how much the mind sympathises with the body. Haller drank plentifully of cold water when he wished for great activity of the brain; Fox, for the same purpose, used brandy. The stimulants of Newton and Hobbes were the fumes of tobacco; those of Pope and Fontenelle, strong coffee. Dr. Johnson, at one period of his life, was a great wine drinker; but, in the latter part of it, found strong tea a good substitute. Don Juan is said to have been written under the influence of gin and water; and it is reported that a certain legal lord, of great learning and talent, plies him-

self well with port when he wishes to shine. Pitt was a great drinker of wine; Sheridan, also, was fond of the bottle. Dr. Paris, in his "Pharmacologia," tells us, that when Mr. Dunning wished to make an extraordinary display of eloquence, he always put a blister on his chest a few hours before the time he was to speak, in order that it might irritate the brain by sympathy during his speech.

C.

—o—

RAPIDITY OF THOUGHT IN DREAMS.

—

THE period of time occupied by a dream is generally exceedingly short—sometimes lasting scarcely more than a minute, at others not more than a second of time; and yet, in that space, we seem to have existed for years—to have taken long journeys or voyages, traversed over countries far distant; and to have endured the feelings of pleasure and pain at long intervals of time. De Quincy tells us he seemed to have lived eighty years in one night; verifying the expression of the bard, in his own sweet dream, that

"A slumbering thought is capable of years,
And curdles a long life into one hour."

J. H.

—o—

EFFECTS OF DREAMS ON OUR WAKING THOUGHTS.

—

THAT oppressive feeling of gloom, which we sometimes feel on rising in the morning, and for which we cannot possibly assign a reason, is supposed to arise from unremembered dreams which have brought all the sins of our life in array before us. You will probably remember in one of the letters of the noble poet (Byron), whom I have just quoted, that he mentions how constantly, at one time, this feeling oppressed him for the first hour or two after rising—there is little doubt that it arose from the nature of his dreams. You know how morbidly sensitive he was in mind, and his long continued abstinence from animal food, and the common necessities of life, had made him equally sensitive in his physical construction; he was just the subject to have such a train of ideas arise in his dreams—as to use his own words, would

"Leave a weight upon his waking thoughts."

We have similar facts given to us in the early life of Cowper, written by himself.

Arthritis, acute and chronic, 649.—pathology of, 678.
VOL. VII.

Articular inflammation, 649.
Ascites, subsequent to delivery, 47.—congenital, 177.—epiploic, cases of, 178.
Assurance of life, 65.—basis of, *ib.*—principle of, 66.—companies, queries of, 68.
Asthma, periodic, of children, 638.
Atmospheric pressure, effects of, 612.
Autopsies of infants, 36.

B.

Bass', Mr., new preparations, 28.
Baudelocque, M., on uterine hæmorrhages 372.
Bengal orphan fund, 29.
Berlin clinic, 442.
Biblical concordances on botany, 484.
Blackbirds, song of, 31.
Black thrush, pathology of, 651.
Bladder, structure of, 656.—irritable, account of, 792.
Bleeding, in lightning stroke, 61.
Blindness, cases of, cured by operation, 541.
Blood, vitality of, 267.—state of, after drowning, 417.—diseases of vessels, 594.—stimulus of, 643.
Blue fever of children, 125.—danger of Prussian, 291.—cholera, contagiousness of, 296.
Board for granting degrees in London, 279.
Bodies, preservation of, 109.
Bones, relative weight of, 255.—injuries and diseases of, 595.—cysts in, 626.
Botany, progress of, in London, 457.—lectures on, *ib.*—utility of, 459.—use of, to medicine, 460.—geological, 482.—principles of, *ib.*
Brain, injuries of, 326.—diseases of, 590.
Breast, extirpation of, 379.
Brick and lime kilns, 291.
Brodie, Sir B., on amputation of the penis, 283.—on the urinary organs, 815.
Brucine, use of, 336.
Bubo, sympathetic, account of, 754.
Bullets, course of, 325.
Burnett's outlines of botany, 313.—lectures on botany, 457.

C.

Calculus, large, removed by lithotrity, 126.—**M. Cross** on, 143.—immense, removal of a, 158.—nine ounces of, extracted, 762.
Caloric, account of, 578.
Cancerous dartres, 623.
Carbonic acid, in amenorrhœa, 282.—in cystitis, *ib.*—in ophthalmia, *ib.*—in inflammations, *ib.*

Carbuncles, facial, case of, 125.
 Cartilaginous tissue, 9.
 Cats, death of, in printing offices, 640.
 Cause of the rigidity of muscles after death, 72.
 Caustics, account of, 529.
 Cellular tissue, congenital induration of, 179.
 Cerebral action, suspension of, 698.
 Certificates for life assurance, 66.
 Cesspools, danger of, 292.
 Charges, extraordinary medical, 768.
 Chelsea garden, history of, 457.
 Chemical hypothesis of disease, 106.
 Chest, Dr. Williams on, 376.—diseases of, in children, 638.
 Chicken-breast, account of, 305.
 Children, spinal diseases of, 302.—Dr. Göelis on, 636.
 Chimnies, height of, 291.
 Chinese doctors, account of, 672.
 Chlorides, account of, 333.
 Cholera, at Marseilles, 30.—French, Mr., on, 248.—reappearance of, in London, 512.—blue, delivery in, 572.—contagion of, 700.
 Chorea, cured by C. ferri, 638.
 Clinic at Berlin, 442.
 Clinical instruction at Hospitals, 250.
 Club-foot, species of, 232.
 Coal gas works, bad effects of, 291.
 Cold water in diseases, 149.
 College of Physicians, meeting of, 447.—of surgeons, no reform in, 217.
 Colon, abscess of, 363.
 Comet, approaching, 540.
 Conception, seasons for, 478.
 Congenital excess of parts, 76.—herniæ, 425.—syphilis, 619.—diseases of the digestive organs, 649.
 Concretions, articular, 534.
 Congestion of nervous centres, 561.
 Contagious infections, 290.
 Contusions, effects of, 324.
 Convulsions, infantile, 721.
 Coombe, Dr., on man, 374.
 Copaiba, medicinal use of, 51.
 Copper, sulph. of, in diarrhœa, 49.
 Coroners' inquests, 385.
 Corrigan's, Dr., lectures, 136, 715.
 Cranium, infantile, fissures in, 671.
 Crosse on calculus, 143.
 Crustacea, Dr. Edwards on, 22.
 Cutaneous inflammations, 64, 621.
 Cyanosis, pathology of, 519.
 Cynanche maligna, account of, 745.

D.

Dartres, varieties of, 621.
 Dead bodies, preservation of, 416.
 Death, sudden, at St. George's Hospital, 670.
 Debilities, different, from Brown's, 551.
 Decomposition, process of, 108.
 Delirium tremens, account of, 167.
 Dementia and amentia, 257.
 Democritus on lunatic asylums, 87.
 Dentition, Ashburner, Dr., on, 147.—physiology of, 684.—anomalies of, 685.

Dermott's Mr., London Anatomist, 148.
 Diabetes mellitus, 318.
 Diaphoretics, account of, 180, 239.
 Diarrhœa, Dr. Corrigan on, 136.
 Dietary of children, 800.
 Digestion, powers of, 169.
 Diseases which shorten life, 68.—feigned, account of, 129.—simultaneous existence of different, 214.—contagious, hereditary, 521.—of the genito-urinary organs, 601.—of children, Dr. Göelis on, 637.
 Dislocations of the neck, 18.
 Dispensaries, comments on, 276.—liable to poor rates, 384.—abuses in, 441.—evils of, 826.
 Disqualifications, certificates for, 131.
 Diuretics, use of, 85, 123.
 Divisions of continuity, 11.—of the lip, 11.—of the palatine arch, 12.—of the thorax, 12.—of abdomen, 12.—of genital organs, 12.
 Drains and cesspools, danger of, 292.
 Dreams, effects of, 832.
 Dropsy, pathology of, 44.—inflammatory, case of, 380.
 Drowning, evidence of, 449.—phenomena of 449.—morbid state in, 450.
 Dublin Journal, review of, 54.
 Duelling, law on, 354.
 Duffin on spinal deformities, 342.
 Dupuytren's, Baron, will, 31.—death, 96.—method of preserving hair, 256.—clinic, 569.
 Duties of practitioners in assurance cases, 66.
 Dyer, Mr., on water dressings, 278.
 Dysentery treated by nux vomica, 405.
